

The δ Foundation

Distinction, Arithmetic, and the Limits of Abstraction

Jonathan Washburn

Recognition Physics Research Institute

Fifth edition, version 5.1 · November 2026

Pith:2026.000055v1 [math.LO] 9 Nov 2026

How to read this book

This book follows a construction. We begin with a distinction that can be repeated and ask what is required to preserve its finite records. We build arithmetic and show that each stage of the number tower, from the tallies through the ratios to the line, is the unique solution of its task; for the line this uses countable choice. We examine the rules by which its statements can be proved, identify the additional principles needed for stronger decisions, and compare the resulting rules with Peano arithmetic and Heyting arithmetic. We then price compactness and linear algebra on the line, compute the values of solutions of polynomial differential equations with rational data to certified precision, whenever one computed trajectory passes a finite check, and build a calculus of δ's own objects in whose computable form statements of compactness can be shown not derivable. Part V connects finite descriptions with finite physical records. The last three parts take up the cost of a comparison that Recognition Science places at the base of physics. We prove that its composition law and calibration force one cost, restate the steps of the forcing chain built on it in our own words and price each one, and carry classical mechanics, the second law, linear gravity, the conventions of a classical library and the theory of learning onto the line, saying for each result whether it is free, what it costs, or that it is proved in classical mathematics.

Elementary algebra and experience following a proof are enough to begin. Parts I and II introduce the logical language they use; prior study of category theory is unnecessary. Chapter 9 is a more demanding introduction to a small dependent type theory. Its examples give the main argument, while its final soundness proof requires a slower reading of substitution and reduction. The chapter provides a route through those details rather than assuming they are already familiar.

Part V requires finite-dimensional complex linear algebra: orthonormal bases, eigenvalues, positive matrices and tensor products. Its control arguments also use differentiation, integration and limits of matrix exponentials. Appendix C explains the notation and the specific moves used here; it is a companion to that background, not a replacement for a first course. The central proofs are part of the text, and each physical construction states the operations it assumes.

Parts VI and VII also use real analysis at the level of a first course (Taylor expansions, integrals, finite Markov chains), the elementary theory of the ordinary differential equations of mechanics, and, in Chapters 23 and 27, singular homology and the algebra of symmetric tensors. Each chapter recalls what it uses. Part VIII uses the compactness of Chapter 13, the calculus of Chapter 16, the records of Section 17.7 and the programs of Chapter 20.

The standard of proof is that of ordinary mathematical proof, and every result is proved in the book: where it is stated, or, when the proof is long and routine, in an appendix that the statement's proof names. One heading marks an exception. A proof headed *Standard theorem* reproves a classical result for the book's own calculus and cites the original with its theorem and page; it states the steps of the adaptation, and the appendix it names proves them. The proof for the fixed machine of Theorem 15.33 is of the long and routine kind: Section 15.9 gives the argument, and Appendix I constructs every stage program and proves its bound. No

proof is a sketch. Standard facts of computability theory and general topology are cited where they are used: the unsolvability of the halting problem, the s-m-n and recursion theorems, and the basic properties of $\beta\mathbb{N}$. In Parts VI to VIII a few results rest on stated inputs, and each says so in its scope box: the numbers for the tick of Recognition Science in Chapter 26 assume five numerical inputs, (T1)–(T5), from interval computations the book does not reproduce; the proofs of Theorems 27.32 and 27.33 give their route and the source of each estimate; a few proofs in Chapters 27 and 30 end in finite exact computations that they describe; and the counts of library theorems in Chapter 28, with two size counts of compiled programs there, report an audit and are not theorems. The price table of Appendix Q records the statement and price of every row. In its key, "exact" means that both directions hold; a row with a reference is proved in this book at the result it names, and most rows without one are not proved here. Section 28.12 proves its headline rows, and most rows that this book proves name the result. A few results of the last sections of Chapters 21 to 29 cite a preprint (Zenodo, 2026) for a full treatment, and Theorem 22.73 is cited from one.

Read the examples before the theorem statements. In each theorem, notice the hypotheses: they identify the circumstances in which its conclusion is forced. In each proof, ask where a hypothesis is used. That habit is especially useful when the book compares a construction with a stronger logical principle. An additional principle matters only if it permits a step that was previously unavailable, and that has to be proved. Chapter 6 shows that, with induction on every formula, one of the book's three named rules, in the form the arithmetic language admits, permits nothing new, while another is exactly as strong as excluded middle.

The δ foundation concerns actual mathematics: the structures that distinction and its consistent development require. Making that claim precise requires us to state the finite constructions with which we begin, the reasoning available for studying them, and the conditions attached to each extension. Those details are the argument.

The companion volume, *The Structure of Reality*, develops the physical forcing chain. The present volume gives the mathematical construction room to be taught on its own. Its last three parts restate the steps of that chain in the book's own words, on the line built from ratios, and prove or price each restated step; no result here rests on the companion volume. They then do the same for classical mechanics, the conventions of a classical library and learning. Its physical chapters identify the finite bridge and the resources its constructions use.

The eight parts can be read at different speeds. Part I develops the arithmetic carrier and its extensions. Part II makes proof rules and their logical resources explicit. Part III compares forms of construction and examines the difference between arbitrarily precise approximation and exact decision, including what completeness of the line costs. Part IV prices compactness and linear algebra, counts the work of computing the values of solutions of polynomial differential equations with rational data to a requested precision, whenever one computed trajectory passes a finite check, and builds a calculus of δ's own objects in which the statements of compactness can be written; in its computable form they are not derivable, even from LPO and with excluded middle as a base rule. Part V asks what finite records and specified physical apparatus can preserve. Part VI proves that the composition law and its calibration force the cost J, restates the forcing chain of Recognition Science and prices it step by step, proves that a circle can be linked only in three dimensions, and reads the light cone off the records of a ledger, naming the premises on the way from posting to time, the square law, charges

and space; it also proves that the verdict of Recognition Science holds with no cited premise, prices the moral code, and asks which values the world's records keep real. Part VII carries orbits, rigid bodies, lattice fields, entropy and the second law onto the line and summarizes what the cost and Regge's action say about gravity, through quartic order and the scattering of four gravitons. Part VIII prices the conventions of a classical library and, in a table of 1467 statements, the mathematics that physics uses; it treats the logic of recorded histories and the learning of laws from records, and collects the open problems of the whole book. Read Parts I to V in order on a first pass; each uses distinctions made by the preceding one. Parts VI to VIII rely on Chapters 6, 7 and 12 and on Chapter 21. From Chapter 21 on, a map is read without unique choice (Section 21.1), so prices there are prices of functions, such as the WLPO function. Each of their chapters names the further sections it uses (for example, Chapter 23 uses Chapter 13, Chapter 24 Section 17.7, Chapter 25 Chapter 15, Chapter 28 Chapters 13, 16 and 20, Chapter 29 Chapter 17, and Chapter 30 Chapter 24).

Appendix C explains the proof moves and matrix notation used along the way. Appendix D collects the arithmetic rules, and Appendix N is a notation guide and glossary. Selected exercise solutions are in Appendix O. Appendix P provides routes back to the main arguments, and Appendix Q lists the price table of the mathematics physics uses. Appendices A and B supply the finite-control construction and the count identity used in the physical chapters. Appendices E and F carry the routine verifications behind Chapters 6 and 12, Appendix K the routine cases of the comparison with Peano arithmetic in Chapter 20, Appendix L the proofs of its two extensions, to one universe and to bounded arithmetic, and Appendix M the arguments for Gödel's second theorem and for finite set theory. Appendices G, H, I and J carry the longer proofs of Chapters 14, 15 and 16; Appendix I constructs the machine of Theorem 15.33 stage by stage.

The book brings several kinds of argument together, and it is worth saying which are recovered and which are its own. Recovered: the arithmetic laws, signed differences and ratios reconstruct standard mathematics (Chapters 3 and 4); the initiality and categoricity arguments (Theorems 2.3 and 2.7) have their classical antecedent in Dedekind [2], and the limits of first-order characterization go back to Skolem [3]; Heyting and Peano arithmetic, the omniscience principles and their separations, and Bishop's constructive analysis are the established theories against which the book's rules and prices are measured [4, 5, 14, 20]; and Gödel's incompleteness theorem [8] and Kaye and Wong's reading of finite set theory [13] are proved again for the book's own calculi (Theorems 20.42 and 20.47), as are Löb's theorem [10], the negative and Friedman translations and the no-counterexample interpretation [65, 67, 66, 68, 55] (Theorems 20.49 and 20.57, Lemma 20.62 and Theorem 20.63). Brouwer's fan theorem [29] and its equivalents in constructive reverse mathematics [37, 30, 32] are the background of Chapter 13, Kleene's tree [51] and Lifschitz's realizability [57] supply two of the book's models, and Pouly and Graça's polynomial-time solution of polynomial differential equations [45] is the classical counterpart of Chapter 15, and the classes of questions that finite records confirm, refute and settle are the characterizations of formal learning theory [64] (Theorem 17.13). The paper on the δ-calculus [1] supplies the arithmetic and recognition framework. The book's own contribution is a way of making the strength of each conclusion visible, together with the results that this makes possible: a four-entry ledger that records which additional rules and which kind of induction a derivation uses (Chapter 6); the exact prices of the three rules, which have two strengths with induction on every formula and four without it (Theo-

rem 6.11 and Propositions 6.13 and 6.14); one classification priced under six combinations of supplied information and requested answer, with the six prices separated pairwise by models of intuitionistic second-order arithmetic (Theorems 7.33 and 7.38); the typed separations of iteration, indexed recursion, dependent elimination and the start discriminator (Chapter 9); the exact prices of the decisions and completeness properties of the line built from ratios (Chapter 12 and Table 12.3); the prices of compactness, where Heine–Borel for $[0, 1]$ and for every compact set presented with its nets is exactly the decidable fan theorem, with no choice principle (Theorems 13.6 and 13.25, Table 13.1); the prices of linear algebra on the line, where selecting a basis and rank–nullity, with independence meaning that only the zero combination vanishes, are each exactly WLPO, with unique choice, part of the reading of maps, used in the converse (Theorem 14.16); a solver for polynomial differential equations with rational data whose answers carry a proved error bound and whose arithmetic is counted exactly, and one fixed one-tape binary machine that, for every problem whose region certificate holds at the level given in the request, answers every request for m bits within $K(m + 1)^{\lambda}$ steps, with one exponent λ for all problems and a constant K that depends on the problem, a machine that does not check the certificate and reads a polynomial field through the request of its quadratized problem (Theorems 15.22, 15.23 and 15.33); a calculus of δ's own objects into which second-order intuitionistic arithmetic compiles, and which with all its terms derives every true sentence built from equations over carriers that do not change between its two stages (Proposition 16.15), while its computable form, the computable calculus, has a model, assembled from Kleene's tree and standard counterexamples of recursive analysis [51, 76, 77, 40], in which LPO is true, so that each question is decided, but the answers cannot be collected into a sequence and the decidable fan theorem and Heine–Borel for presented compact sets, written with equations, are false, so that neither is derivable there, even from LPO and with excluded middle as a base rule (Theorems 16.11, 16.27, 16.32 and 16.34); what deciding questions about growing records costs: a question that a given recorder settles, by a proof without excluded middle, is decided with the binary Markov principle, and one settled question costs exactly that principle (Theorem 17.17); the verdict of a law tested at finite precision, which always exists, and the price of exactness: deciding an equation costs WLPO, and turning its failure into a refutation costs the binary Markov principle (Theorem 17.22); models of intuitionistic second-order arithmetic for prices strictly between pairs of the six (Corollary 7.49), where the principles $\mathrm{MP}^{\vee}$, WMP and LLPO_n and several of their separations are known (Section 7.13); the price of converting a classical theorem into one without excluded middle, shape by shape, for the shapes of the book's arithmetic language, in which a quantifier-free formula has no bounded quantifiers (Theorem 20.66); the comparison of a language of functions with the rules and with Peano arithmetic, compiled rule by rule (Theorems 20.26 and 20.39); and a finite bridge to physical records that carries effective names, controls, errors, resources and a conservation bound through one account (Theorems 18.11 and 19.5). With excluded middle, the rules prove exactly the theorems of Peano arithmetic (Theorem 8.11), and with no added principle exactly those of Heyting arithmetic. These claims belong to the specified languages and representations.

The last three parts add results of a different kind: what the physical derivations of Recognition Science, and the classical mathematics that physics uses, cost on the line. On $\mathbb{R}_{\delta}$ the composition law and its calibration force the cost J with no omniscience principle and no choice (Theorem 21.14), and one bit of calibration, $J(2) = \frac{1}{4}$, with any one mild regularity condition

such as a bound on one interval, already does (Theorem 21.42); the verdict of Recognition Science holds with no cited premise, its transcendence input proved in classical mathematics (Theorem 22.58); of the 130 rows of the price table of the forcing chain, as the book restates it, 119 are free, ten have an exact price, one is bracketed and none is open (Chapter 22); three is the only dimension in which a circle can be linked, again with no omniscience and no choice, which is the topological fact behind the dimension step (Chapter 23); the mechanics of Kepler and Newton, the perihelion advance of relativistic test orbits to second order and the second law hold with explicit constants, on the line or, where the chapters say so, in classical mathematics (Chapters 25 and 26); on transverse-traceless strains the long-wave form of J is the Fierz–Pauli form of linearized gravity, and the cost built from J agrees with Regge's action, read as the gravitational action, to second order only, so at the Euclidean background of the lattice J has no post-Newtonian parameter β of its own, while the long-wave vertices of Regge's action on the Kuhn lattice are one half of Einstein's through quartic order on every Euclidean background of the Kuhn family, and its gravitons scatter at tree level and long wavelength as general relativity's on every flat background of the family off its poles (Chapter 27); with the code's hypothesis in its free form, every conclusion of the main theorem of the moral code is free on the line, and only decisions over every conceivable record carry a price (Section 22.14); the conventions of a classical library have prices on the line, most of them exact, and of 1467 statements of the mathematics physics uses 1166 are free, 279 have an exact price in the table's sense and 22 are open (Chapter 28 and Appendix Q); and learning a law from records has exact prices too (Chapter 29). Recovered there are the laws of Kepler, Newton and Lagrange, the Laplace–Runge–Lenz vector, Chetaev's instability argument, Doeblin's contraction, Regge's calculus and the Fierz–Pauli form, Ostrowski's theorem, de Finetti's theorem, Morse and Hedlund's bound, Littlestone's dimension and the learning criteria of Gold and of Case and Smith, each credited where it is used.

The physical chapters use established matrix and dilation theory [22, 23, 24]. Their task is to connect complete finite descriptions to the stated register, controls and error accounting, and to derive a recorder bound for the specified conserved charges. The conservation argument belongs to the line of work begun by Wigner and Araki and Yanase [26, 27].

Contents

How to read this book **ii**

I Distinction becomes arithmetic 1

1 A distinction that can be repeated 2

1.1 Start, then take one more step . . . 2

1.2 Why a proof can follow the construction . . . 3

1.3 A familiar notation, with a proved translation . . . 4

1.4 From an orbit to a realization . . . 5

Questions to work through . . . 5

2 Why a faithful tally has one structure 6

2.1 The data a translation must preserve . . . 6

2.2 There is exactly one reading . . . 7

2.3 What makes the reading faithful? . . . 7

2.4 The exact uniqueness result . . . 9

2.5 Where the force of the argument lies . . . 10

Questions to work through . . . 10

3 Addition, multiplication, and order 11

3.1 Addition follows the second record . . . 11

3.2 Multiplication repeats an addition . . . 12

3.3 Why multiplication distributes . . . 13

3.4 The step determines both operations . . . 14

3.5 Comparing two finite records . . . 15

3.6 Subtraction stops at the start . . . 16

Questions to work through . . . 17

4 Differences and ratios 18

4.1 Keep both sides of a difference . . . 18

4.2 Operations must survive a change of representative . . . 19
4.3 The integer laws follow on the classes . . . 20
4.4 Reading the signed construction . . . 21
4.5 A ratio needs a nonzero denominator . . . 21
4.6 Constructing arithmetic on ratio classes . . . 22
4.7 Why a reciprocal keeps the sign in the numerator . . . 23
4.8 Checking the field laws . . . 24
4.9 Each extension is determined by its task . . . 25
Questions to work through . . . 27

II What a proof is allowed to use 28

5 The language and the rules 29
5.1 Expressions are finite constructions . . . 29
5.2 One complete argument . . . 30
5.3 The permitted inferences . . . 30
5.4 Reading the expressions as arithmetic . . . 32
5.5 Why every permitted step preserves truth . . . 34
5.6 The same induction, now inside the language . . . 35
5.7 What each family of rules supplies . . . 35
Questions to work through . . . 39

6 The price of an additional principle 40
6.1 A witness, a decision, and a double negation . . . 40
6.2 A ledger for a finite argument . . . 42
6.3 No added principle is not the same as an empty ledger . . . 42
6.4 The record agrees with the derivation . . . 43
6.5 Soundness with the prices attached . . . 44
6.6 A route's price and a theorem's exact strength . . . 45
6.7 What the three rules cost . . . 45
Questions to work through . . . 61

7 What can recognize the same record? 62

7.1 Identifications that respect addition 62

7.2 How a period reaches an earlier collision 63

7.3 The constructive classification 64

7.4 What changes when the collision is not supplied 65

7.5 What a decision procedure alone can buy 66

7.6 The unrestricted catalogue and excluded middle 69

7.7 What the classification tells us about a reader 70

7.8 Signed records keep only the pure periods 71

7.9 One classification, six prices 73

7.10 A system and its models of truth values 74

7.11 The six equivalences inside the system 80

7.12 Four models, and why the six prices are different 89

7.13 Prices between the six 94

7.14 One halting question, priced instance by instance 102

Questions to work through 114

8 Changing the representation 116

8.1 An interpretation is fixed by its operations 116

8.2 Arithmetic on lists of one mark 117

8.3 Terms agree under corresponding assignments 118

8.4 Truth is preserved in both directions 119

8.5 What survives a one-way translation 120

8.6 What happens to the proof and its ledger 122

8.7 A second proof language: Peano arithmetic 122

8.8 A quotient represents what a reading retains 124

8.9 The limits are part of the invariance theorem 125

Questions to work through 125

III Construction, iteration and the continuum 127

9 Iteration, recursion and induction 128

9.1 Three ways to proceed from a start 128

9.2 The language in which the question is exact . . . 129
9.3 What indexed recursion immediately gives . . . 131
9.4 An iterator can merge two roots . . . 132
9.5 Recursion can leave a whole chain unreached . . . 133
9.6 Induction does not invent a discriminator . . . 135
9.7 The strict sequence of resources . . . 136
9.8 Why the countermodels cover every rule . . . 137
9.8.1 A total interpretation and its limits . . . 137
9.8.2 Substitution and safe expressions . . . 138
9.8.3 Joining conversions without changing the language . . . 139
9.8.4 Soundness of the complete typing derivations . . . 141
Questions to work through . . . 143

10 Finite construction and effective description 144
10.1 An explicit budget for a tally . . . 144
10.2 Arithmetic carries its own finite bounds . . . 145
10.3 A record with a decoder . . . 146
10.4 A finite rule can describe an unbounded calculation . . . 146
10.5 Storing the program preserves its execution . . . 148
10.6 One program for every requested precision . . . 149
10.7 A finite prefix is a different quantifier . . . 150
Questions to work through . . . 151

11 The continuum through rational enclosures 152
11.1 Why every later interval constrains every earlier one . . . 152
11.2 A unique value lies in every enclosure . . . 153
11.3 When two protocols describe the same point . . . 153
11.4 Rationals and arithmetic act on the intervals . . . 154
11.5 Every classical real has such a display . . . 155
11.6 Why finite prefixes do not provide a uniform name . . . 157
Questions to work through . . . 158

12 Exact comparison has a cost **159**

12.1 Finite stages and exact predicates . . . 159

12.2 Questions about a binary sequence . . . 161

12.3 Encoding an event as a small jump . . . 161

12.4 Exact zero decisions are equivalent to WLPO . . . 163

12.5 Sign trichotomy is equivalent to LPO . . . 163

12.6 One-sided order is equivalent to LLPO . . . 164

12.7 The difference between denying and finding . . . 165

12.8 One line built from ratios . . . 168

12.9 What completeness costs . . . 175

12.9.1 Countable choice decides nothing . . . 175

12.9.2 Limits and located cuts: where countable choice enters . . . 181

12.9.3 The line is determined by its task . . . 189

12.9.4 The table of completeness prices . . . 192

12.9.5 Order tools for the proofs of the table . . . 194

12.9.6 Deciding a point against a ratio . . . 195

12.9.7 Two cuts that bound a set . . . 196

12.9.8 Monotone sequences and sequential compactness cost LPO . . . 197

12.9.9 Least upper bounds cost WLPO, LPO, WEM or EM . . . 200

12.9.10 Roots, maxima and expansions cost LLPO or nothing . . . 203

12.9.11 Without unique choice, excluded middle does not replace countable choice . . . 211

12.9.12 A located cut that unique choice does not make a point . . . 215

12.9.13 Countable choice proves the four assertions without excluded middle . . . 218

12.9.14 LLPO does not replace countable choice . . . 219

12.9.15 The same prices away from the line . . . 225

12.9.16 Monotone convergence splits as LPO does . . . 229

12.10 A price table for the calculus on the line . . . 230

12.11 Integrals over the whole line and space, and what completeness costs . . . 241

Questions to work through . . . 247

IV Compactness, algebra and computation 249

13 What compactness costs 250

13.1 Bars and the fan theorems . . . 251
13.2 Heine–Borel on $[0, 1]$ is the decidable fan theorem . . . 252
13.3 Where the fan theorem sits . . . 255
13.4 Uniform continuity . . . 258
13.5 Compact sets presented with their nets . . . 263
13.6 Heine–Borel, positive bounds and infima for presented sets . . . 265
13.7 Heine–Cantor for presented sets . . . 270
13.8 Bishop compactness . . . 272
Questions to work through . . . 275

14 What linear algebra costs 276

14.1 Selections, bases and three kinds of division . . . 277
14.2 Cancelling without inverting . . . 278
14.3 A basis is a sequence of divisions . . . 279
14.4 Linear algebra costs exactly WLPO . . . 282
14.5 The sign of a nonzero point . . . 284
14.6 Dividing by a nonzero point . . . 286
14.7 Signs as units . . . 290
14.8 The prices . . . 292
14.9 Without unique choice . . . 292
Questions to work through . . . 292

15 Differential equations to certified precision 293

15.1 A number is a program with a proof of its precision . . . 293
15.2 Carrying every rounding error forward . . . 296
15.3 The number of steps at a fixed order . . . 297
15.4 Taylor coefficients of a quadratic field . . . 298
15.5 A fixed number of steps of growing order . . . 301
15.6 Counting the work . . . 303
15.7 Polynomial fields become quadratic . . . 305

15.8 What the certified point is 306
15.9 One machine for every problem and every precision 307
Questions to work through 314

16 A calculus of δ's own objects 315
16.1 Objects that exist at two stages 316
16.2 Terms, formulas and their reading 317
16.3 Derivations and the twenty-nine base rules 319
16.4 Every derivation holds at both stages 321
16.5 Intuitionistic second-order arithmetic inside the calculus 323
16.6 The full calculus has no recursive model 326
16.7 The computable calculus and its model 329
16.8 LPO decides each row but cannot collect the rows 333
16.9 Kleene's tree 335
16.10 Compactness is not derivable in the computable calculus 336
16.11 What remains open 342
Questions to work through 343

V Mathematics and finite physical records 344

17 What a finite record can establish 345
17.1 The target, the record and the reader 345
17.2 Several worlds can remain compatible with one record 346
17.3 A finite capacity bound 347
17.4 Adaptive tests still produce a bounded transcript 348
17.5 An error tolerance gives a separation bound 349
17.6 Finite length without a common budget 350
17.7 What a record can confirm, refute or settle 351
17.8 The physical task left by the mathematics 360
Questions to work through 361

18 The construction of finite operations 362
18.1 An operation with a retained outcome 362

18.2 An explicit reversible extension 364
18.3 A fixed register and a complete reader 365
18.4 An error bound that keeps a reference system 366
18.5 Two descriptions of finite operations 367
18.6 Searching with a margin 368
18.7 Recovering the matrix description 369
18.8 Enacting a sequence with positive energy 370
18.8.1 Retaining the phase 371
18.9 The finite bridge and its physical interfaces 372
Questions to work through 374

19 Conservation and the cost of keeping a record 375
19.1 The event, the interaction and the pointer 375
19.2 Accuracy controls the noise of a sharp event 376
19.3 What exact conservation does to the pulled-back event 377
19.4 The native source and its two charges 378
19.5 A four-entry witness inside the actual source 379
19.6 How much charge spread can the recorder supply? 380
19.7 The two-charge recorder theorem 381
19.8 What the resource is, and what the result establishes 382
Questions to work through 383

20 What has been forced 384
20.1 The arithmetic structure is unique 384
20.2 Identifying records and extending logic are visible choices 385

Part I

Distinction becomes arithmetic

Chapter 1

A distinction that can be repeated

Suppose we record arrivals by making a mark. Before anyone arrives, there is no mark. The first arrival adds one. The next arrival adds another. We can change the pen, the shape of the mark, or the name we give the record. What must survive those changes if the record is still to count the same arrivals?

The question is small enough to answer completely. It is also the beginning of a much larger question: how much mathematics is already determined when we insist that distinctions can be made, retained, and repeated faithfully?

We begin with the record itself. We need a starting record and an operation that adds one step. We then ask what their finite repetition constructs. The arithmetic operations will come later. At this point, even the familiar decimal numerals would conceal more than they explain.

1.1 Start, then take one more step

Write 0_δ for the starting record. Write S for the operation that takes one further step. The first few expressions are

$$0_\delta, \qquad S(0_\delta), \qquad S(S(0_\delta)), \qquad S(S(S(0_\delta))).$$

Each expression says how it was built. The last expression, for example, starts at 0_δ and applies the step three times. Nothing in this notation specifies the material of a recorder or the duration of an event. Those are questions about a realization. Here we are constructing the finite records that a faithful realization must distinguish.

Definition 1.1 (The finite distinction orbit)**.** The orbit $\mathbb{N}_\delta$ consists of the finite expressions generated by these two rules:

1. 0_δ is an expression.
2. If a is an expression, then $S(a)$ is an expression.

There are no further ways to construct an expression. Equality is equality of the constructed expressions: the starting expression is different from every step expression, and two step expressions are equal exactly when their inner expressions are equal.

The final sentence matters. A device might return to an earlier state after several updates. Such a device can read the orbit, but its states do not retain every distinction made in the orbit. We will study identifications of records later. First we need the object before any such identification (Figure 1.1).

Two facts can now be read directly from the construction.

$$0_\delta \xrightarrow{\ S\ } S(0_\delta) \xrightarrow{\ S\ } S(S(0_\delta)) \longrightarrow \cdots$$

Figure 1.1. The orbit is generated from a start by finite repetition of a step. The arrows describe construction. No period or identification has been imposed.

Proposition 1.2 (A start is not a step; steps preserve distinction)**.** *For all $a, b \in \mathbb{N}_\delta$,*

$$0_\delta \neq S(a), \qquad S(a) = S(b) \implies a = b.$$

Proof. The expression 0_δ is built by the first rule. An expression $S(a)$ is built by the second. The equality of expressions does not identify these different outer forms, so $0_\delta \neq S(a)$.

If $S(a) = S(b)$, both expressions have the same outer constructor. Equality of these expressions therefore requires equality of the expressions to which that constructor was applied. Hence $a = b$. □

The second property is called *injectivity* of the step: different inputs cannot become the same output after one step. It is the elementary form of preserving a distinction. The first property says that stepping never produces the starting record. Together they tell us how to compare constructed records without assuming arithmetic in advance.

1.2 Why a proof can follow the construction

A finite expression has a finite construction. To establish a property of all expressions, it is enough to establish it at the start and show that one further step preserves it. The proof follows the only two ways an expression can be formed.

Proposition 1.3 (Induction on the orbit)**.** *Let $P(a)$ be a property of orbit expressions. Suppose that*

1. *$P(0_\delta)$ holds;*
2. *for every $a \in \mathbb{N}_\delta$, $P(a)$ implies $P(S(a))$.*

Then $P(a)$ holds for every $a \in \mathbb{N}_\delta$.

Proof. Take an expression together with its finite construction. If it was built by the starting rule, the first premise supplies the property. If it was built by applying the step to an earlier expression, the property of that earlier expression and the second premise supply the property of the new one. Applying this reasoning along the finite construction establishes the property at its final expression. These are all the construction rules, so they cover every expression in the orbit. □

This proof makes a background commitment visible. We are reasoning about finite inductively generated expressions and are allowed to follow their construction. That is the setting in which the orbit has been defined. The resulting induction principle belongs to that setting.

We have not produced a language, a notion of finite construction, or the rules for reasoning about it from an absence of all rules.

Keeping this point explicit helps us ask a sharper question. Given this construction, which further structures are determined? And when a stronger conclusion needs a further principle, where does that principle enter? Much of this book is devoted to making those dependencies visible.

1.3 A familiar notation, with a proved translation

The expressions become cumbersome quickly. We would like to use ordinary natural-number notation without losing the construction it abbreviates. For that purpose, construct two maps.

The first map, $r : \mathbb{N}_\delta \to \mathbb{N}$, reads an orbit expression as its ordinary natural-number index:

$$r(0_\delta) = 0, \qquad r(S(a)) = r(a) + 1. \tag{1.1}$$

The second map, $e : \mathbb{N} \to \mathbb{N}_\delta$, expands an index into an orbit expression:

$$e(0) = 0_\delta, \qquad e(n+1) = S(e(n)). \tag{1.2}$$

Here $\mathbb{N}$ is the usual natural-number system used in the surrounding mathematics. Introducing it here provides a comparison with familiar notation. The orbit itself was already specified by its finite construction.

Theorem 1.4 (Reading and expansion are inverse)**.** *For every $n \in \mathbb{N}$ and $a \in \mathbb{N}_\delta$,*

$$r(e(n)) = n, \qquad e(r(a)) = a.$$

Consequently, reading and expansion give mutually inverse identifications between the two carriers.

Proof. First prove $r(e(n)) = n$ by induction on n. At zero,

$$r(e(0)) = r(0_\delta) = 0.$$

Suppose $r(e(n)) = n$. Then the recursive rules give

$$r(e(n+1)) = r(S(e(n))) = r(e(n)) + 1 = n + 1.$$

This proves the first identity.

For the second identity, use induction on the orbit. At the starting expression,

$$e(r(0_\delta)) = e(0) = 0_\delta.$$

If $e(r(a)) = a$, then

$$e(r(S(a))) = e(r(a) + 1) = S(e(r(a))) = S(a).$$

The orbit induction principle therefore proves $e(r(a)) = a$ for every a. The two identities are exactly the assertion that the maps are inverse. □

The result allows notation to become lighter without becoming ambiguous. When it is useful, we can write 1_δ for $S(0_\delta)$ and 2_δ for $S(S(0_\delta))$. These names refer to particular expressions. They do not add operations or impose equations on the orbit.

The proof also shows what a successful change of representation should provide. A proposed correspondence must do more than assign labels. It must tell us how to go in both directions and establish that no information is lost on either return journey. Here both directions are explicit.

1.4 From an orbit to a realization

The constructed orbit and a physical tally answer different questions. The orbit specifies the finite records. A tally implements a way of representing them. To examine that representation, we need to say what the tally does at the start and what it does after one more step.

This leads to the next chapter's central construction. Let another system have a starting point b and an update s. There is an evident way to read the orbit into it: send 0_δ to b, then send each additional orbit step to one application of s. What is less obvious, until proved, is that these two requirements leave no other reading.

That uniqueness does not yet say that the target retains every distinction. We will prove the unique reading first, then identify the additional conditions under which it is a one-to-one correspondence. This order keeps the force of each premise visible.

Questions to work through

1. In the proof of Proposition 1.2, which part uses the fact that the two constructors have different outer forms, and which part uses equality of their inner expressions?

2. Reproduce the two induction steps in Theorem 1.4 without looking at the proof. Explain why the first induction runs over $\mathbb{N}$ and the second over $\mathbb{N}_\delta$.

3. Which background rule is used to pass from the two construction cases to a statement about every finite orbit expression?

Chapter 2

Why a faithful tally has one structure

A tally need not look like a string of marks. It can use words, positions, or some other family of states. To compare it with the orbit, the relevant data are a starting state and a rule for the next state. We can ask for a translation that respects those data before asking whether the translation is faithful.

The distinction between those two questions is essential. Every pointed step system receives a unique reading of the orbit. Only a system that preserves distinctions and contains no unreachable extra elements is necessarily another presentation of the whole orbit.

These mapping arguments have a classical antecedent in Dedekind's treatment of arithmetic [2]. We give the construction and its proof so that the conditions behind uniqueness remain visible.

2.1 The data a translation must preserve

Definition 2.1 (A pointed step system)**.** A pointed step system is a carrier M, a designated element $b \in M$ and a function $s : M \to M$. We write it as (M, b, s).

At this stage there are no further conditions. In particular, we have not said that s is injective, that b is different from every output of s, or that every element of M is generated from b.

Definition 2.2 (A structure-preserving map)**.** A map $f : \mathbb{N}_\delta \to M$ preserves the starting point and the step when

$$f(0_\delta) = b, \qquad f(S(a)) = s(f(a)) \quad \text{for every } a \in \mathbb{N}_\delta. \tag{2.1}$$

The second equation says that the order of translation and stepping does not matter. We may take a step in the orbit and translate the result, or translate first and take a step in the target. Both routes must agree.

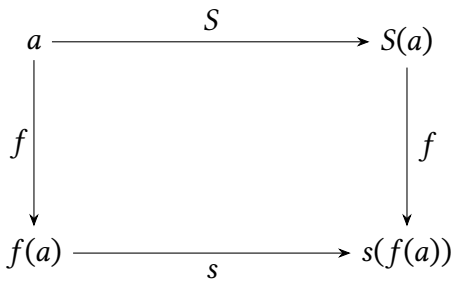

Figure 2.1. Preserving the step means that both routes have the same result. The equation $f(0_\delta) = b$ separately fixes the starting point.

2.2 There is exactly one reading

The required map can be constructed directly. Define $R_M : \mathbb{N}_\delta \to M$ by recursion:

$$R_M(0_\delta) = b, \qquad R_M(S(a)) = s(R_M(a)). \tag{2.2}$$

To evaluate R_M on an expression, follow the construction of the expression. Start with b and apply s once for each outer step. The expression is finite, so this instruction specifies its value through a finite recursive construction.

Theorem 2.3 (The unique reading of the orbit)**.** *For every pointed step system (M, b, s), there is exactly one map $f : \mathbb{N}_\delta \to M$ preserving the starting point and the step.*

Proof. The recursively constructed R_M satisfies both equations in (2.1), so such a map exists.

For uniqueness, let f be any map satisfying those equations. We prove $f(a) = R_M(a)$ by induction on a. At the starting expression,

$$f(0_\delta) = b = R_M(0_\delta).$$

Suppose $f(a) = R_M(a)$. Preservation of the step and the recursive rule give

$$f(S(a)) = s(f(a)) = s(R_M(a)) = R_M(S(a)).$$

Induction proves equality at every orbit expression. Thus every permitted map agrees with R_M, and there is exactly one. □

This property is called *initiality*. The orbit is initial among pointed step systems because every such system receives exactly one structure-preserving map from it. The name abbreviates the theorem; the content is the existence and uniqueness just proved.

Notice what the proof used. It followed the construction of the source orbit. It required no injectivity, separation or induction property in the target M. The map therefore exists even when the target identifies some of the records. Initiality tells us that the reading is determined. It does not tell us that the reading loses nothing.

2.3 What makes the reading faithful?

There are two possible failures to exclude. First, two different orbit expressions might receive the same target value. Second, the target might contain elements that no orbit expression reaches. The first is a failure of injectivity; the second is a failure of surjectivity.

The hypotheses below address both.

Definition 2.4 (A faithful generated step system)**.** A pointed step system (M, b, s) is faithful and generated when:

1. *The step is injective:* $s(x) = s(y)$ implies $x = y$.
2. *The start is not a step:* $s(x) \neq b$ for every $x \in M$.

3. *Induction holds on the target:* for every property P of elements of M, if $P(b)$ holds and $P(x)$ implies $P(s(x))$ for every x, then $P(y)$ holds for every $y \in M$.

The third condition quantifies over properties in the surrounding mathematics. It is the full generation principle used in the argument below, and it cannot be weakened to the properties expressible by formulas of an arithmetic language. Skolem constructed systems with a start, a step, addition and multiplication that satisfy every first-order arithmetic sentence true of the natural numbers, every instance of induction for such formulas included, and that nevertheless contain elements no tally reaches [3]. In such a system the property used in Lemma 2.6, "is reached from the orbit," cannot be written as a formula of that language.

Lemma 2.5 (No two orbit records are merged)**.** *If (M, b, s) is a faithful generated step system, then R_M is injective.*

Proof. We prove that $R_M(a) = R_M(c)$ implies $a = c$, using induction on a.

First let $a = 0_\delta$. If $c = 0_\delta$, the conclusion is immediate. If $c = S(d)$, the assumed equality becomes

$$b = s(R_M(d)),$$

contrary to separation of the start from every step. Thus c must also be 0_δ.

Now suppose the result has been proved for a, and consider an equality $R_M(S(a)) = R_M(c)$. If $c = 0_\delta$, this equality says $s(R_M(a)) = b$, again contradicting separation. The remaining case is $c = S(d)$. The equality then reads

$$s(R_M(a)) = s(R_M(d)).$$

Injectivity of s gives $R_M(a) = R_M(d)$. The induction hypothesis gives $a = d$, and hence $S(a) = S(d) = c$.

These cases exhaust the possible forms of c at each induction step. The reading is therefore injective. □

The argument tells us exactly where each condition works. Separation rules out a comparison between the start and a step. Injectivity removes a common outer step so that the comparison can be reduced to earlier expressions. No assumption about reaching every target element was needed.

Lemma 2.6 (Every target element is reached)**.** *If (M, b, s) is a faithful generated step system, then R_M is surjective.*

Proof. Apply target induction to the property

$$P(y) \quad \Longleftrightarrow \quad \text{there is an } a \in \mathbb{N}_\delta \text{ with } R_M(a) = y.$$

The property holds at b, witnessed by 0_δ, since $R_M(0_\delta) = b$. Suppose it holds at x, witnessed by an expression a. Then

$$R_M(S(a)) = s(R_M(a)) = s(x),$$

so $S(a)$ witnesses the property at $s(x)$. Target induction now gives the property at every $y \in M$. This is surjectivity. □

Here the target's generation principle does all the work. We chose the property "is reached from the orbit," proved it at the start, and showed that it survives a step. The principle then excludes any extra target element outside the reading's image.

2.4 The exact uniqueness result

A bijective structure-preserving map is an isomorphism of pointed step systems. It identifies their elements while preserving the specified start and step. The preceding results now fit together.

Theorem 2.7 (Uniqueness of a faithful generated tally)**.** *For every faithful generated step system (M, b, s), the canonical reading $R_M : \mathbb{N}_\delta \to M$ is bijective. It is the unique bijective map preserving the starting point and the step.*

Proof. By Lemma 2.5, the first two hypotheses make R_M injective. By Lemma 2.6, the third makes it surjective. It is therefore bijective and already preserves the structure by its construction.

Any other bijective structure-preserving map is, in particular, a structure-preserving map. The uniqueness established in Theorem 2.3 forces it to equal R_M. Thus the isomorphism is unique. □

The result is stronger than saying that some convenient labels can be matched. There is only one matching compatible with the starting point and the step. Changing the names or the carrier does not introduce a choice into that matching.

It is also more precise than the statement that every system with a step is arithmetic. A raw step system always receives a reading. To identify its whole carrier with the orbit, we used injectivity, separation and generation. The conclusion carries those conditions with it.

The conditions are not only sufficient. They are exactly what a bijective reading requires.

Proposition 2.8 (The faithfulness conditions are exact)**.** *Let (M, b, s) be a pointed step system.*

1. *Target induction holds exactly when R_M is surjective.*
2. *The system is faithful and generated exactly when R_M is bijective.*

Proof. The proof of Lemma 2.6 used only target induction, so target induction gives surjectivity. Conversely, suppose R_M is surjective, and let P satisfy $P(b)$ and $P(x) \Rightarrow P(s(x))$ for every x. Induction on the orbit proves $P(R_M(a))$ for every a, since $R_M(0_\delta) = b$ and $R_M(S(a)) = s(R_M(a))$. Every $y \in M$ is some $R_M(a)$, so $P(y)$ holds.

Theorem 2.7 proved the forward half of the second assertion. Conversely, let R_M be bijective. The first assertion gives target induction. If $s(x) = s(y)$, write $x = R_M(a)$ and $y = R_M(c)$; then $R_M(S(a)) = R_M(S(c))$, so $S(a) = S(c)$ by injectivity of R_M, and Proposition 1.2 gives $a = c$ and hence $x = y$. If $s(x) = b$ with $x = R_M(a)$, then $R_M(S(a)) = R_M(0_\delta)$, so $S(a) = 0_\delta$, contrary to Proposition 1.2. □

Injectivity of the reading needs less than the first two conditions. The proof of Lemma 2.5 used them only at elements the reading reaches, and there it needs them exactly: the reading is injective precisely when the step is injective on reached elements and never takes a reached element to the start. The converse is the argument just given for the second assertion, applied to reached elements only, so that no surjectivity is needed to write them as $R_M(a)$ and $R_M(c)$. Add to the orbit one extra element $*$ with $s(*) = 0_\delta$. The start is now a step, yet the reading is still injective. What fails is surjectivity: nothing reaches $*$.

2.5 Where the force of the argument lies

There are three distinct achievements here. First, we constructed a map from the orbit into an arbitrary pointed step system. Second, we proved that no other map preserves the specified data. Third, for faithful generated targets, we proved that this map reaches every element and merges none.

The first two give initiality. The third gives categoricity within the stated class of targets. Their combination gives a unique isomorphism. Keeping these achievements separate makes the theorem easier to use: a later construction may need only the unique reading, while a change of arithmetic carrier needs the full correspondence.

This is a familiar kind of mathematical uniqueness theorem. Its role here is foundational: it shows that the arithmetic carrier obtained from finite distinction is fixed up to its unique structure-preserving correspondence. The further work is to construct operations on that carrier and to identify what additional reasoning principles are needed for stronger statements. The number of symbols used to describe the carrier does not answer either question. The constructions and their proofs do.

Questions to work through

1. In Theorem 2.3, identify the exact induction hypothesis and the equation that uses preservation of the target step. Which of the three target conditions in Definition 2.4 appears in this proof?

2. In Lemma 2.5, mark each use of separation and each use of injectivity. Explain why the target induction principle is absent.

3. State the property to which target induction is applied in Lemma 2.6. Give the witness at the start and the witness after a step.

4. Why does uniqueness among all structure-preserving maps imply uniqueness among bijective structure-preserving maps?

5. In the system obtained by adding $*$ with $s(*) = 0_\delta$, decide which conditions of Definition 2.4 hold. Exhibit a property for which target induction fails, and explain which assertion of Proposition 2.8 this illustrates.

Chapter 3

Addition, multiplication, and order

A tally tells us how many steps have been taken. Arithmetic begins when we use one tally to act on another. To add, start at one orbit position and take the steps recorded by the other. To multiply, repeat an addition. To compare, remove matching steps until one of the records reaches its start.

These instructions concern the expressions already constructed. We do not enlarge their carrier or postulate a table of arithmetic laws. We define the operations, then prove what the definitions require. The order of the proofs matters: a familiar identity cannot justify an earlier step merely because we recognize it from ordinary arithmetic.

For the rest of this chapter, write 0 for 0_δ and 1 for $S(0)$. The letters a, b, c denote elements of $\mathbb{N}_\delta$. Products such as ab mean the multiplication defined below.

3.1 Addition follows the second record

Definition 3.1 (Addition)**.** Define addition by the two recursive clauses

$$a + 0 = a, \qquad a + S(b) = S(a + b). \tag{3.1}$$

The second input controls the recursion. If it is the starting record, there is nothing to do. If it has one more step, perform the earlier addition and then take one more step. Each recursive call removes an outer step from that input, so evaluation ends on every constructed expression.

The definition is deliberately asymmetric. It gives $a + 0 = a$ immediately, but it does not give $0 + a = a$ immediately. It tells us how to move a step out of the second input, but not out of the first. Both missing facts have proofs.

Lemma 3.2 (Moving a step through addition)**.** *For all $a, b \in \mathbb{N}_\delta$,*

$$0 + a = a, \qquad S(a) + b = S(a + b).$$

Proof. For the first identity, induct on a. At 0 the identity is $0 + 0 = 0$, which is a defining clause. If $0 + a = a$, then

$$0 + S(a) = S(0 + a) = S(a).$$

For the second identity, fix a and induct on b. At 0, both sides are $S(a)$. If $S(a) + b = S(a + b)$, then

$$S(a) + S(b) = S(S(a) + b) = S(S(a + b)) = S(a + S(b)).$$

This is the required identity at $S(b)$. □

The second proof illustrates a recurring technique. An equation is easy to use when it matches the argument on which the definition recurses. If it does not, first prove a lemma that moves the construction into that position.

Theorem 3.3 (Order and grouping of addition)**.** *Addition is commutative and associative:*

$$a + b = b + a, \qquad (a + b) + c = a + (b + c).$$

Proof. For commutativity, induct on a, keeping b arbitrary. At 0, the two sides agree by the defining zero clause and Lemma 3.2. If $a + b = b + a$, then

$$S(a) + b = S(a + b) = S(b + a) = b + S(a).$$

For associativity, induct on c. At 0, both sides reduce to $a + b$. If $(a + b) + c = a + (b + c)$, then

$$\begin{aligned}(a + b) + S(c) &= S((a + b) + c)\\ &= S(a + (b + c))\\ &= a + S(b + c)\\ &= a + (b + S(c)).\end{aligned}$$

The first, third and fourth equalities use the recursive addition clause; the second uses the induction hypothesis. □

We may now rearrange and regroup finite sums. The permission has been earned by these proofs. It was not part of the definition of addition.

Proposition 3.4 (Cancellation)**.** *If $a + b = a + c$, then $b = c$. If $a + c = b + c$, then $a = b$.*

Proof. For the first assertion, induct on a. At 0, remove $0+$ from both sides by Lemma 3.2. At $S(a)$, the equality becomes $S(a + b) = S(a + c)$. Injectivity of S gives $a + b = a + c$, and the induction hypothesis gives $b = c$. For the second assertion, commute the common right addend to the left and apply the first assertion. □

Cancellation will do substantial work in the next chapter. When two signed descriptions contain the same contribution on both sides of a comparison, it lets us remove that contribution without changing the comparison.

3.2 Multiplication repeats an addition

Definition 3.5 (Multiplication)**.** Define multiplication by

$$a \cdot 0 = 0, \qquad a \cdot S(b) = a \cdot b + a. \tag{3.2}$$

The second input again controls the recursion. The starting case performs no additions. Each further step adds one more copy of a to the result. Thus the operation is built from the earlier addition, just as addition was built from the step.

Lemma 3.6 (The other argument of multiplication)**.** *For all $a, b \in \mathbb{N}_\delta$,*

$$0 \cdot b = 0, \qquad S(a) \cdot b = a \cdot b + b.$$

Proof. Induction on b proves the first assertion. Its base case is a defining clause. In the step, $0 \cdot S(b) = 0 \cdot b + 0 = 0$.

For the second assertion, again induct on b. At 0, both sides are 0. At the next step, the induction hypothesis gives

$$\begin{aligned} S(a) \cdot S(b) &= S(a) \cdot b + S(a) \\ &= (a \cdot b + b) + S(a) \\ &= S((a \cdot b + b) + a) \\ &= S((a \cdot b + a) + b) \\ &= (a \cdot b + a) + S(b) \\ &= a \cdot S(b) + S(b). \end{aligned}$$

The middle rearrangement uses only the addition laws already established. □

Proposition 3.7 (Commutativity and the unit)**.** *For all $a, b \in \mathbb{N}_\delta$,*

$$ab = ba, \qquad a1 = 1a = a.$$

Proof. Induct on a for commutativity. The zero case follows from the two zero laws. In the step,

$$S(a)b = ab + b = ba + b = bS(a).$$

For the unit, $a1 = aS(0) = a0 + a = 0 + a = a$. Commutativity gives $1a = a$. □

3.3 Why multiplication distributes

To multiply by a sum, the second input asks for two successive groups of additions. We should therefore obtain the sum of the two products. The following induction makes that explanation exact.

Theorem 3.8 (Distributivity)**.** *For all $a, b, c \in \mathbb{N}_\delta$,*

$$a(b + c) = ab + ac, \qquad (a + b)c = ac + bc.$$

Proof. For the first identity, fix a, b and induct on c. At 0, both sides reduce to ab. If $a(b + c) = ab + ac$, then

$$\begin{aligned} a(b + S(c)) &= aS(b + c) \\ &= a(b + c) + a \\ &= (ab + ac) + a \\ &= ab + (ac + a) \\ &= ab + aS(c). \end{aligned}$$

The fourth equality is associativity of addition. For the second identity, commute the product, apply the first identity and commute the two resulting products:

$$(a+b)c = c(a+b) = ca + cb = ac + bc. \qquad \square$$

Proposition 3.9 (Grouping of multiplication)**.** *For all $a, b, c \in \mathbb{N}_\delta$, $(ab)c = a(bc)$.*

Proof. Induct on c. Both sides are 0 at the start. At a successor,

$$(ab)S(c) = (ab)c + ab = a(bc) + ab = a(bc + b) = a(bS(c)).$$

The equalities use, in order, the multiplication clause, the induction hypothesis, distributivity and the multiplication clause again. $\square$

This completes the dependency chain for the elementary algebra: recursive addition, addition laws, recursive multiplication, commutativity, distributivity and associativity. Later expansions of products of sums depend on this chain.

3.4 The step determines both operations

We defined addition and multiplication by recursion, then proved their laws. The question can be turned around. Suppose someone proposes other operations $\oplus$ and $\otimes$ on $\mathbb{N}_\delta$ and claims only a few familiar laws for them. Could they differ from ours? Not once adding one is required to be the step.

Theorem 3.10 (A few laws force the operations)**.** *Let $\oplus$ and $\otimes$ be binary operations on $\mathbb{N}_\delta$.*

1. *If $\oplus$ is associative, and $a \oplus 0 = a$ and $a \oplus 1 = S(a)$ for every a, then $a \oplus b = a + b$ for all a, b.*
2. *If $a \otimes 0 = 0$, $a \otimes 1 = a$ and $a \otimes (b+c) = a \otimes b + a \otimes c$ for all a, b, c, then $a \otimes b = ab$ for all a, b.*

Proof. For the first assertion, fix a and induct on b. At 0, the hypothesis gives $a \oplus 0 = a = a + 0$. Suppose $a \oplus b = a + b$. Since $S(b) = b \oplus 1$ by hypothesis,

$$a \oplus S(b) = a \oplus (b \oplus 1) = (a \oplus b) \oplus 1 = S(a \oplus b) = S(a + b) = a + S(b).$$

The equalities use the step hypothesis, associativity, the step hypothesis again, the induction hypothesis and the addition clause.

For the second assertion, again fix a and induct on b. At 0 both sides are 0. The addition clauses give $b + 1 = S(b + 0) = S(b)$, so if $a \otimes b = ab$, then

$$a \otimes S(b) = a \otimes (b + 1) = a \otimes b + a \otimes 1 = ab + a = aS(b). \qquad \square$$

The hypotheses do separate work. Associativity cannot be omitted from the first assertion. The operation that agrees with $+$ when its second input is 0 or 1, and returns its first input otherwise, satisfies the other two conditions. It gives $0 \oplus 2 = 0$, and it is not associative: $(0 \oplus 1) \oplus 1 = 2$, while $0 \oplus (1 \oplus 1) = 0$. The second assertion uses no commutativity.

These laws belong to a familiar list. A *commutative semiring* is a set with two associative and commutative operations, an element neutral for the first and an element neutral for the second, such that multiplying by the first neutral element gives that element and multiplication distributes over addition. The theorems of this chapter show that $\mathbb{N}_\delta$, with 0, 1, + and $\cdot$, is a commutative semiring.

Proposition 3.11 (The orbit maps uniquely into every commutative semiring)**.** *For every commutative semiring A, with neutral elements 0_A and 1_A, there is exactly one map $f : \mathbb{N}_\delta \to A$ with*

$$f(0) = 0_A, \qquad f(1) = 1_A, \qquad f(a+b) = f(a) + f(b), \qquad f(ab) = f(a)f(b).$$

Proof. Let f be the canonical reading of Chapter 2 into the pointed step system $(A, 0_A, x \mapsto x + 1_A)$. Then $f(1) = 0_A + 1_A = 1_A$. For additivity, induct on b; the base case uses the neutral element, and the step is

$$f(a + S(b)) = f(S(a+b)) = f(a+b) + 1_A = f(a) + f(b) + 1_A = f(a) + f(S(b)).$$

Multiplicativity follows in the same way: the base case uses $f(a) \cdot 0_A = 0_A$, and

$$f(aS(b)) = f(ab + a) = f(a)f(b) + f(a) = f(a)\big(f(b) + 1_A\big) = f(a)f(S(b)).$$

For uniqueness, any map g with these properties satisfies $g(0) = 0_A$ and $g(S(n)) = g(n+1) = g(n) + 1_A$. It therefore preserves the start and the step of the same pointed system, and Theorem 2.3 gives $g = f$. □

Corollary 3.12 (The only semiring whose unit step is the tally step)**.** *Let $\oplus$, $\otimes$, e and u make $\mathbb{N}_\delta$ a commutative semiring, with e neutral for $\oplus$ and u neutral for $\otimes$. If $a \oplus u = S(a)$ for every a, then $e = 0$, $u = 1$, $\oplus = +$ and $\otimes = \cdot$.*

Proof. The element e is 0 or a step. Suppose $e = S(w)$. Then $w \oplus u = S(w) = e$, and

$$0 = 0 \oplus e = 0 \oplus (w \oplus u) = (0 \oplus w) \oplus u = S(0 \oplus w),$$

contrary to Proposition 1.2. Hence $e = 0$, and $u = e \oplus u = S(e) = 1$. The first part of Theorem 3.10 now gives $\oplus = +$. The semiring laws give $a \otimes 0 = 0$, $a \otimes 1 = a$ and distributivity over +, so the second part gives $\otimes = \cdot$. □

The arithmetic of the tally is therefore not one convenient choice among several. Ask for a commutative semiring on the orbit in which adding the unit takes one step, and exactly one structure remains. The step carries that content: other commutative semiring structures on $\mathbb{N}_\delta$ keep its start and add differently, as the last question at the end of the chapter shows.

3.5 Comparing two finite records

Comparison need not inspect a decimal numeral. The expressions themselves carry enough information. Compare their outer forms. If both are steps, remove one step from each and compare what remains.

Definition 3.13 (Finite comparison)**.** Let $L(a, b)$ have the values true or false, with recursive clauses

$$\begin{aligned} L(0, b) &= \text{true}, \\ L(S(a), 0) &= \text{false}, \\ L(S(a), S(b)) &= L(a, b). \end{aligned}$$

Write $a \leq b$ when $L(a, b) = \text{true}$.

The cases are exhaustive. The first input reaches 0, or the second does, or both have a step to remove. On each recursive call, an outer step is removed from both inputs. Every finite comparison therefore ends with an answer. This fact will later distinguish finite arithmetic from comparison of arbitrary continuum descriptions.

Theorem 3.14 (Agreement with the natural-number reading)**.** *Let $r : \mathbb{N}_\delta \to \mathbb{N}$ be the reading of Chapter 1. Then*

$$r(a + b) = r(a) + r(b), \qquad r(ab) = r(a)r(b),$$

and

$$L(a, b) = \text{true} \quad \Longleftrightarrow \quad r(a) \leq r(b).$$

Proof. For addition, induct on b. At 0 the assertion reduces to $r(a) = r(a)$. For the step, use $r(S(x)) = r(x) + 1$ and the induction hypothesis:

$$r(a + S(b)) = r(S(a + b)) = r(a) + r(b) + 1 = r(a) + r(S(b)).$$

For multiplication, induct on b again. The zero case is immediate. In the step, the addition identity just proved gives

$$r(aS(b)) = r(ab + a) = r(a)r(b) + r(a) = r(a)r(S(b)).$$

For comparison, follow its three recursive cases. At $(0, b)$, the left side is true and $0 \leq r(b)$. At $(S(a), 0)$, the left side is false and $r(a) + 1 \leq 0$ is false. At $(S(a), S(b))$, remove the common successor: $r(a) + 1 \leq r(b) + 1$ is equivalent to $r(a) \leq r(b)$. The induction hypothesis identifies this last comparison with $L(a, b) = \text{true}$. □

The theorem connects the constructed arithmetic with its familiar notation. It does not supply the definitions retrospectively: the recursive operations and comparison were specified before their readings were proved.

3.6 Subtraction stops at the start

Removing matching steps also supplies a finite subtraction procedure. Define the *truncated difference* $a \dot{-} b$ by

$$\begin{aligned} a \dot{-} 0 &= a, \\ 0 \dot{-} S(b) &= 0, \\ S(a) \dot{-} S(b) &= a \dot{-} b. \end{aligned} \tag{3.3}$$

There is no expression before 0 in this carrier. If the first input runs out before the second, the procedure returns 0. This is a useful operation, but it does not retain a negative difference.

Proposition 3.15 (Reading a truncated difference)**.** *The natural-number reading of $a \dot{-} b$ is the ordinary truncated natural difference $r(a) \dot{-} r(b)$.*

Proof. Induct on a, treating b as arbitrary. If $a = 0$, the result is 0 whether b is 0 or a successor. If $a = S(c)$ and $b = 0$, both sides give $r(S(c))$. If $b = S(d)$, both truncated subtractions remove their common successor, reducing the assertion to the induction hypothesis at (c, d). □

The next chapter keeps both sides of a difference instead of stopping when one side runs out. That change in representation is enough to make signed arithmetic possible.

Questions to work through

1. In the proof of commutativity of addition, identify the exact point where the lemma for a step in the first argument is needed.

2. Reconstruct the cancellation proof without using the map r. Which property of the step permits the induction to continue?

3. In the distributivity proof, mark each equality by its justification: definition, induction hypothesis or an earlier theorem.

4. Explain why the comparison procedure terminates on the finite expressions. Which part of that explanation would need replacement for an input given by an unending approximation procedure?

5. Verify the operation described after Theorem 3.10: check $a \oplus 0 = a$ and $a \oplus 1 = S(a)$, then locate the first step of the theorem's proof that fails for it.

6. Exchange 1 and 2 in the natural-number reading and transport the ordinary operations along the resulting bijection. Show that the result is a commutative semiring on $\mathbb{N}_\delta$ whose neutral element for addition is 0, compute $1 \oplus 1$, and identify the hypothesis of Corollary 3.12 that fails.

Chapter 4

Differences and ratios

Suppose one record counts contributions and another counts removals. Keeping only their truncated difference loses information when removals exceed contributions. Keeping the two records separately avoids that loss. It also creates a new problem: different pairs can describe the same difference.

The same problem appears with ratios. Changing the unit of comparison can change both parts of a fraction while leaving its value unchanged. Arithmetic must respect these changes of description. Otherwise the result of a calculation would depend on how we happened to write its inputs.

This chapter constructs the two extensions in that order. First we identify balanced pairs of orbit records. Then we identify ratios by cross multiplication. At each stage we must prove that the identification is consistent and that the operations preserve it.

4.1 Keep both sides of a difference

Definition 4.1 (A signed record and its balance)**.** A signed record is a pair (a, b) of elements of $\mathbb{N}_\delta$. Its first entry records the positive side and its second entry the negative side. Define

$$(a, b) \sim (c, d) \quad \Longleftrightarrow \quad a + d = c + b. \tag{4.1}$$

The right side uses only orbit addition. It does not subtract anything. It compares the first positive side together with the second negative side against the second positive side together with the first negative side. Equality of those totals is the condition for balance.

The notation (a, b) still names a particular pair. The notation $[a, b]$ will name its *class*: all pairs balanced with it. Before using classes, we must show that balance is an equivalence relation. This means that a pair balances with itself, balance can be reversed, and two successive balances compose.

Proposition 4.2 (Balance is an equivalence relation)**.** *The relation $\sim$ is reflexive, symmetric and transitive.*

Proof. Reflexivity is the identity $a + b = a + b$. Symmetry reverses the equality $a + d = c + b$.

For transitivity, suppose

$$a + d = c + b, \qquad c + f = e + d.$$

We must prove $a + f = e + b$. Add f to the first equality, then use the second equality and the addition laws:

$$(a + f) + d = (a + d) + f = (c + b) + f = (c + f) + b = (e + d) + b = (e + b) + d.$$

Cancel the common addend d by Proposition 3.4. The result is the required balance. □

Definition 4.3 (Constructed integers)**.** The carrier $\mathbb{Z}_\delta$ consists of signed records identified by balance. Thus $[a,b] = [c,d]$ exactly when $a + d = c + b$.

This operation of forming classes is called taking a *quotient*. Here the word has no connection with division. It means that an explicitly specified equivalence relation determines when descriptions count as the same object. The equivalence proof is what makes the classes coherent.

4.2 Operations must survive a change of representative

The natural candidate operations on pairs are

$$\begin{aligned} (a,b) + (c,d) &= (a + c, b + d), \\ -(a,b) &= (b,a), \\ (a,b)(c,d) &= (ac + bd, ad + bc). \end{aligned} \tag{4.2}$$

The product places equal-sign contributions on the positive side and opposite-sign contributions on the negative side. Every entry is an orbit expression, so all three formulas construct signed records.

To turn these formulas into operations on $\mathbb{Z}_\delta$, we must prove more: replacing an input by a balanced pair must produce a balanced output. This requirement is called *representative independence*.

Theorem 4.4 (Signed arithmetic is representative independent)**.** *Addition, negation and multiplication in* (4.2) *preserve balance. They therefore define operations on* $\mathbb{Z}_\delta$.

Proof. Suppose $(a,b) \sim (a',b')$, so $a + b' = a' + b$.

For addition of a fixed pair (c,d), rearranging terms gives

$$(a + c) + (b' + d) = (a + b') + (c + d) = (a' + b) + (c + d) = (a' + c) + (b + d).$$

This is exactly the balance of the two sums. The same argument with the two summands exchanged handles replacement of the other input.

For negation, the required equation is $b + a' = b' + a$. It is the assumed balance with its sides reversed and its summands commuted.

For multiplication by (c,d), the two sides of the required balance are

$$(ac + bd) + (a'd + b'c), \qquad (a'c + b'd) + (ad + bc).$$

Group the terms in the first expression by their factors c and d:

$$\begin{aligned} (ac + bd) + (a'd + b'c) &= (a + b')c + (b + a')d \\ &= (a' + b)c + (b' + a)d \\ &= (a'c + b'd) + (ad + bc). \end{aligned}$$

The middle equality uses the given balance and its commuted form. The other equalities use distributivity and the addition laws from Chapter 3. Exchanging the two factors handles replacement of the second input. Replacing both inputs is now justified in two successive steps, using transitivity of balance. □

We may consequently write the same operation symbols on classes. In particular, set

$$0 = [0, 0], \qquad 1 = [1, 0], \qquad -[a, b] = [b, a].$$

The role of the brackets matters. A pair and its negative usually differ as records, but their sum has class 0 because its two entries balance.

4.3 The integer laws follow on the classes

Theorem 4.5 (The laws of signed arithmetic)**.** *Addition on $\mathbb{Z}_\delta$ is commutative and associative, has identity 0, and satisfies $x + (-x) = 0$. Multiplication is commutative and associative, has identity 1, and distributes over addition.*

Proof. Choose representatives $x = [a, b]$, $y = [c, d]$, $z = [e, f]$.

Commutativity and associativity of addition hold in each entry by the corresponding orbit laws. Adding $[0, 0]$ leaves both entries unchanged. Also

$$x + (-x) = [a + b, b + a] = [0, 0],$$

because $a + b = b + a$ is the balance condition with $[0, 0]$.

For multiplication, commutativity of the orbit product makes the two entries of xy equal to the two entries of yx. Multiplying by $[1, 0]$ gives $[a, b]$ using the unit and zero laws.

To check associativity, expand both $(xy)z$ and $x(yz)$. After regrouping, each has positive entry

$$ace + bde + adf + bcf$$

and negative entry

$$acf + bdf + ade + bce.$$

Every regrouping is justified by the associative and distributive orbit laws. Thus the representatives themselves agree.

For left distributivity, $x(y + z)$ has entries

$$\big(a(c + e) + b(d + f),\ a(d + f) + b(c + e)\big).$$

Expansion gives

$$\big(ac + ae + bd + bf,\ ad + af + bc + be\big),$$

which, after regrouping, are the entries of $xy + xz$. Right distributivity follows by commuting the product and applying left distributivity. □

These are the laws of a commutative ring. The name packages the identities we have just proved. Subtraction is now defined by $x - y = x + (-y)$; unlike truncated subtraction, it retains a negative result.

4.4 Reading the signed construction

We can compare the constructed integers with familiar integer notation. Let r be the natural-number reading from Chapter 1, and define the reading of a pair by

$$I(a,b) = r(a) - r(b) \quad \text{in } \mathbb{Z}. \tag{4.3}$$

Here the right side is a comparison with ordinary signed arithmetic. It was not used to define the pairs, balance, or their operations.

Proposition 4.6 (The signed reading is faithful)**.** *Two signed records balance exactly when their readings under I agree. The induced map $I : \mathbb{Z}_\delta \to \mathbb{Z}$ is bijective and preserves zero, one, addition, negation and multiplication.*

Proof. The addition reading of Theorem 3.14 gives

$$\begin{aligned} (a,b) \sim (c,d) \quad &\iff \quad r(a) + r(d) = r(c) + r(b) \\ &\iff \quad r(a) - r(b) = r(c) - r(d). \end{aligned}$$

The first equivalence also uses faithfulness of r. The second is ordinary integer rearrangement. Thus I is well defined on classes and injective.

Every nonnegative integer n is the reading of $[e(n), 0]$, where e is the expansion map from Chapter 1. Every negative integer $-n$, for $n > 0$, is the reading of $[0, e(n)]$. This proves surjectivity.

Preservation of zero and one follows by reading their representatives. For addition and negation, expand the definitions:

$$\begin{aligned} I([a+c, b+d]) &= (r(a) - r(b)) + (r(c) - r(d)), \\ I([b,a]) &= -(r(a) - r(b)). \end{aligned}$$

For multiplication, the two orbit reading identities give

$$\begin{aligned} I([ac+bd, ad+bc]) &= r(a)r(c) + r(b)r(d) - r(a)r(d) - r(b)r(c) \\ &= (r(a) - r(b))(r(c) - r(d)). \end{aligned}$$

Thus the operations agree under the reading. □

The proof distinguishes construction from comparison. The carrier and its laws were built from orbit records; the bijection then identifies that construction with the usual integers. We can use this faithful reading to check an integer identity without changing the constructed objects.

4.5 A ratio needs a nonzero denominator

A ratio record consists of a signed pair and a nonzero orbit denominator. Keeping the denominator in $\mathbb{N}_\delta$ places its sign in the numerator. We will write u, v, w for the integer classes of the chosen numerator pairs, and abbreviate a ratio record by (u, d). The record retains

its actual pair; the abbreviation saves us from writing both of its entries in every formula. The letters d, e, f denote nonzero orbit denominators, also read as the corresponding positive integers when they occur in signed products.

Representative independence of signed arithmetic ensures that replacing a numerator pair by a balanced pair does not change any cross comparison below. This is why the abbreviated notation is legitimate.

Definition 4.7 (Cross equality)**.** Two ratio records (u, d) and (v, e) are cross equal when

$$ue = vd. \tag{4.4}$$

The equation is equality of constructed integers. Equivalently, before passing to signed classes, the two scaled signed records balance.

The denominator restriction does real work. It ensures that a common denominator can be cancelled in the proof that cross equality is transitive.

Proposition 4.8 (Cross equality is an equivalence relation)**.** *Cross equality on ratio records is reflexive, symmetric and transitive.*

Proof. Reflexivity is $ud = ud$; symmetry reverses a cross equality. For transitivity, suppose $ue = vd$ and $vf = we$. Multiply the first equality by f and the second by d. The integer laws give

$$(uf)e = (ue)f = (vd)f = (vf)d = (we)d = (wd)e.$$

The common factor e is nonzero. Apply the faithful integer reading of Proposition 4.6, cancel that nonzero integer factor, and use faithfulness to return to constructed integers. The result is $uf = wd$, as required. □

The cancellation used here is ordinary integer cancellation. Its use is explicit: the preceding proposition supplied an operation-preserving bijection, so an integer equality proved after reading is also an equality of the constructed classes. No rational arithmetic has entered this proof.

Definition 4.9 (Constructed rationals)**.** The carrier $\mathbb{Q}_\delta$ consists of ratio records identified by cross equality. Write $\langle u; d\rangle$ for the class of (u, d).

The angle brackets keep this second quotient visually separate from the signed class $[a, b]$. Once the construction is understood, the familiar notation u/d can be used for $\langle u; d\rangle$.

4.6 Constructing arithmetic on ratio classes

Define

$$\begin{aligned} \langle u; d\rangle + \langle v; e\rangle &= \langle ue + vd; de\rangle, \\ -\langle u; d\rangle &= \langle -u; d\rangle, \\ \langle u; d\rangle\langle v; e\rangle &= \langle uv; de\rangle. \end{aligned} \tag{4.5}$$

The new denominator is allowed: a product of two nonzero orbit positions is nonzero. This follows either from their faithful natural-number readings or directly from repeated addition of a nonzero position.

Theorem 4.10 (Rational arithmetic is representative independent)**.** *The operations in* (4.5) *preserve cross equality.*

Proof. Suppose $ud' = u'd$ and $ve' = v'e$. These are the hypotheses for replacing (u, d) by (u', d') and (v, e) by (v', e').

For addition, cross multiplication of the proposed outputs gives

$$\begin{aligned}(ue + vd)(d'e') &= (ud')ee' + (ve')dd' \\ &= (u'd)ee' + (v'e)dd' \\ &= (u'e' + v'd')(de).\end{aligned}$$

Thus the two sums are cross equal.

For multiplication,

$$(uv)(d'e') = (ud')(ve') = (u'd)(v'e) = (u'v')(de).$$

For negation, $ud' = u'd$ gives $(-u)d' = (-u')d$ by negating both sides. All three operations are therefore well defined on ratio classes. □

The formulas were specified as constructions. The theorem proves that they respect the identification, which is the exact condition needed to lift them to classes. It does not by itself show that no other construction could serve. Section 4.9 proves that uniqueness.

4.7 Why a reciprocal keeps the sign in the numerator

For a nonzero numerator u, let $|u|$ denote its positive magnitude. This magnitude has a finite construction. For a signed representative (a, b), remove matching steps and add the two remaining truncated differences:

$$|(a, b)| = (a \dot{-} b) + (b \dot{-} a). \tag{4.6}$$

Its natural-number reading is $|r(a) - r(b)|$. To verify this, compare $r(a)$ and $r(b)$. In the first order, the second truncated difference is zero and the first is $r(a) - r(b)$; in the other order their roles are reversed. The truncated-difference reading from the previous chapter therefore gives the stated absolute value. In particular, the magnitude is nonzero exactly when the signed class is nonzero.

The sign is also decided by finite comparison: (a, b) is nonnegative exactly when $L(b, a)$ is true. This agrees with $0 \le r(a) - r(b)$ by Theorem 3.14. No search through an infinite description is involved.

Define the reciprocal on a ratio with nonzero numerator by

$$\langle u; d\rangle^{-1} = \begin{cases} \langle d; |u|\rangle, & u > 0, \\ \langle -d; |u|\rangle, & u < 0. \end{cases} \tag{4.7}$$

Both cases have a nonzero orbit denominator. To make the operation defined on every class, set $0^{-1} = 0$. This last clause is a convention for the value of a total operation; the inverse cancellation theorem retains its nonzero hypothesis.

Proposition 4.11 (The reciprocal is well defined and cancels)**.** *Cross-equal ratio records have cross-equal reciprocals. For every nonzero $q \in \mathbb{Q}_\delta$,*

$$qq^{-1} = q^{-1}q = 1, \qquad 1 = \langle 1; 1\rangle.$$

Proof. Suppose $ue = vd$ with d, e positive. If $u = 0$, cancellation of the nonzero factor d gives $v = 0$; both reciprocal records have zero class. The same argument in reverse shows that nonzero numerators remain nonzero.

In the nonzero case, u and v have the same sign. Indeed, multiplication by a positive integer preserves sign, so opposite signs would contradict $ue = vd$. If both are positive, the reciprocal cross equation is $dv = eu$, the original equality reversed. If both are negative, it is $(-d)(-v) = (-e)(-u)$, again the same equality. This proves representative independence in all cases.

Now let $q = \langle u; d\rangle$ be nonzero. For $u > 0$, its product with the reciprocal is $\langle ud; du\rangle$, cross equal to $\langle 1; 1\rangle$. For $u < 0$, the product is $\langle u(-d); d(-u)\rangle$, whose numerator and denominator also agree. Commutativity gives cancellation in the opposite order. □

4.8 Checking the field laws

Theorem 4.12 (The rational field laws)**.** *The constructed rationals have commutative, associative addition with zero and additive inverses; commutative, associative multiplication with one; distributivity; distinct zero and one; and multiplicative inverses for nonzero elements.*

Proof. Write three representatives as $(u, d), (v, e), (w, f)$. For addition, commutativity exchanges $ue + vd$ with $vd + ue$ and de with ed. The two groupings of a three-term sum, after expansion, have the common denominator def and numerator $uef + vdf + wde$. The two numerators agree by the integer laws, and the denominators agree by the orbit laws. This proves associativity.

Adding $\langle 0; 1\rangle$ leaves $\langle u; d\rangle$ unchanged. Adding its negative produces $\langle 0; d^2\rangle$, which is cross equal to $\langle 0; 1\rangle$.

For multiplication, the two orders give uv over de, and the two groupings of three factors give uvw over def. The integer and orbit laws justify all rearrangements. Multiplying by $\langle 1; 1\rangle$ leaves both parts unchanged.

For left distributivity, the representative of the left side is

$$\langle u(vf + we); def\rangle.$$

The representative obtained by adding the two products on the right is

$$\langle uvdf + uwde; d^2ef\rangle.$$

The second numerator and denominator are each the first multiplied by d, so cross multiplication proves equality. Commutativity supplies right distributivity.

Zero and one are distinct because their cross equality would assert $0 = 1$ in the integer construction, contradicting its faithful reading. Proposition 4.11 supplies the inverses of nonzero elements. □

The construction has now reached a field using finite records, balanced identifications, cross multiplication and explicit operations. It has not introduced a procedure for deciding every possible mathematical question. The finite comparisons used here terminate because they act on finite constructed data.

4.9 Each extension is determined by its task

The constructions of this chapter specified pairs, relations and formulas. A reader may ask whether different choices would have served as well. Each extension answers a definite question, and each is the unique answer.

Signed records make subtraction possible while keeping the orbit's addition. Write $\iota(n) = [n, 0]$. A *group* is a set with an associative operation, written $+$, a neutral element and inverses; it is a *commutative group* when the operation is also commutative. A map f from $\mathbb{N}_\delta$ into a group is *additive* when $f(a + b) = f(a) + f(b)$ for all a, b.

Theorem 4.13 (Signed records complete the orbit's addition)**.** *The map ι is additive. For every group G, commutative or not, and every additive map $f : \mathbb{N}_\delta \to G$, there is exactly one additive map $g : \mathbb{Z}_\delta \to G$ with $g(\iota(n)) = f(n)$ for every n. It is*

$$g([a, b]) = f(a) - f(b),$$

and its values lie in the cyclic subgroup of G generated by $f(1)$.

Proof. Additivity of ι is the addition formula $[a, 0] + [b, 0] = [a + b, 0 + 0] = [a + b, 0]$. An additive map sends 0 to the neutral element, since $f(0) = f(0 + 0) = f(0) + f(0)$, and then $f(a + 1) = f(a) + f(1)$ shows, by induction on a, that $f(a)$ is the sum of a copies of $f(1)$. So every value of f, and every negative of a value, is a sum of copies of $f(1)$ or of $-f(1)$, and any two such sums commute. The computations below involve only these elements, so they may be rearranged as in a commutative group, whether or not G is one. The formula for g is representative independent: if $a + d = c + b$, then $f(a) + f(d) = f(c) + f(b)$, so $f(a) - f(b) = f(c) - f(d)$. It is additive, because $g([a + c, b + d]) = f(a + c) - f(b + d) = \big(f(a) - f(b)\big) + \big(f(c) - f(d)\big)$. Since $f(0)$ is the neutral element, $g(\iota(n)) = f(n) - f(0) = f(n)$. Each value $f(a) - f(b)$ is the sum of a copies of $f(1)$ and b copies of $-f(1)$, so it lies in the cyclic subgroup generated by $f(1)$. For uniqueness, every class satisfies $[a, b] = \iota(a) + \big(-\iota(b)\big)$, and an additive map h on $\mathbb{Z}_\delta$ preserves negatives, because $h(x) + h(-x) = h(0)$ is the neutral element. So any such map takes $[a, b]$ to $f(a) - f(b)$. □

The pair $(\mathbb{Z}_\delta, \iota)$ is determined by this property up to exactly one isomorphism compatible with the maps from the orbit: two pairs with the property map into each other, and uniqueness forces both composites to be identities. The map matters, not only the carrier. The rationals with $n \mapsto \langle \iota(n); 1 \rangle$, and the integers with $n \mapsto 2n$, both fail. In each, the element assigned to 1 has a half, and an additive map into the integers extending the natural-number reading would have to send that half to an integer h with $h + h = 1$.

Corollary 4.14 (The constructed integers map uniquely into every commutative ring)**.** *For every commutative ring R there is exactly one map $\mathbb{Z}_\delta \to R$ preserving* 1*, addition and multiplication.*

Proof. Let $f : \mathbb{N}_\delta \to R$ be the map of Proposition 3.11, and let g be its extension given by Theorem 4.13. It sends $1 = [1,0]$ to 1_R, and it preserves products:

$$g\big([ac+bd, ad+bc]\big) = f(a)f(c)+f(b)f(d)-f(a)f(d)-f(b)f(c) = \big(f(a)-f(b)\big)\big(f(c)-f(d)\big).$$

Conversely, if h preserves 1, addition and multiplication, then so does $h \circ \iota$, because ι preserves them, and $h \circ \iota$ sends 0 to 0_R because it is additive. Proposition 3.11 gives $h \circ \iota = f$, and the uniqueness in Theorem 4.13 gives $h = g$. □

A field K has *characteristic zero* when $1_K + \cdots + 1_K$, with one or more terms, is never 0_K. Equivalently, the map $f : \mathbb{N}_\delta \to K$ of Proposition 3.11 sends every nonzero tally to a nonzero element.

Theorem 4.15 (The constructed rationals come first among fields of characteristic zero)**.** *For every field K of characteristic zero there is exactly one map $\mathbb{Q}_\delta \to K$ preserving* 1*, addition and multiplication. It sends $\langle u; d\rangle$ to $g(u)/f(d)$, where f and g are the maps of Proposition 3.11 and Corollary 4.14.*

Proof. The denominator $f(d)$ is nonzero because d is nonzero. If $ue = vd$, the ring map g gives $g(u)f(e) = g(v)f(d)$, so $g(u)/f(d) = g(v)/f(e)$: the formula is representative independent. It preserves sums, since

$$\frac{g(ue+vd)}{f(de)} = \frac{g(u)f(e)+g(v)f(d)}{f(d)f(e)} = \frac{g(u)}{f(d)} + \frac{g(v)}{f(e)},$$

it preserves products in the same way, and it sends $\langle 1;1\rangle$ to 1_K. Conversely, let k preserve 1, addition and multiplication. On the classes $\langle u;1\rangle$ it preserves these operations as a function of u, so Corollary 4.14 gives $k(\langle u;1\rangle) = g(u)$. The cross equality $\langle u;d\rangle\langle \iota(d);1\rangle = \langle u;1\rangle$ then gives $k(\langle u;d\rangle)\, f(d) = g(u)$. □

Two fields with this property are isomorphic by exactly one isomorphism of fields. The ordinary rationals are one of them, so exactly one isomorphism of fields connects $\mathbb{Q}_\delta$ with them. The real numbers have characteristic zero but do not come first: a map from them into the rationals preserving the operations would send $\sqrt{2}$ to a rational whose square is 2.

The order used in this chapter's sign test is also forced. Call a subset P of a commutative ring a *positive cone* when it is closed under addition and multiplication, every element x satisfies $x \in P$, $x = 0$ or $-x \in P$, and no element has both $x \in P$ and $-x \in P$.

Proposition 4.16 (Only one order fits the arithmetic)**.** *The classes of $\mathbb{Z}_\delta$ read as positive integers form a positive cone, and they form the only one. Likewise, the classes $\langle u; d\rangle$ with positive numerator form the only positive cone of $\mathbb{Q}_\delta$.*

Proof. The displayed sets are cones: their readings are closed under addition and multiplication, and the sign of an integer satisfies the other two conditions. For ratios, the sign of the numerator is representative independent by the argument in Proposition 4.11.

Let P be any positive cone. The last condition with $x = 0$ shows $0 \notin P$. If $x \neq 0$, then x or $-x$ lies in P, and in either case $x \cdot x = (-x)(-x) \in P$. Hence $1 = 1 \cdot 1 \in P$, and by addition every $\iota(n)$ with $n \neq 0$ lies in P. In $\mathbb{Z}_\delta$ these are exactly the classes read as positive integers. A class read as negative has its negative in P, so it is not in P. Thus P is the displayed cone. In $\mathbb{Q}_\delta$, also $\langle 1; d\rangle = \langle \iota(d); 1\rangle\langle 1; d\rangle^2 \in P$. A ratio with positive numerator, $\langle u; d\rangle = \langle u; 1\rangle\langle 1; d\rangle$, therefore lies in P, and a ratio with negative numerator does not, because its negative does. □

The order is therefore part of the arithmetic rather than an additional choice. Any ordering compatible with addition and multiplication in this sense is the one read from the finite comparison. The line built from these ratios in Chapter 12 is determined by its task from the other side: every Archimedean ordered field maps into it in exactly one way that preserves the arithmetic and the order, once countable choice is granted (Theorem 12.38). Which further conclusions require additional principles is the question of the next part.

Questions to work through

1. In the transitivity proof for balance, explain why equality of $a + d$ and $c + b$ is more useful than trying to subtract in $\mathbb{N}_\delta$.

2. Identify the two different tasks in defining an operation on classes: constructing its output and proving representative independence. Locate both tasks for signed multiplication.

3. Explain precisely where a nonzero denominator is used in the transitivity proof for cross equality.

4. Reproduce the two sign cases of the reciprocal proof. Explain why assigning $0^{-1} = 0$ does not establish inverse cancellation at zero.

5. Show directly that the integers with $n \mapsto 2n$ fail Theorem 4.13: take f to be the natural-number reading and find the equation that has no integer solution.

6. Using only the three cone conditions, show that every positive cone of $\mathbb{Q}_\delta$ contains $\langle 1; d\rangle$ for every nonzero d. Which condition excludes a cone containing -1?

Part II

What a proof is allowed to use

Chapter 5

The language and the rules

The equation $1 + 1 = 2$ can be read at two levels. We can calculate with the constructed numbers and establish the equality. We can also write a finite argument whose permitted steps are completely specified. The first activity concerns numbers. The second makes the argument itself an object we can study.

This distinction matters when we ask what a result requires. A calculation may be valid, yet conceal the use of a stronger principle in one of its steps. To expose that use, we need to say which expressions are allowed, which inferences count as steps, and how those expressions are interpreted.

We begin with arithmetic. This choice gives us a domain already constructed in Part I and a small language whose rules can be stated in full. It also keeps two questions separate: what the arithmetic structure is, and what a particular formal argument can establish about it.

5.1 Expressions are finite constructions

An arithmetic expression such as $S(0)+S(0)$ names a number. A statement such as $S(0)+S(0) = S(S(0))$ says something that can be proved. We call the first kind of expression a *term* and the second a *formula*.

Definition 5.1 (The arithmetic language)**.** Terms are built from variables $x_0, x_1, \ldots$, the symbol 0, and the operations S, $+$ and $\cdot$. Formulas are built from equalities of terms, the false formula $\bot$, conjunction $\wedge$, disjunction $\vee$, implication $\to$, and the quantifiers $\forall$ and $\exists$. Negation abbreviates implication to falsehood:

$$\neg\varphi \;:=\; \varphi \to \bot.$$

Each term and formula is a finite expression generated by these rules.

The symbols 1 and 2 remain abbreviations for $S(0)$ and $S(S(0))$. An equality between two terms is a formula; it does not assert that the two written expressions have the same shape. Thus $1 + 1$ and 2 are different terms, and $1 + 1 = 2$ is a statement about their values.

We use positions for variables so that the treatment of quantifiers is exact. Immediately inside a quantifier, x_0 denotes its newly bound variable. The earlier variables move up one position. Inside two nested quantifiers, x_0 refers to the inner one and x_1 to the outer one. Ordinary notation such as $\forall x\, \varphi(x)$ will be used when this binding convention is unambiguous.

Two operations on expressions are needed. *Lifting* inserts space for a new variable. *Substitution* replaces a variable by a term. They must respect the distinction between a free variable and one bound by a quantifier.

Definition 5.2 (Lifting and substitution)**.** To lift an expression by d at cutoff c, leave a variable x_n unchanged when $n < c$, and replace it by x_{n+d} otherwise. Apply the operation to each constituent expression; on entering a quantifier, increase c by one. Write $\varphi\uparrow$ for lifting by one at cutoff zero.

To substitute a term t at position k, replace x_k by t, lower an index $n > k$ to $n - 1$, and leave an index $n < k$ unchanged. Again act on each constituent expression. Under a quantifier, substitute at $k + 1$ and first lift the free variables of t by one. Write $\varphi(t)$ for substitution at position zero.

The lowering in substitution has a purpose: instantiating a quantifier removes its variable position. The lifting under a quantifier prevents a free variable in the substituted term from becoming bound accidentally. For example, let φ be $\forall(x_0 = x_1)$: every number equals the value of the free variable, which is written x_1 inside the quantifier. Substitute the term x_0 at position zero. Under the quantifier the rule substitutes at position one and first lifts the term to x_1, so $\varphi(x_0)$ is $\forall(x_0 = x_1)$ again: every number equals the value of x_0, which is false in $\mathbb{N}$. Replacing x_1 by x_0 without the lift would give $\forall(x_0 = x_0)$, which is true: the quantifier would have captured the substituted variable and changed the meaning. These operations are determined by the finite expression. Neither asks whether a formula is true.

5.2 One complete argument

A *context* Γ is a finite list of formulas admitted temporarily as hypotheses. A judgment

$$\Gamma \vdash \varphi$$

says that a finite derivation of φ from those hypotheses has been given. A blank context is written simply $\vdash \varphi$.

Here is the promised proof of $1 + 1 = 2$. Two arithmetic rules supply

$$1 + 0 = 1, \qquad 1 + S(0) = S(1 + 0).$$

Equality substitution replaces $1 + 0$ by 1 in the second formula. The whole derivation is therefore

$$\frac{\vdash 1 + 0 = 1 \qquad \vdash 1 + S(0) = S(1 + 0)}{\vdash 1 + S(0) = S(1)} \quad \text{equality substitution.} \tag{5.1}$$

The concluding formula is $1 + 1 = 2$ after expanding the numeral abbreviations. There is no induction in this argument, and there is no decision about an arbitrary formula. Its two leaves are defining equations of addition.

For complete precision, the formula with a substitution position is $1 + S(0) = S(x_0)$. Filling that position with $1 + 0$ produces the second premise; filling it with 1 produces the conclusion. This is the general equality rule in a small case.

5.3 The permitted inferences

We now give the rules behind judgments. Each displayed premise must itself have a finite derivation. Temporary hypotheses appear to the left of $\vdash$. A rule with no premises starts a branch of the derivation tree.

Hypotheses and equality

Any formula listed in Γ may be used. Equality has reflexivity and substitution:

$$\Gamma \vdash t = t, \qquad \frac{\Gamma \vdash t = s \qquad \Gamma \vdash \varphi(t)}{\Gamma \vdash \varphi(s)}.$$

The terms and the formula with its substitution position are specified as part of the application of the rule. A resemblance between formulas is not enough; the premise must be the indicated instance.

The arithmetic structure

The start and the step satisfy

$$\Gamma \vdash \neg(S(t) = 0), \qquad \frac{\Gamma \vdash S(t) = S(u)}{\Gamma \vdash t = u}.$$

The recursive operations supply four further formulas:

$$\Gamma \vdash t + 0 = t, \qquad \Gamma \vdash t + S(u) = S(t + u),$$
$$\Gamma \vdash t \cdot 0 = 0, \qquad \Gamma \vdash t \cdot S(u) = t \cdot u + t.$$

These are rules of the arithmetic language. Their validity in the constructed carrier was established in Part I. Writing them as rules does not erase the construction that licenses their interpretation.

Induction has the form

$$\frac{\Gamma \vdash \varphi(0) \qquad \Gamma \vdash \forall x\big(\varphi(x) \to \varphi(S(x))\big)}{\Gamma \vdash \forall x\, \varphi(x)}. \tag{5.2}$$

Here the bound induction variable is fresh relative to the hypotheses. In the second premise, $\varphi(S(x))$ denotes φ with x_0 replaced by $S(x_0)$ and every other position unchanged, that is, the substitution of $S(x_0)$ at position one in $\varphi\uparrow$. Other parameters of φ may remain free. The language permits this rule for every formula; the next chapter records separately whether the formula itself contains a quantifier.

Combining and using propositions

Implication is introduced by discharging a temporary hypothesis and used by applying it:

$$\frac{\Gamma, \varphi \vdash \psi}{\Gamma \vdash \varphi \to \psi}, \qquad \frac{\Gamma \vdash \varphi \to \psi \qquad \Gamma \vdash \varphi}{\Gamma \vdash \psi}.$$

The comma means that the indicated hypothesis has been added to the context. For conjunction, proofs of both components give a proof of their conjunction; either component can then be recovered:

$$\frac{\Gamma \vdash \varphi \qquad \Gamma \vdash \psi}{\Gamma \vdash \varphi \wedge \psi}, \qquad \frac{\Gamma \vdash \varphi \wedge \psi}{\Gamma \vdash \varphi}, \qquad \frac{\Gamma \vdash \varphi \wedge \psi}{\Gamma \vdash \psi}.$$

For disjunction, a proof of either component gives the disjunction. To use a disjunction, both cases must lead to the same conclusion:

$$\frac{\Gamma \vdash \varphi}{\Gamma \vdash \varphi \vee \psi}, \qquad \frac{\Gamma \vdash \psi}{\Gamma \vdash \varphi \vee \psi},$$

$$\frac{\Gamma \vdash \varphi \vee \psi \qquad \Gamma, \varphi \vdash \chi \qquad \Gamma, \psi \vdash \chi}{\Gamma \vdash \chi}.$$

Finally, from a derivation of $\bot$ one may infer any specified formula. This is the rule for an impossible case. None of these rules supplies a proof of $\varphi \vee \neg\varphi$ for an arbitrary φ.

Quantifiers and a genuinely arbitrary value

Universal introduction proves a formula at a fresh variable; universal elimination substitutes a term:

$$\frac{\Gamma\uparrow \vdash \varphi}{\Gamma \vdash \forall\varphi}, \qquad \frac{\Gamma \vdash \forall\varphi}{\Gamma \vdash \varphi(t)}.$$

Every formula in $\Gamma \uparrow$ has been lifted over the fresh variable. The hypotheses therefore cannot constrain that variable. This is the exact force of calling it arbitrary.

Existential introduction exhibits a witness. Existential elimination uses a fresh witness without letting it escape into the conclusion:

$$\frac{\Gamma \vdash \varphi(t)}{\Gamma \vdash \exists\varphi}, \qquad \frac{\Gamma \vdash \exists\varphi \qquad \Gamma\uparrow, \varphi \vdash \psi\uparrow}{\Gamma \vdash \psi}.$$

The last condition matters. The conclusion must be the lifted form of a formula from the original context, so it cannot depend on the particular witness chosen inside the branch.

Together these are the base arithmetic rules. A derivation is a finite tree assembled from them, with matching premises at every junction. Its validity as a derivation is a question about expressions and rules. To connect it to arithmetic truth, we still need an interpretation theorem.

5.4 Reading the expressions as arithmetic

We use the ordinary natural-number reading proved faithful in Chapter 1. An *environment* ρ assigns a natural number to each free variable position. Write $[n, \rho]$ for the extended environment with

$$[n, \rho](0) = n, \qquad [n, \rho](k+1) = \rho(k).$$

The new variable receives n and the earlier assignments are retained.

Definition 5.3 (Evaluation and satisfaction)**.** The value $E_\rho(t)$ of a term is defined recursively:

$$E_\rho(x_k) = \rho(k), \qquad E_\rho(0) = 0,$$
$$E_\rho(S(t)) = E_\rho(t) + 1, \qquad E_\rho(t + u) = E_\rho(t) + E_\rho(u),$$
$$E_\rho(t \cdot u) = E_\rho(t)E_\rho(u).$$

Write $\rho \vDash \varphi$ when the formula is satisfied. Equality is interpreted as equality of term values and $\bot$ as falsehood. Conjunction, disjunction and implication are interpreted by their corresponding constructive logical operations. Quantifiers are read by

$$\rho \vDash \forall\varphi \iff \text{for every } n \in \mathbb{N},\ [n, \rho] \vDash \varphi,$$
$$\rho \vDash \exists\varphi \iff \text{there is } n \in \mathbb{N} \text{ with } [n, \rho] \vDash \varphi.$$

An environment satisfies a context when it satisfies every formula in it.

The formulas of the language are finite objects. The assertions that they are satisfied are made in the surrounding mathematics. That surrounding reasoning is called the *metatheory*. It supplies the finite inductive constructions, equality and logical reasoning being used to study the language. We have made this background visible; we have not eliminated it.

Three identities ensure that manipulating an expression corresponds to manipulating its interpretation.

Lemma 5.4 (Binding respects interpretation)**.** *For every formula φ, term t, environment ρ and natural number n,*

$$[n, \rho] \vDash \varphi\uparrow \iff \rho \vDash \varphi, \tag{5.3}$$
$$\rho \vDash \varphi(t) \iff [E_\rho(t), \rho] \vDash \varphi. \tag{5.4}$$

Replacing the induction variable by its successor correspondingly replaces its assigned value n by $n + 1$.

Proof. First check terms. Lifting a variable moves its position past the newly inserted entry, so its value remains its previous assignment. Substitution at position k has three cases: the variable is x_k, is below k, or is above k. Its value is respectively the substituted term's value, the unchanged earlier assignment, or the assignment shifted down one position. These are exactly the environment changes specified by the operations. Zero is unchanged; the successor, sum and product cases follow by applying their evaluation clauses to the already established identities for their constituent terms. This proves the term identities by structural induction.

Now induct on formulas. An equality uses the term identities on both sides. Falsehood is unchanged. Each propositional connective applies to the corresponding already established interpretations of its components. Under a quantifier, the new bound position receives its own value and the cutoff increases by one. For substitution, lifting the inserted term keeps its value independent of this newly bound position. Thus the extended environments agree at position zero and at every later position. For a universal formula this argument applies to every assigned value; for an existential formula it applies to its witness, in both directions. These are all the formula constructors, proving the two equivalences.

For the final assertion, the inserted term $S(x_0)$ has value $n+1$ when x_0 has value n. The other free positions remain fixed by the lifting and substitution convention. Apply the substitution identity. □

This is the bookkeeping behind the freshness conditions. Its purpose is to make the soundness proof about the same assignments before and after a rule is applied.

5.5 Why every permitted step preserves truth

Theorem 5.5 (Soundness of the base arithmetic rules)**.** *Suppose a finite derivation of* $\Gamma \vdash \varphi$ *uses the base rules listed in this chapter. If* ρ *satisfies every hypothesis in* Γ*, then* $\rho \vDash \varphi$*.*

Proof. Induct on the derivation tree, keeping the context and environment arbitrary. For each final rule, the induction hypotheses say that its premise derivations preserve satisfaction in their respective contexts. We check every kind of rule.

Hypothesis and equality. A selected hypothesis is true because the whole context is satisfied. Reflexivity evaluates to equality of a value with itself. For substitution, the first premise gives $E_\rho(t) = E_\rho(s)$. The second, by Lemma 5.4, gives satisfaction of the hole formula with $E_\rho(t)$ in its first position. Replace that equal value by $E_\rho(s)$ and use the same lemma in reverse.

The arithmetic rules. A successor value is not zero, and equality of successor values implies equality of the preceding values. The four operation equations evaluate to the recursive arithmetic identities. Thus these rule conclusions are satisfied. In the injectivity rule the premise supplies the required equality of successors.

Implication. To introduce an implication, assume the antecedent is satisfied. The augmented context is then satisfied, so the induction hypothesis for the branch gives the consequent. This proves the interpreted implication. To eliminate one, the premise interpretations give an implication and its antecedent; applying the former to the latter gives the consequent.

Conjunction, disjunction and falsehood. Conjunction introduction combines the two satisfied components; either elimination selects the required component. A disjunction introduction supplies its proved side. In disjunction elimination, the interpreted disjunction gives one of its two alternatives. Add that alternative to the satisfied context and apply the induction hypothesis for the corresponding branch. Both branches have the same concluding formula. If the premise is falsehood, its interpreted truth is impossible, and the falsehood rule is sound.

Universal quantification. For introduction, choose an arbitrary natural number n and extend ρ to $[n, \rho]$. Every lifted hypothesis is satisfied by (5.3). The induction hypothesis therefore gives the body of the universal formula at n. Since n was arbitrary, the universal statement is satisfied. For elimination, apply the interpreted universal statement to $E_\rho(t)$, then use (5.4) to obtain the desired instance.

Existential quantification. Introduction uses $E_\rho(t)$ as its witness; the substitution identity supplies the body at that witness. For elimination, the first premise supplies a witness n. The extended environment satisfies the lifted original hypotheses and the existential body. The branch induction hypothesis gives $\psi\uparrow$ in this environment. Equation (5.3) then returns ψ

under the original ρ. This is where the restriction on the conclusion of existential elimination is used.

Induction. The first premise gives the body at zero. The second gives, at every n, an implication from the body at n to the body at $n+1$; Lemma 5.4 identifies the successor instance. Induction in the surrounding natural-number mathematics now gives the body at every n. This is precisely satisfaction of the universal conclusion. The context remains satisfied throughout because its formulas do not acquire the fresh induction variable.

Every base rule has been covered. Since the derivation tree is finite, the induction reaches its conclusion. □

The last case shows the scope of the result plainly. Soundness of the object-language induction rule was proved using induction in the metatheory. This is a proof about the stated language in its stated arithmetic interpretation. It is not an internal proof, written in that language, of its own unrestricted soundness.

The proof also shows which facts about the natural numbers it used. The arithmetic rules needed the recursive identities, separation of the start from every step, and injectivity of the step. The induction rule needed induction. The remaining cases used only that quantifiers range over the numbers. Section 5.7 uses this observation to show what each family of rules supplies.

5.6 The same induction, now inside the language

Chapter 3 proved $0 + a = a$ about the constructed operation. We can now display an object-language proof of its universal formula. Set $\varphi(x)$ to $0 + x = x$. The base is the rule $0 + 0 = 0$. For the step, temporarily assume $0 + x = x$. The recursive rule gives

$$0 + S(x) = S(0 + x).$$

Equality substitution changes the right side to $S(x)$. Discharge the temporary hypothesis and generalize the fresh variable to obtain

$$\forall x\big(0 + x = x \;\rightarrow\; 0 + S(x) = S(x)\big).$$

Apply (5.2). The conclusion is

$$\vdash \forall x(0 + x = x). \tag{5.5}$$

Soundness now reads this finite derivation as a true arithmetic statement. The formula on which we inducted was the equality $0 + x = x$, with no quantifier inside it. The quantifier in the conclusion does not change that fact. This distinction will matter for the induction record in the next chapter.

5.7 What each family of rules supplies

Besides the four recursive equations, which define the operations, the arithmetic rules fall into three families. *Separation* is the rule $\neg(S(t) = 0)$: a step never returns to the start. *Injectivity*

is the rule from $S(t) = S(u)$ to $t = u$: equal successors have equal predecessors. *Induction* is rule (5.2). They are the object-language counterparts of the three conditions of Definition 2.4. We can now ask what each family contributes that the others cannot.

Begin with what needs no induction at all. The defining equations already settle every closed calculation.

Proposition 5.6 (Closed calculations need no induction)**.** *Let φ be a quantifier-free formula with no free variables. If φ is true, then $\vdash \varphi$ has a derivation that uses no induction rule. If φ is false, then $\vdash \neg\varphi$ has such a derivation. Neither derivation uses an additional principle.*

Proof. First, every closed term is provably equal to the numeral of its value, with no induction. Proceed by recursion on the term in the metatheory. A numeral needs nothing; for $S(t)$, substitution replaces t by its numeral $\bar{n}$, and $S(\bar{n})$ is the numeral $\overline{n+1}$. For a sum, equality substitution replaces the summands by their numerals $\bar{m}$ and $\bar{n}$; then n uses of the successor equation for addition and one use of its zero equation turn $\bar{m} + \bar{n}$ into $\overline{m+n}$. Products are treated the same way with the multiplication equations, using the case of sums. Symmetry and transitivity of equality, each one use of equality substitution together with reflexivity, combine these steps.

The values of closed terms can be computed and compared, so each closed quantifier-free formula is either true or false. We prove both claims together by induction on φ. Take an equation $t = s$ with values m and n. If $m = n$, both sides are provably equal to the same numeral, so $t = s$ follows. If $m < n$, assume $t = s$, hence $\bar{m} = \bar{n}$. Injectivity, applied m times, gives $0 = \overline{n-m}$. The right side is a successor, so separation refutes it; discharging the assumption proves $\neg(t = s)$. The case $m > n$ is symmetric. Falsehood is refuted by $\bot \to \bot$, which discharges the hypothesis $\bot$. A true conjunction combines two derivations, and a false one refutes the false component. A true disjunction introduces its true side, and a false one refutes both sides by disjunction elimination. A true implication has a true consequent or a false antecedent, and either gives the implication; a false one has a true antecedent and a false consequent, which together refute it. No step introduces an induction rule. □

So every closed instance of a familiar law, such as $0 + \bar{n} = \bar{n}$, $\bar{m} + \bar{n} = \bar{n} + \bar{m}$ or $\neg(S(\bar{n}) = \bar{n})$, has a derivation with no induction. The universal statements are a different matter. To show that something cannot be derived, we need an interpretation in which the permitted rules still preserve truth while the statement fails. The proof of Theorem 5.5 supplies one almost at once, because the particular facts about the natural numbers entered only at the arithmetic rules and at induction.

Definition 5.7 (A structure for the arithmetic language)**.** A *structure* M consists of a carrier, an element 0_M, an operation S_M of one argument, and operations $+_M$ and $\cdot_M$ of two. Environments assign elements of the carrier to variable positions. Evaluation and satisfaction are given by the clauses of Definition 5.3 with M in place of $\mathbb{N}$, and quantifiers range over the carrier. Write $M, \rho \vDash \varphi$.

Theorem 5.8 (Soundness in other structures)**.** *Let a finite derivation of $\Gamma \vdash \varphi$ use the base rules, and let ρ be an environment in a structure M that satisfies every formula of Γ. Then $M, \rho \vDash \varphi$ in each of the following cases.*

1. *The derivation contains no induction rule, and M satisfies the six arithmetic rules: $S_M(a) \neq 0_M$, S_M is injective, and the four recursive equations hold for all elements.*
2. *The derivation contains no separation rule, and M has exactly one element.*
3. *The derivation contains no injectivity rule, and M is the* Boolean structure *on $\{0, 1\}$ with $S(a) = 1$, $a + b = \max(a, b)$ and $a \cdot b = \min(a, b)$.*

Proof. Lemma 5.4 holds in every structure, with the same proof, because that proof used only the evaluation clauses. Now repeat the proof of Theorem 5.5. The hypothesis, equality, propositional and quantifier cases go through unchanged, with quantifiers ranging over the carrier of M. Only the arithmetic rules and induction need attention.

In the first case each arithmetic rule is true in M by hypothesis, and the induction case does not arise.

In the second case every equation is satisfied, so reflexivity, substitution, injectivity and the four recursive equations all hold. Induction holds as well, since its base already gives the body at the only element. Separation is the one rule that fails, and it does not occur.

In the third case check the equations directly:

$$a + 0 = a, \qquad a + S(b) = \max(a, 1) = 1 = S(a + b),$$
$$a \cdot 0 = 0, \qquad a \cdot S(b) = \min(a, 1) = a = \max(\min(a, b), a) = a \cdot b + a.$$

Separation holds because $S(a) = 1 \neq 0$. Induction holds because the base gives the body at 0, and one use of the step gives it at $1 = S(0)$, the only other element. Injectivity fails, since $S(0) = S(1)$, and it does not occur. □

The first case is the interesting one. Let W consist of the natural numbers together with two further elements a and b. On natural numbers the operations are the usual ones. In addition,

$$S(a) = a, \qquad S(b) = b, \qquad a + n = a, \qquad b + n = b, \qquad x + a = x + b = b$$

for every natural number n and every element x. A product is 0 when either factor is 0, the usual product when both factors are natural numbers, and b in every other case.

The six arithmetic rules hold in W. No element steps to 0, and S is injective because a and b are fixed points that no natural number reaches. For $x + 0 = x$ there is nothing new to check. For $x + S(y) = S(x + y)$, the new cases are of two kinds: if x is a or b and y is a number, both sides are x; if y is a or b, then $S(y) = y$ and both sides are b. The rule $x \cdot 0 = 0$ is built into the table. For $x \cdot S(y) = x \cdot y + x$, both sides are 0 when $x = 0$; when $x \neq 0$ and x or y is a or b, both sides are b. In W, three familiar laws fail:

$$S(a) = a, \qquad 0 + a = b \neq a, \qquad a + 0 = a \neq b = 0 + a.$$

Corollary 5.9 (What only induction supplies)**.** *None of the formulas*

$$\forall x \neg(S(x) = x), \qquad \forall x(0 + x = x), \qquad \forall x \forall y(x + y = y + x)$$

has a derivation from the base rules without an induction rule. Each has a derivation whose induction formulas are all quantifier-free, and each of their closed instances has a derivation with no induction.

Proof. An induction-free derivation of any of them would make it true in W, by the first case of Theorem 5.8; the displayed values refute each one. The derivation of $\forall x(0+x = x)$ is (5.5). For $\forall x \neg(S(x) = x)$, induct on the quantifier-free formula $\neg(S(x) = x)$: separation gives the base, and in the step injectivity turns $S(S(x)) = S(x)$ into $S(x) = x$, contradicting the hypothesis. Commutativity follows the proofs of Lemma 3.2 and Theorem 3.3, with each induction on an equation in which the other variable is a parameter. The closed instances are covered by Proposition 5.6. □

The other two cases of Theorem 5.8 complete the picture. Every equation holds in the one-point structure, so no derivation from no hypotheses that avoids separation proves any formula $\neg(t = s)$, not even $\neg(S(0) = 0)$. In the Boolean structure, $S(S(0))$ and $S(0)$ both have value 1, so no derivation from no hypotheses that avoids injectivity proves $\neg(S(S(0)) = S(0))$. With all three families present, each of these statements has a derivation with no additional principle and only quantifier-free induction. Each family therefore supplies a statement that the other two cannot:

Family removed	A structure satisfying the rest	A statement lost
separation	one element	$\neg(S(0) = 0)$
injectivity	the Boolean structure	$\neg(S(S(0)) = S(0))$
induction	W	$\forall x \neg(S(x) = x)$

The same method shows that the statement "every number is zero or a successor", $\forall x(x = 0 \vee \exists y(x = S(y)))$, needs induction. Let C consist of the natural numbers together with a second chain $c_0, c_1, c_2, \ldots$, with $S(c_k) = c_{k+1}$. Set $x + c_0 = c_0$ and $x \cdot c_0 = c_0$ for every element x, and let the recursive equations $x + 0 = x$, $x + S(y) = S(x + y)$, $x \cdot 0 = 0$ and $x \cdot S(y) = x \cdot y + x$ determine every other sum and product. Every element is reached from 0 or from c_0 by steps, so this defines both operations, and the four recursive equations hold by construction. Separation and injectivity hold because S moves one place along each chain. The element c_0 is neither zero nor a successor, so the statement fails in C, and by the first case of Theorem 5.8 it has no derivation without induction. It has one by induction on the formula $x = 0 \vee \exists y(x = S(y))$, which contains a quantifier. The structure W, by contrast, satisfies the statement, since $a = S(a)$ and $b = S(b)$. Corollary 5.9 therefore survives when the statement is added as a hypothesis. In this language, then, induction supplies the passage from all the instances of a law to the universal law itself.

Remark 5.10. Chapter 6 adds rules for excluded middle and two related principles. Every formula has a decided truth value in the one-point and Boolean structures, so those rules are true there, and the second and third cases of Theorem 5.8 extend to derivations that use them. Corollary 5.9 also extends, with or without the hypothesis that every number is zero or a successor. With excluded middle in the metatheory the added rules are true in W. Without it, one reads disjunction and existence in W through double negation. Induction-free derivations remain sound under that reading, with or without the added rules, and because equality in W is decidable the reading agrees with ordinary truth on the three universal formulas of the corollary. With that hypothesis and the excluded-middle rule, the induction-free rules present Robinson's arithmetic, so Robinson's arithmetic proves none of the three formulas.

We now have both sides of the connection. A derivation gives a finite record of permitted reasoning; an interpretation gives arithmetic content to its expressions; soundness proves that the first preserves the second. The next task is to retain this connection when the rules are enlarged.

Questions to work through

1. In (5.1), identify the hole formula and the two terms substituted into it. Which rule supplies each premise?

2. Explain why a fresh variable may receive an arbitrary value in the universal-introduction case of the soundness proof. Where is the same fact used for existential elimination?

3. Locate the two inductions in the soundness argument: induction on the derivation and the induction used to interpret the induction rule. What is the object of each?

4. In (5.5), distinguish the formula used for induction from the formula finally proved. Does the first contain a quantifier?

5. Check the six arithmetic rules in the structure W. Once $S(a) = a$, which values can $x + a$ take, given the rule $x + S(y) = S(x + y)$ at $y = a$? Why would a structure with only the one new element a fail to refute $\forall x(0 + x = x)$?

6. Derive $0 + S(S(0)) = S(S(0))$ without induction. Explain why no induction-free derivation of $\forall x(0 + x = x)$ exists, although every instance has one.

7. Which rule fails in the Boolean structure? Explain why no derivation from no hypotheses that avoids that rule can prove $\neg(S(S(0)) = S(0))$, and give a derivation that uses it.

Chapter 6

The price of an additional principle

Consider the formula

$$(0 = 0) \vee \neg(0 = 0).$$

One way to obtain it is to invoke excluded middle: every formula holds or its negation holds. Another way is to prove $0 = 0$ by reflexivity and then introduce the left side of the disjunction. The second argument never asks for a decision about an arbitrary formula.

The conclusion is identical. The resources used by the two arguments are different. If we record the first argument faithfully, excluded middle appears in its record. It would be a mistake to infer that the conclusion therefore requires excluded middle. The second argument has already answered that question.

This chapter makes resource accounting precise. We will distinguish the principles a derivation uses, the conditions under which its conclusion is true, and the separate work needed to prove that a principle is unavoidable for a whole mathematical assertion. We then carry out that work for the three additional rules themselves. With induction on every formula they generate exactly two theories, which we name; without induction, or with induction on quantifier-free formulas only, they mark four strengths.

6.1 A witness, a decision, and a double negation

To establish $\exists n\, P(n)$ constructively, one supplies a value of n together with the required evidence for $P(n)$. To establish $\neg\neg\exists n\, P(n)$, one gives a contradiction from the assumption that there is no such value. The second form does not itself display a witness. A rule that converts it to the first is therefore a substantive addition to the permitted steps.

Similarly, deciding each individual instance $P(n)$ does not include a specified bound on where a successful instance might occur. Finite inspection of initial values and a decision about the entire unbounded predicate are different tasks. This difference motivates the following principles.

Definition 6.1 (Three named additional principles)**.** *Excluded middle*, abbreviated EM, states

$$P \vee \neg P \qquad \text{for every proposition } P.$$

The *limited principle of omniscience*, in the predicate form used here and abbreviated LPO, states

$$\big[\forall n\,(P(n) \vee \neg P(n))\big] \longrightarrow \big[(\exists n\, P(n)) \vee (\forall n\, \neg P(n))\big]. \tag{6.1}$$

Markov's principle, abbreviated MP, states

$$\big[\forall n\,(P(n) \vee \neg P(n))\big] \longrightarrow \big[\neg\neg\exists n\, P(n) \longrightarrow \exists n\, P(n)\big]. \tag{6.2}$$

Here n ranges over the natural numbers and P is an arbitrary predicate in the surrounding mathematics.

EM concerns every proposition. LPO concerns a family with an individual decision for every member and returns a global alternative. MP uses such individual decisions together with a double-negated existence assertion to obtain existence. Stating these principles separately lets a theorem say which one it actually uses.

There is also an object-language version of each principle. To the arithmetic rules of Chapter 5, we may add the schemas

$$\Gamma \vdash \varphi \vee \neg\varphi, \qquad \text{EM}, \tag{6.3}$$

$$\Gamma \vdash (\forall x(\varphi(x) \vee \neg\varphi(x))) \to ((\exists x\,\varphi(x)) \vee (\forall x\,\neg\varphi(x))), \qquad \text{LPO}, \tag{6.4}$$

$$\Gamma \vdash \neg\neg\exists x\,\varphi(x) \to \exists x\,\varphi(x), \qquad \text{MP}, \tag{6.5}$$

where the MP rule is permitted only when φ is quantifier-free. These are schemas over the finite formulas of the arithmetic language. Definition 6.1 concerns propositions and predicates in the metatheory. The latter principles suffice to interpret the former rules; the two levels should not be silently identified. Section 6.7 shows how far apart they are. With induction on every formula, the MP schema permits nothing new and the LPO schema proves every instance of the EM schema. As principles about arbitrary predicates in the metatheory, the three keep the separate strengths they have in constructive mathematics [4].

Why does the object-language MP rule omit an explicit premise giving individual decisions? Its restriction supplies that premise.

Lemma 6.2 (Quantifier-free formulas can be decided)**.** *If φ contains no quantifier, then for every environment ρ,*

$$(\rho \vDash \varphi) \vee \neg(\rho \vDash \varphi).$$

Proof. Induct on the formula. For equality, evaluate the two terms and compare their natural-number values. Falsehood has the negative answer. For a conjunction, decide its two components: both positive answers give the conjunction, and a negative answer to either refutes it. For a disjunction, a positive answer to either supplies a side; two negative answers refute both possible sides.

For an implication $A \to B$, first decide B. If B holds, the implication follows. If B does not hold, decide A. A proof of A then refutes the implication, since applying it would prove B; a refutation of A proves the implication by eliminating the impossible antecedent. These are all cases because the formula has no quantifier. □

The lemma decides a fixed finite formula at a fixed environment. By itself it says nothing about an existential formula, which has infinitely many instances. The restriction on the MP schema is part of its mathematical statement, and replacing it by an unrestricted schema would change the rule being studied. The restriction also has a consequence that is not visible here. In this language an existential formula over a quantifier-free body can be decided by a finite search, and Section 6.7 shows that the restricted rule therefore permits nothing new once induction on every formula is allowed.

6.2 A ledger for a finite argument

The word *cost* in this part of the book means a recorded logical resource. It is neither elapsed time nor an energy quantity. The later physical chapters introduce their own physical resources with their units and hypotheses.

Definition 6.3 (The four-entry ledger)**.** A ledger is a tuple

$$O = (e, \ell, m; i), \qquad e, \ell, m, i \in \{\text{false}, \text{true}\}.$$

The first three entries record use of EM, LPO and MP. The final entry records whether an induction formula with a quantifier was used. The empty ledger has all four entries false. Ledgers combine by taking the Boolean inclusive-or separately in each entry; write this combination as $O_1 \sqcup O_2$.

A base rule contributes no entry of its own, with one stated exception: an induction rule contributes the final entry when its induction formula contains a quantifier. An EM, LPO or MP rule contributes its corresponding entry. At a rule with premises, combine all their ledgers and the rule's own contribution.

This defines the ledger of a finite derivation by following its tree. An entry says that the resource occurred at least once. It does not count how often it occurred. In particular, using the same resource twice does not change its Boolean entry after the first use.

Proposition 6.4 (Resources cannot disappear in combination)**.** *A named principle present in either input ledger is present in their combination. Moreover,*

$$O_1 \sqcup O_2 = \emptyset \quad \Longleftrightarrow \quad O_1 = \emptyset \text{ and } O_2 = \emptyset,$$

where $\emptyset$ denotes the empty four-entry ledger.

Proof. Each output entry is the inclusive-or of the corresponding input entries. It is true whenever either input is true, and false exactly when both inputs are false. Apply this observation to all four entries. □

No rearrangement of the surrounding base rules erases an occurrence already recorded in a premise. Removing a resource requires changing the derivation itself, for example by replacing a branch with a proof that avoids the additional rule.

6.3 No added principle is not the same as an empty ledger

We need two descriptions. A derivation is *posit-free* when it uses none of the three additional principles. Its first three entries are then false. A derivation has an *empty ledger* only when its fourth entry is also false. Thus empty-ledger proofs restrict the induction formulas to the quantifier-free tier, while posit-free proofs may use induction on quantified formulas.

In this accounting convention, the verdict "forced" tests the first three entries. It is accompanied by the induction tier. The verdict is relative to the stated base rules and to this alphabet of

additional principles. Reading it as "no background assumptions of any kind" would discard the language, the base rules and the metatheory that made the argument possible.

The distinction can be seen directly in examples already available. The proof of $1 + 1 = 2$ has no induction and an empty ledger. The proof of $\forall x(0 + x = x)$ uses induction, but its induction formula is the quantifier-free equality $0 + x = x$. Its ledger is also empty.

For a contrasting induction, let φ be $\forall y(y = y)$, independent of the induction variable x. Its base follows by reflexivity and universal introduction. Its step is the identity implication $\varphi \to \varphi$, generalized over x. Induction gives $\forall x \forall y(y = y)$. This derivation posts the final entry because φ contains a quantifier, even though no EM, LPO or MP rule occurs. The record describes this particular use of induction; it is not a claim that this trivial conclusion needs that use.

6.4 The record agrees with the derivation

There are two ways to obtain the resource record. One is to carry it through each valid inference while verifying the premises and conclusion. The other is to ignore those formulas and simply inspect the rule labels and induction formulas in the whole tree. The latter inspection by itself does not establish that the tree is a valid derivation. On a valid tree, the two records agree exactly.

Theorem 6.5 (Agreement of resource accounting)**.** *For every accepted finite derivation, its threaded ledger equals the ledger obtained by inspecting its rule occurrences. Consequently its first three entries are false if and only if the tree contains no EM, LPO or MP rule. Its induction entry is true if and only if it contains induction on a formula with a quantifier.*

Proof. Induct on the tree. At a hypothesis, equality-reflexivity or arithmetic leaf, both records are empty. At an additional-principle leaf, both contain exactly its named entry. A one-premise base rule carries its premise ledger unchanged in both accounts. A two-premise rule combines the two records by $\sqcup$; disjunction elimination combines its three records. The induction hypotheses identify every premise record, so the combined records agree.

At an induction node, both accounts combine the base and step records. They then inspect the same finite formula: if it is quantifier-free, neither adds an entry; if it has a quantifier, both add the final entry. This covers all rules and proves equality of the two accounts.

For the consequences, an inclusive-or over finitely many occurrences is false exactly when all its inputs are false, by repeated application of Proposition 6.4. Therefore absence of the three posit entries is equivalent to absence of their three rule kinds. The same reasoning, with the induction formula test, gives the characterization of the final entry. □

The acceptance hypothesis cannot be dropped when interpreting the record as a proof's resources. A tree with mismatched premise formulas can have a perfectly clear list of rule labels. That list does not repair the invalid inference.

6.5 Soundness with the prices attached

A ledger has a semantic use as well as a syntactic one. It tells us which additional metatheoretic principles suffice to justify a derivation.

Theorem 6.6 (Conditional soundness)**.** *Let a derivation of $\Gamma \vdash \varphi$ have ledger O. Assume the metatheoretic EM principle if its EM entry is true, LPO if its LPO entry is true, and MP if its MP entry is true. Every environment satisfying Γ then satisfies φ.*

Proof. Use the derivation induction of Theorem 5.5. All base-rule cases are unchanged. The principle assumptions required for a premise are available because a true premise entry remains true in the conclusion ledger, by Proposition 6.4. It remains to check the three new leaves.

At an EM leaf, apply the supplied EM principle to the proposition $\rho \Vdash \varphi$. This gives precisely the interpretation of $\varphi \vee \neg\varphi$.

At an LPO leaf, suppose the interpreted premise says that each instance of the body is decidable. Apply the supplied LPO principle to

$$P(n) \quad \text{defined by} \quad [n, \rho] \Vdash \varphi.$$

Its existential alternative is the interpretation of $\exists\varphi$; its universal negative alternative is the interpretation of $\forall\neg\varphi$. This is the required implication.

At an MP leaf, the rule requires the body to be quantifier-free. Lemma 6.2 supplies a decision for each instance of the same predicate $P(n)$. The supplied MP principle then converts the double-negated existential premise into the existential conclusion.

The induction entry requires no further principle in this semantic theorem: the surrounding natural-number mathematics already supplies induction on the interpreted formula, as explicitly used in the base soundness proof. Its use inside the derivation remains recorded. □

Corollary 6.7 (Soundness without the three additional principles)**.** *For a posit-free derivation, conditional soundness requires none of EM, LPO or MP. This holds at either recorded induction tier.*

Proof. All three principle entries are false, so none of the three conditional assumptions in Theorem 6.6 is required. □

This establishes sufficiency, with the source of each permission visible. It does not say that every conclusion with an EM-labelled proof is unprovable without EM. The opening example proves the contrary. The assumptions in Theorem 6.6 can also be weakened: Corollary 6.15 shows that an MP entry requires no principle at all, and that an EM or LPO entry requires only the metatheoretic LPO for the predicates that formulas define, which is the least assumption under which every derivation with such an entry is sound.

6.6 A route's price and a theorem's exact strength

The two proofs of $(0 = 0) \vee \neg(0 = 0)$ give a useful complete comparison. The EM-rule proof has ledger

$$(\text{true}, \text{false}, \text{false}; \text{false}).$$

The reflexivity-and-disjunction proof has the empty ledger. Both have the same conclusion. The record is exact about each tree, but the first record overstates what is necessary to prove that conclusion.

The rule occurrence also retains more information than its Boolean entry: it specifies the particular formula to which the principle was applied. In this case that formula is $0 = 0$, whose positive side is already provable. Forgetting the formula and retaining only the name EM loses the reason that this occurrence can be discharged.

There is a second limitation. The named alphabet in this chapter contains three principles. It is a useful way to report their use, but three names need not mark three strengths, and no fixed alphabet can distinguish every intermediate principle someone might formulate. Over the base rules with induction on every formula, the three names mark exactly two strengths (Theorem 6.11). A conclusion's intrinsic logical strength is a question about derivability and reductions over a specified base, not merely about which names a chosen record can print.

To prove an *exact* logical cost, two directions are needed. First, derive the mathematical assertion using the proposed principle. Second, show that the assertion itself yields that principle over the same retained base. The second direction is a *reversal*. It supplies the lower bound that inspection of one proof cannot supply.

6.7 What the three rules cost

We now apply the two-direction test to the three rules themselves. Say that a rule *reduces* to a set of rules when every instance of its schema has a derivation, from no hypotheses, whose additional rules all belong to that set. A rule that reduces to a set can be removed from any derivation. Replace each of its leaves by the derivation of the same instance, with the leaf's hypotheses added to its context. A derivation stays valid when unused hypotheses are added, each lifted wherever a quantifier rule lifts the context; an induction on the derivation proves this, because no rule requires a hypothesis to be absent. The conclusion and the context of the whole derivation do not change. Its ledger can change in the induction entry, since some replacement derivations below use induction on formulas with quantifiers.

The answers depend on which induction rules the replacement derivations may use. We first allow induction on every formula.

The restricted Markov rule permits nothing new

The MP rule applies only to a quantifier-free body. In this language such a body cannot describe a search whose outcome is unknown. The reason is a fact about polynomials.

Lemma 6.8 (Quantifier-free formulas are eventually constant)**.** *Let φ be quantifier-free and let ρ be an environment. There is a number B, computed from ρ by evaluating terms, such that*

$$[n, \rho] \vDash \varphi \quad \Longleftrightarrow \quad [B, \rho] \vDash \varphi \qquad \text{for every } n \geq B.$$

Proof. Fix ρ. Each term t has the value

$$p_t(n) = c_0 + c_1 n + \cdots + c_k n^k$$

under $[n, \rho]$, for natural-number coefficients c_i that do not depend on n. Induct on t: the variable x_0 gives the polynomial n; another variable and 0 give constants; S adds one to c_0; sums and products of such polynomials are again such polynomials. Each coefficient is the value of a term in the other variables, built by the same recursion.

Let B be one more than the sum of all coefficients of both sides of every equation in φ. If every coefficient is 0, every equation holds at every n and there is nothing to prove. Otherwise $B \geq 2$. For $n \geq B$ every coefficient is less than n, so $c_0 + c_1 n + \cdots + c_k n^k$ is the base-n expansion with digits $c_0, \ldots, c_k$. Base-n expansions are unique. Hence an equation $t = s$ holds at such an n exactly when t and s have the same coefficients, after the shorter list is padded with zeros. That condition does not mention n. Each equation in φ therefore has one truth value for all $n \geq B$, and so does every combination of equations by $\wedge$, $\vee$, $\to$ and $\bot$. □

Take, for example, $\varphi(x)$ to be $x + x = y$, with x the searched variable and y a parameter. The left side has coefficients $(0, 2)$ and the right side has (y), so $B = y + 3$. When $n \geq y + 3$ the digit lists $(0, 2)$ and $(y, 0)$ differ, and the equation fails. Whether some n satisfies it is settled by checking $n = 0, 1, \ldots, y + 3$.

Theorem 6.9 (The restricted Markov rule costs nothing)**.** *Let φ be quantifier-free, let ρ be an environment, and let B be the bound of Lemma 6.8.*

1. *$\rho \vDash \exists \varphi$ holds exactly when $[n, \rho] \vDash \varphi$ for some $n \leq B$. It is therefore decided by finitely many applications of Lemma 6.2.*
2. *Consequently $\rho \vDash \neg\neg\exists \varphi \to \exists \varphi$ holds with none of EM, LPO or MP in the metatheory.*
3. *Every instance of the MP schema has a derivation from the base rules, with induction on every formula permitted, and with no EM, LPO or MP rule. The derivation constructed below uses induction on formulas that contain quantifiers.*

Conditions and scope.

Base and premises

The arithmetic language of Chapter 5, a quantifier-free formula φ with one searched variable, an environment ρ and the bound B of Lemma 6.8. Parts 1 and 2 concern the interpretation, with no added principle in the metatheory. Part 3 concerns the object-language schema (6.5), which applies only to quantifier-free bodies, over the base rules with induction on every formula permitted.

Conclusion

$\exists\varphi$ at ρ is decided by a search up to B; its interpreted Markov instance holds with none of EM, LPO or MP; and every instance of the restricted schema (6.5) has a derivation with no EM, LPO or MP rule, which uses induction on formulas with quantifiers.

Not claimed

Markov's principle for arbitrary decidable predicates, the principle of Definition 6.1, which is a different principle.

Proof. For the first assertion, a witness $n > B$ can be replaced by B, by the lemma; then examine $n = 0, 1, \dots, B$, deciding each instance by Lemma 6.2. For the second, run that search. If it finds an instance, the existential holds. If it finds none, the first assertion gives $\neg\exists\varphi$, which contradicts the double-negated premise, and the impossible case gives the conclusion.

The third assertion carries out the same argument inside the language. Every derivation below is from no hypotheses unless a context is shown, uses no EM, LPO or MP rule, and keeps the parameters of φ free; we write x for the searched variable. We use the abbreviations

$$u \le w \text{ for } \exists j(u{+}j = w), \qquad u < w \text{ for } \exists j(u{+}S(j) = w), \qquad A \leftrightarrow B \text{ for } (A \to B)\wedge(B \to A).$$

Appendix E.1 derives the arithmetic used along the way: the laws of addition and multiplication, each by induction on an equation; the decision $\psi \vee \neg\psi$ of every quantifier-free ψ; and five facts proved by induction on formulas with quantifiers, namely that every number is 0 or a successor, the decision of equality, the uniqueness of remainders, cancellation of a nonzero factor, and the comparison $x < y \vee y \le x$ (Lemma E.1).

Coefficients and the bound. The proof of Lemma 6.8 assigns to every term s a list of coefficients, lowest degree first. We use the same recursion on terms, keeping each coefficient as a term in the parameters: x has the list $(0, S(0))$, a parameter p has (p), and 0 has the empty list; $S(s)$ replaces the first coefficient c of s by $S(c)$, or the empty list by $(S(0))$; $s + r$ adds the two lists entry by entry, keeping the longer tail; and $s{\cdot}r$ is computed by $(c, c_1, \dots){\cdot}\vec{d} = (0, (c_1, \dots){\cdot}\vec{d}) + (c{\cdot}\vec{d})$, where $c \cdot \vec{d}$ multiplies every entry of $\vec{d}$ by c, and the empty list times $\vec{d}$ is empty. Let Σ be the sum $c_0 + (c_1 + (\cdots + (c_N + 0)))$ of all the coefficients of both sides of every equation of φ, and let T be $S(\Sigma)$. Its value is the bound B of Lemma 6.8. For a term X, the *polynomial form* of a list is

$$h_X() = 0, \qquad h_X(c, c_1, \dots, c_k) = h_X(c_1, \dots, c_k) \cdot X + c,$$

so that $h_X(c_0, \dots, c_k)$ is $c_0 + c_1X + \cdots + c_kX^k$ arranged by Horner's rule.

Every term equals its polynomial form. For every term s and every term X,

$$\vdash s(X) = h_X(\text{coefficients of } s),$$

where $s(X)$ substitutes X for x. This is one derivation for each s, built by recursion on s in the metatheory, and it uses only the laws of addition and multiplication. For instance, x itself is $(0 \cdot X + S(0)) \cdot X + 0$ because $0 \cdot X = 0$ and $S(0) \cdot X = X$; for a sum, $(a \cdot X + c) + (b \cdot X + d) = (a + b) \cdot X + (c + d)$; for a product, $(a \cdot X + c) \cdot h = (a \cdot h) \cdot X + c \cdot h$. The remaining cases are in Lemma E.2.

Digits below the base are unique. The heart of the argument is one digit:

$$\vdash c < X \to d < X \to U \cdot X + c = V \cdot X + d \to (c = d \wedge U = V). \tag{6.6}$$

Write $c + S(k) = X$ and $d + S(l) = X$. Uniqueness of remainders, with divisor X, gives $c = d$. Cancelling c leaves $U \cdot X = V \cdot X$, and X is the successor $S(c + k)$, so cancellation of a nonzero factor gives $U = V$. Conversely, $c = d$ and $U = V$ give the equation by substitution. Now say that two lists have *equal digits* when the formula $D(\vec{c}, \vec{d})$ holds, where D compares the lists entry by entry after padding the shorter one with zeros: $D((c, \vec{c}), (d, \vec{d}))$ is $c = d \wedge D(\vec{c}, \vec{d})$, a missing entry is compared with 0, and $D((), ())$ is $0 = 0$. Recursion on the two lists, applying (6.6) at each entry and writing the empty form 0 as $0 \cdot X + 0$ where one list runs out, gives

$$0 < X,\ \text{every } c_i < X,\ \text{every } d_i < X \ \vdash\ h_X(\vec{c}) = h_X(\vec{d}) \leftrightarrow D(\vec{c}, \vec{d}). \tag{6.7}$$

The hypothesis $0 < X$ is needed for the padding digit 0.

Beyond the bound, φ does not depend on x. Let D_φ be the formula obtained from φ by replacing each equation $s = r$ with $D(\text{coefficients of } s, \text{coefficients of } r)$. It contains neither x nor any new variable. Suppose $T \le X$. Every coefficient c of φ is one of the summands of Σ, so $c \le \Sigma$, and $S(\Sigma) \le X$ then gives $c < X$; likewise $0 \le \Sigma$ gives $0 < X$. By the normal forms and (6.7), each equation of $\varphi(X)$ is equivalent to its digit comparison, and these equivalences pass through $\wedge$, $\vee$, $\to$ and $\bot$. So

$$T \le X \ \vdash\ \varphi(X) \leftrightarrow D_\varphi.$$

Apply this at $X = T + z$, using $T \le T + z$ with witness z, and at $X = T$, using $T \le T$ with witness 0. Both sides are equivalent to the same D_φ, so universal introduction gives

$$\vdash \forall z \big(\varphi(T + z) \leftrightarrow \varphi(T)\big). \tag{6.8}$$

This is the derivable form of Lemma 6.8.

The bounded search. Let $Q(n)$ be the formula

$$\exists x\, \varphi(x)\ \vee\ \forall y \big(y < n \to \neg\varphi(y)\big).$$

We prove $\vdash \forall n\, Q(n)$ by induction on n; the induction formula contains quantifiers. At $n = 0$ take the right side: $y < 0$ is impossible, since $y + S(j) = 0$ gives $S(y + j) = 0$ against separation. For the step assume $Q(n)$. If its left side holds, so does that of $Q(S(n))$. Otherwise every $y < n$ has $\neg\varphi(y)$. Decide the quantifier-free $\varphi(n)$. If it holds, n witnesses $\exists x\, \varphi(x)$. If not, let $y < S(n)$. Then $y < n$ or $y = n$ (Lemma E.1); in the first case $\neg\varphi(y)$ is assumed, and in the second it follows from $\neg\varphi(n)$ by equality substitution. So the right side of $Q(S(n))$ holds.

The alternative. We now derive

$$\forall z \big(\varphi(T + z) \leftrightarrow \varphi(T)\big)\ \vdash\ \exists x\, \varphi(x) \vee \forall x \neg\varphi(x).$$

Instantiate the bounded search at $n = T$. If $\exists x\, \varphi(x)$, take the left side. Otherwise every $y < T$ has $\neg\varphi(y)$; decide $\varphi(T)$. If it holds, T is a witness. If not, take any x and compare it with T: $x < T$ or $T \le x$ (Lemma E.1). In the first case $\neg\varphi(x)$ is assumed. In the second, open $T \le x$ as $T + z = x$; the hypothesis at z gives $\varphi(T + z) \to \varphi(T)$, so $\neg\varphi(T)$ gives $\neg\varphi(T + z)$, and equality substitution along $T + z = x$ gives $\neg\varphi(x)$. Universal introduction yields $\forall x \neg\varphi(x)$.

The Markov instance. Discharge the hypothesis of the alternative with (6.8), and assume $\neg\neg\exists x\, \varphi(x)$. In the first case of the alternative the conclusion $\exists x\, \varphi(x)$ is at hand. In the second,

$\forall x\,\neg\varphi(x)$ gives $\neg\exists x\,\varphi(x)$: a witness y with $\varphi(y)$ meets $\neg\varphi(y)$, and existential elimination closes. Applying the premise yields $\bot$, and the rule for an impossible case gives $\exists x\,\varphi(x)$. Implication introduction completes the derivation of $\neg\neg\exists x\,\varphi \to \exists x\,\varphi$.

No EM, LPO or MP rule occurs. The induction formulas of the bounded search, of the comparison of numbers, of the uniqueness of remainders, of the cancellation of a nonzero factor, of the decision of equality and of the split into zero and successor contain quantifiers, so the induction entry of the ledger is true. □

The theorem explains why, once induction on every formula is allowed, the restriction leaves nothing for Markov's principle to do in this language. Markov's principle concerns a search that is decidable at each step but whose stopping point is unknown, such as the search for the step at which a computation halts. A quantifier-free body comes with a bound, computed from its parameters, beyond which nothing changes, so its search is bounded in advance. No quantifier-free formula $\theta(e, n)$ can therefore say that n codes a halting computation of the program with code e on input e: a search up to the bound would then decide whether that program halts, and no program decides that [21]. Programs and their numerical codes are treated in Chapter 10. Describing a computation with only 0, S, $+$ and $\cdot$ requires quantifiers. For the same reason, a version of LPO restricted to quantifier-free bodies would decide nothing new in the interpretation: its conclusion is settled by the same finite search. The principle of Definition 6.1, which applies to every decidable predicate of the metatheory, is a different matter.

The LPO rule proves excluded middle

The LPO rule has no such restriction. Its premise asks for a decision of every instance, and the rule itself supplies decisions for quantified formulas, one quantifier at a time.

Theorem 6.10 (The LPO and EM rules prove the same formulas)**.** *Permit induction on every formula. For every formula φ and every context Γ, the judgment $\Gamma \vdash \varphi \vee \neg\varphi$ has a derivation from the base rules and the LPO rule, with no EM or MP rule. Conversely, every instance of the LPO schema has a derivation from the base rules and the EM rule, with no induction.*

Proof. Start with equality. Induction on x, with the induction formula $\forall y(x = y \vee \neg(x = y))$, proves

$$\vdash \forall x\,\forall y\big(x = y \vee \neg(x = y)\big). \tag{6.9}$$

The base and the step each split into cases according to whether y is 0 or a successor. An induction on y with a quantifier-free formula performs that split, since its step does not use its own hypothesis. In the base, $0 = 0$ holds by reflexivity and $\neg(0 = S(y))$ by separation. In the step, $\neg(S(x) = 0)$ holds by separation; for $S(x)$ and $S(y)$, the hypothesis decides $x = y$, and its two answers give $S(x) = S(y)$ by substitution and $\neg(S(x) = S(y))$ by injectivity.

Now prove $\Gamma \vdash \varphi \vee \neg\varphi$ for every formula φ and every context Γ together, by induction on φ. Allowing every context matters, because the quantifier cases pass to a lifted context.

Equations are instances of (6.9). *Falsehood* takes the right alternative, $\bot \to \bot$. For a *conjunction*, *disjunction* or *implication*, apply disjunction elimination to the decisions of its two components and argue by cases, exactly as in the proof of Lemma 6.2.

An existential formula $\exists\psi$. The induction hypothesis in the lifted context, followed by universal introduction, gives $\forall x(\psi \vee \neg\psi)$. This is the premise of the LPO rule at ψ, which returns $(\exists x\,\psi) \vee (\forall x\,\neg\psi)$. In the second case existential elimination turns $\forall x\,\neg\psi$ into $\neg\exists x\,\psi$.

A universal formula $\forall\psi$. From $\forall x(\psi \vee \neg\psi)$ obtain $\forall x(\neg\psi \vee \neg\neg\psi)$, since ψ gives $\neg\neg\psi$. The LPO rule at $\neg\psi$ returns $(\exists x\,\neg\psi) \vee (\forall x\,\neg\neg\psi)$. A witness of $\neg\psi$ refutes $\forall x\,\psi$. In the other case decide ψ at an arbitrary x: the negative answer contradicts $\neg\neg\psi$, so ψ holds, and universal introduction gives $\forall x\,\psi$.

Only the LPO rule introduces a principle in these derivations. For the converse, the EM rule at $\exists x\,\varphi$ gives $(\exists x\,\varphi) \vee \neg\exists x\,\varphi$, and $\neg\exists x\,\varphi$ gives $\forall x\,\neg\varphi$: assume φ at a fresh x, introduce the existential, and reach a contradiction. The premise of the LPO instance is not even used. □

The only inductions in these derivations are those in the proof of (6.9), and they serve only the equations. The MP rule can do that job instead. For an equation $t = s$, let β be $t = s \vee \neg(t = s)$, and let z be a variable that does not occur in it. The formula $\neg\neg\beta$ has a derivation with no added rule: from $\neg\beta$ we obtain $\neg(t = s)$, hence β, a contradiction. So $\neg\neg\exists z\,\beta$ is derivable, and the MP rule at the quantifier-free β returns $\exists z\,\beta$, hence β. Thus excluded middle also follows from the LPO and MP rules together, with no induction at all.

Two strengths, or four

Theorem 6.11 (The price of each rule when induction is unrestricted)**.** *Allow induction on every formula. Then:*

1. *MP reduces to the empty set of rules;*
2. *EM reduces to LPO, and LPO reduces to EM;*
3. *neither LPO nor EM reduces to MP, and in particular neither reduces to the empty set.*

Give MP level 0 *and LPO and EM level* 1*, and give a set of rules the largest level of its members, or* 0 *if it is empty. A rule reduces to a set exactly when its level is at most the level of the set.*

Conditions and scope.

Base and premises
The base rules of Chapter 5, with induction on every formula permitted in the replacement derivations; the rules EM, LPO and MP of (6.3)–(6.5), the MP rule restricted to quantifier-free bodies; reduction as defined at the start of Section 6.7.

Conclusion
The restricted MP rule reduces to the empty set; EM and LPO reduce to each other; neither LPO nor EM reduces to MP. Two levels, 0 for MP and 1 for LPO and EM, decide every reduction.

Proof. The proof of the third assertion uses material from later in the book: the programs of Definition 10.5 with the pairing (10.3) and the codes (10.4), the arithmetic description of

computations and the universal program of Sections 20.3.3 and 20.3.4, and Theorem E.9 with Lemmas E.6–E.11. On a first reading it may be deferred until after Section 20.3.4.

The first two assertions are Theorems 6.9 and 6.10. For the third it suffices to treat LPO. If EM reduced to MP, so would LPO: in the derivation of an LPO instance from one EM rule given by Theorem 6.10, replace the EM leaf by a derivation of the same instance from MP rules, as in Section 6.7. And a rule that reduces to the empty set reduces to {MP}. We show that LPO does not reduce to MP, using Kleene's realizability interpretation [50, 4] and a classical metatheory.

Programs. The programs are those of Definition 10.5, with the codes of (10.4). Decoding never fails, so every number is the code of exactly one program; write $\{r\}(a)\downarrow v$ when the program with code r returns v on input a. Every number is a pair $\langle r_1, r_2\rangle$ in exactly one way, by the round trip for (10.3). Besides the constructors of Definition 10.5 we use two standard facts of computability [19, Chapter XII]. A program can run a code it has computed: there is a universal program, which returns v on $\langle r, a\rangle$ exactly when $\{r\}(a)\downarrow v$; the program U of Section 20.3.4 is one. And a program can fix part of an input. Let K_a be the program that composes the successor a times with the zero program, so that it returns a on every input. On input b the program $r \circ \mathrm{pair}(K_a, \mathrm{id})$, where id, the pairing of the two projections, returns its input by the round trip for (10.3), runs r on $\langle a, b\rangle$, and its code is computed from r and a by (10.4).

Realizers. Let ρ be an environment. A number r *realizes* a formula at ρ according to the following clauses.

- r realizes $t = s$ when t and s have the same value under ρ; nothing realizes $\bot$.
- $\langle r_1, r_2\rangle$ realizes $\varphi \wedge \psi$ when r_1 realizes φ and r_2 realizes ψ.
- $\langle i, r'\rangle$ realizes $\varphi \vee \psi$ when $i = 0$ and r' realizes φ, or $i \neq 0$ and r' realizes ψ.
- r realizes $\varphi \to \psi$ when, for every a that realizes φ at ρ, $\{r\}(a)\downarrow v$ for some v that realizes ψ at ρ.
- r realizes $\forall\varphi$ when, for every number n, $\{r\}(n)\downarrow v$ for some v that realizes φ at $[n, \rho]$.
- $\langle n, r'\rangle$ realizes $\exists\varphi$ when r' realizes φ at $[n, \rho]$.

So a realizer of an existential statement carries its witness, and a realizer of a disjunction says which side holds. Since nothing realizes $\bot$, a number realizes $\neg\varphi$ exactly when no number realizes φ, and then every number does. A formula with no free variables is realized or not independently of ρ.

Derivations are realized. Realizers of formulas with free variables must be computed uniformly from the values of those variables. For a finite list $l = (l_0, \ldots, l_{m-1})$ let ρ_l be the environment with $\rho_l(k) = l_k$ for $k < m$ and $\rho_l(k) = 0$ otherwise, and code lists by $\ulcorner()\urcorner = 0$ and $\ulcorner(n, l)\urcorner = \langle n, \ulcorner l\urcorner\rangle + 1$. Then $\rho_{(n,l)} = [n, \rho_l]$, and the value of a term under ρ_l is computed from $\ulcorner l\urcorner$. Theorem E.9 proves the following. *For every derivation of $\gamma_1, \ldots, \gamma_k \vdash \varphi$ whose additional rules are all MP rules, with any induction rules, there is a program c such that for every list l and all numbers $a_1, \ldots, a_k$ with a_i realizing γ_i at ρ_l, c returns on input $\langle \ulcorner l\urcorner, \ulcorner(a_1, \ldots, a_k)\urcorner\rangle$ a number that realizes φ at ρ_l.* The program is built along the derivation. Three cases show why the statement has this form.

Universal introduction derives $\forall\varphi$ from a derivation of φ in the lifted context. A realizer of $\forall\varphi$ must be one program that works for every value n of the new variable. Given l and the a_i, it is the program that, on n, runs the program of the premise on $\langle\ulcorner(n,l)\urcorner,\ulcorner(a_1,\dots,a_k)\urcorner\rangle$; its code is computed by fixing part of an input. The same a_i realize the lifted hypotheses at $\rho_{(n,l)}=[n,\rho_l]$, because realizability respects lifting as satisfaction does (Lemma E.6).

Induction derives $\forall x\,\varphi$ from $\varphi(0)$ and $\forall x(\varphi(x)\to\varphi(S(x)))$. Let r_0 and s be the realizers that the premises' programs return. The realizer of the conclusion is the program that, on n, computes v_n by primitive recursion: $v_0=r_0$, and v_{y+1} is obtained by running s on y and then running the program so obtained on v_y. Its code is computed from r_0 and s, which the premises' programs return on the given input, by fixing part of an input. Induction on n shows that v_n realizes φ at $[n,\rho_l]$. The step uses the final assertion of Lemma E.6: a realizer of $\varphi(S(x))$ at $[y,\rho_l]$ realizes φ at $[y+1,\rho_l]$. Nothing here depends on the shape of φ, so induction on every formula is realized.

An MP rule concludes $\neg\neg\exists x\,\varphi\to\exists x\,\varphi$ with φ quantifier-free. Truth of a quantifier-free formula under ρ_l is computed from $\ulcorner l\urcorner$ by evaluating terms, and a true quantifier-free formula has a realizer computed in the same way, while a realized one is true (Lemma E.7). The realizer returned for the MP instance is the code of the program that ignores its input and searches $n=0,1,2,\dots$ for the first n with $[n,\rho_l]\vDash\varphi$, then returns $\langle n,q\rangle$ with q the computed realizer of φ at $[n,\rho_l]$. Let b realize $\neg\neg\exists x\,\varphi$ at ρ_l. If no n satisfied φ, no number would realize $\exists x\,\varphi$, since its second component would realize, hence make true, an instance of φ; then 0 would realize $\neg\exists x\,\varphi$, and $\{b\}(0)$ would return a realizer of $\bot$, which does not exist. So, by the classical metatheory, some n satisfies φ, and the search stops. The realizer b is never run; it only guarantees that the search ends.

A derivation of a formula with no free variables, from no hypotheses, therefore yields a realizer: run its program on $\langle\ulcorner()\urcorner,\ulcorner()\urcorner\rangle$.

An LPO instance with no realizer. Section 20.3.3 reads a program step by step within an *allowance*. By Lemma E.11 there is a formula $\theta(e,x)$, with the two free variables shown, such that

(i) θ is built from equations by $\wedge$, $\vee$, $\forall$ and $\exists$, with no implication;

(ii) $\theta(e,x)$ is true exactly when program e returns a value on input 0 within allowance x, and program e returns a value on input 0 exactly when it does so within some allowance;

(iii) a program decides, from e and x, whether $\theta(e,x)$ is true, and when it is, computes a number that realizes it.

By (i), a number that realizes $\theta(e,x)$ makes it true: each clause passes realizability of the parts to truth of the whole (Lemma E.8). Consequently, when $\theta(e,x)$ is false every number realizes $\neg\theta(e,x)$.

Let Λ be the closed formula

$$\forall e\Big[\forall x\big(\theta(e,x)\vee\neg\theta(e,x)\big)\to\Big(\exists x\,\theta(e,x)\vee\forall x\,\neg\theta(e,x)\Big)\Big].$$

The formula in brackets is the LPO instance at θ, with e free. If LPO reduced to MP, that instance would have a derivation from no hypotheses whose additional rules are MP rules,

and universal introduction, which adds no rule, would turn it into such a derivation of Λ. Then some number r would realize Λ.

For each e, let $p(e)$ be the code of the program that, on x, returns $\langle 0, q\rangle$ with q a realizer of $\theta(e,x)$ when $\theta(e,x)$ is true, and $\langle 1, 0\rangle$ when it is false. By (iii) and the consequence of (i), $p(e)$ realizes $\forall x(\theta(e,x) \vee \neg\theta(e,x))$, and $p(e)$ is computed from e by fixing part of an input. Now let F be the program that, on e, runs r on e, runs the result on $p(e)$, and returns the first component of what it obtains. Since r realizes Λ, F returns a value on every e, and the pair it inspects realizes $\exists x\,\theta(e,x) \vee \forall x\neg\theta(e,x)$. If the first component is 0, the second realizes $\exists x\,\theta(e,x)$; it carries a witness x and a realizer of $\theta(e,x)$, so $\theta(e,x)$ is true and program e returns a value on input 0. If the first component is not 0, the second realizes $\forall x\neg\theta(e,x)$. Were $\theta(e,x)$ true for some x, (iii) would supply a realizer of it, and the realizer of $\neg\theta(e,x)$ would turn that into a realizer of $\bot$. So $\theta(e,x)$ is false for every x, and by (ii) program e returns no value on input 0. Thus F decides, for every e, whether program e halts on input 0.

No program does that. If one did, compose it with the computation of the code of $e \circ K_e$, the program that ignores its input and runs e on e. The result would decide whether program e halts on input e, and no program decides that [21]. Hence Λ has no realizer, the LPO instance at θ has no derivation from MP rules, and LPO does not reduce to MP.

For the final statement, a rule reduces to every set that contains it, and a rule that reduces to a set reduces to every larger set. MP has level 0 and reduces to the empty set by the first assertion, hence to every set. LPO and EM have level 1. A set of level 1 contains LPO or EM, and each of these reduces to the other by the second assertion, so both reduce to such a set. A set of level 0 is contained in {MP}, and by the third assertion neither LPO nor EM reduces to it. □

In constructive mathematics the principles of Definition 6.1 form a chain of strictly increasing strength, MP below LPO below EM [4]. For the rules over this language, with induction on every formula, the chain collapses in two places: the restricted Markov rule (the quantifier-free schema (6.5)) costs nothing, and LPO costs as much as EM. The theorem also leaves no freedom in assigning prices. Suppose each rule receives a degree in an ordered system with a least element and joins, so that a rule reducing to a set never has a degree above the join of the set's degrees, the empty set having the least element as its join. Then MP must receive the least degree and LPO must receive the degree of EM. The two-level chart is the finest such assignment: every other one is obtained from it by exactly one map that preserves the least element, joins and the degrees of the rules.

Remark 6.12 (Heyting arithmetic and Peano arithmetic)**.** The two strengths have standard names, and both identifications are proved against presentations written with no ledger. The base rules of Chapter 5, with induction for every formula, have the language, the successor, addition and multiplication laws and the induction of *Heyting arithmetic*, the intuitionistic first-order theory of 0, S, $+$ and $\cdot$ [4], and we use that name for the posit-free derivations. Chapter 8 shows that they are exactly the translations of derivations in the usual presentation of Heyting arithmetic, up to the way the injectivity of the successor is written (Corollary 8.12). In particular, from every finite context, the posit-free derivations prove exactly what Heyting arithmetic proves. With the EM rule added they correspond to *Peano arithmetic*, the classical theory. Theorem 8.11 in Chapter 8 proves this second identification: from every finite context,

the derivations whose LPO and MP entries are false prove exactly what Peano arithmetic proves. Together with Theorem 6.11 this covers every combination of the three rules, with induction on every formula permitted. If MP may be used but neither EM nor LPO, removing the MP leaves of a derivation gives a posit-free derivation of the same judgment, so the derivable judgments are those of Heyting arithmetic. If EM or LPO may be used, removing the MP leaves and exchanging LPO leaves for EM derivations, or EM leaves for LPO derivations when only LPO is permitted, shows that the derivable judgments are exactly those of Peano arithmetic. The two theories differ, by the third assertion of Theorem 6.11.

Without any induction rule, the picture changes.

Proposition 6.13 (The price of each rule without induction)**.** *Consider only derivations that contain no induction rule. Then EM reduces to LPO and MP together, and each of LPO and MP reduces to EM. LPO does not reduce to MP, MP does not reduce to LPO, and EM reduces to neither of them alone. The three rules therefore mark four strengths: no rule; MP; LPO; and EM, which is equivalent to LPO and MP together.*

Conditions and scope.

Base and premises
Derivations that contain no induction rule, over the base rules of Chapter 5 and the rules EM, LPO and MP of (6.3)–(6.5), the MP rule restricted to quantifier-free bodies.

Conclusion
EM reduces to LPO and MP together, and each of LPO and MP reduces to EM; LPO does not reduce to MP, MP does not reduce to LPO, and EM reduces to neither alone. The rules mark four strengths: no rule, MP, LPO, and EM.

Proof. We first give the three positive reductions, then the four separations, and finally read off the four strengths. Every derivation in the first part is free of induction rules.

The positive reductions. The converse half of Theorem 6.10 derives every LPO instance from one EM rule, at $\exists x\,\varphi$, without induction. For MP, let φ be quantifier-free and assume $\neg\neg\exists x\,\varphi$. The EM rule at $\exists x\,\varphi$ gives $(\exists x\,\varphi) \vee \neg\exists x\,\varphi$. In the first case the conclusion is at hand. In the second, implication elimination applies the hypothesis $\neg\neg\exists x\,\varphi$ to $\neg\exists x\,\varphi$ and yields $\bot$, and the rule for an impossible case gives $\exists x\,\varphi$. Disjunction elimination and implication introduction give the MP instance, with one EM rule and no induction. For EM from LPO and MP, recall that the proof of Theorem 6.10 derives $\Gamma \vdash \varphi \vee \neg\varphi$ by induction on φ, and that induction rules enter it only where an equation $t = s$ is decided through (6.9). Replace each such decision by the derivation of the remark that follows the theorem: with β the formula $t = s \vee \neg(t = s)$ and z a variable that does not occur in it, that derivation proves $\neg\neg\exists z\,\beta$ with no added rule, applies the MP rule at the quantifier-free body β, and recovers β by existential elimination. Hypotheses that it does not use may be added to its context, as in Section 6.7. The result derives every EM instance from LPO and MP rules with no induction rule.

The separations from MP. The third assertion of Theorem 6.11 shows that neither LPO nor EM reduces to MP even when induction on every formula is permitted. A derivation without induction is in particular a derivation, so neither reduces to MP here, and neither reduces to the empty set.

Two stages. The separations from LPO use a model with two stages, and from here on the argument uses a classical metatheory. A *two-stage structure* consists of two structures M_0 and M_1 in the sense of Definition 5.7, each satisfying the six arithmetic rules, and a map h from M_0 *onto* M_1 that preserves 0, S, $+$ and $\cdot$. We call M_0 the earlier stage, M_1 the later stage and h the passage. For an environment ρ in M_0 write $h\rho$ for the environment $k \mapsto h(\rho(k))$ in M_1. A formula is *forced* at ρ, written $\rho \Vdash \varphi$, according to the following clauses:

- $\rho \Vdash t = s$ when t and s have the same value in M_0 under ρ; $\bot$ is never forced;
- $\rho \Vdash \varphi \wedge \psi$ when both are forced, and $\rho \Vdash \varphi \vee \psi$ when one of them is forced;
- $\rho \Vdash \varphi \to \psi$ when $\rho \Vdash \varphi$ implies $\rho \Vdash \psi$, and also $M_1, h\rho \vDash \varphi$ implies $M_1, h\rho \vDash \psi$;
- $\rho \Vdash \forall\varphi$ when $[a, \rho] \Vdash \varphi$ for every element a of M_0, and also $M_1, [b, h\rho] \vDash \varphi$ for every element b of M_1;
- $\rho \Vdash \exists\varphi$ when $[a, \rho] \Vdash \varphi$ for some element a of M_0.

Equations, disjunctions and existential statements are thus read at the earlier stage alone, while an implication or a universal statement must also hold at the later stage. In particular $\rho \Vdash \neg\varphi$ holds exactly when φ is not forced at ρ and is false in M_1 under $h\rho$.

Appendix E proves three facts about these clauses. Forcing *persists*: if $\rho \Vdash \varphi$, then $M_1, h\rho \vDash \varphi$ (Lemma E.3). Forcing respects lifting and substitution in the way Lemma 5.4 describes for satisfaction (the same lemma). And every derivation with no induction rule whose additional rules are all LPO rules is *sound* for forcing: if ρ forces every formula of its context, ρ forces its conclusion (Theorem E.5). The proof of soundness is a rule-by-rule check. Its one case that is not routine is the LPO rule, and it explains why the passage must be onto. Suppose $\rho \Vdash \forall x(\varphi \vee \neg\varphi)$. If some element a of M_0 has $[a, \rho] \Vdash \varphi$, the left alternative $\exists x\varphi$ is forced. Otherwise every a forces $\neg\varphi$, so φ is false in M_1 at every $h(a)$. Because h is onto, these are all the elements of M_1, so $\forall x\neg\varphi$ is forced as well. At the later stage alone the LPO instance is true by classical reasoning.

The model. The later stage is $\mathbb{N}$. The earlier stage C has the elements $0, 1, 2, \ldots$ and a second copy $0', 1', 2', \ldots$, all distinct; its zero is the unprimed 0. Write $|a|$ for the number obtained by erasing a prime. Set $S(n) = n + 1$ and $S(n') = (n + 1)'$. The sum $a + b$ has erased value $|a| + |b|$ and carries a prime exactly when a or b does. The product $a \cdot b$ has erased value $|a|\,|b|$ and carries a prime exactly when a or b does, except that $a \cdot 0 = 0$ for every a. Thus $3' \cdot 0 = 0$ while $0 \cdot 0' = 0'$; the operations of C are not commutative.

C satisfies the six arithmetic rules. A successor is never the unprimed 0: $S(n) = n + 1$, and $S(n')$ is primed. The successor adds one to the erased value and keeps the prime, so it is injective. The equation $a + 0 = a$ holds because adding the unprimed 0 changes neither the value nor the prime, and $a \cdot 0 = 0$ is the exception. In $a + S(b) = S(a + b)$ both sides have erased value $|a| + |b| + 1$ and carry a prime exactly when a or b does. In $a \cdot S(b) = a \cdot b + a$ both sides have erased value $|a|\,|b| + |a|$. Since $S(b)$ is never the unprimed 0, the left side carries a prime exactly when a or b does. On the right, if b is the unprimed 0 then $a \cdot b = 0$ and the sum is primed exactly when a is, which agrees with the left side; otherwise $a \cdot b$ is primed exactly when a or b is, and so is the sum. The passage $h(a) = |a|$ preserves 0 and S, and it preserves sums

and products because they were defined through erased values; the exception has the value $0 = |a| \cdot 0$. It is onto, since $h(n) = n$. So C, $\mathbb{N}$ and h form a two-stage structure.

Excluded middle fails. Let ρ send x to $0'$. The equation $x = 0$ is not forced, because $0'$ and 0 are different elements of C. Its negation is not forced either, because $h(0') = 0$ makes $x = 0$ true in $\mathbb{N}$ under $h\rho$. So the EM instance $x = 0 \vee \neg(x = 0)$ is not forced at ρ, and neither is $\forall x(x = 0 \vee \neg(x = 0))$, whose earlier clause fails at the element $0'$. A derivation from no hypotheses is forced at every environment, since the empty context is forced. By the soundness theorem, neither formula has a derivation without induction whose additional rules are LPO rules. So EM does not reduce to LPO.

Markov's principle fails. Let β be $x = 0 \vee \neg(x = 0)$ and let z be a variable that does not occur in it, so that $\neg\neg\exists z\,\beta \to \exists z\,\beta$ is an instance of the MP schema at the quantifier-free body β. It is the instance the remark after Theorem 6.10 uses to decide $x = 0$. Take ρ with $x \mapsto 0'$ again. In $\mathbb{N}$ under $h\rho$ the formula β is true, since x has the value 0; so $\exists z\,\beta$ is true there and $\neg\exists z\,\beta$ is false. Hence $\neg\exists z\,\beta$ is not forced at ρ (its later clause fails), and $\neg\neg\exists z\,\beta$ is forced: its earlier clause holds because $\neg\exists z\,\beta$ is not forced, and its later clause because $\exists z\,\beta$ is true in $\mathbb{N}$. But $\exists z\,\beta$ is not forced. Written with positions, its body is the lifted formula $\beta\uparrow$, so a witness c in C would give $[c, \rho] \Vdash \beta\uparrow$, which by the lifting half of Lemma E.3 says $\rho \Vdash \beta$; we have just seen that this fails. The first clause of the implication therefore fails, and the MP instance is not forced at ρ. By the soundness theorem it has no derivation without induction whose additional rules are LPO rules, and MP does not reduce to LPO.

Four strengths. Give EM the degree $(1, 1)$, LPO the degree $(1, 0)$ and MP the degree $(0, 1)$, and give a set of rules the coordinatewise maximum of the degrees of its members, or $(0, 0)$ if it is empty. A rule reduces without induction to a set exactly when its degree is at most the degree of the set in both coordinates. If the degree is at most that of the set, then either the rule belongs to the set, or it is LPO or MP and the set contains EM, or it is EM and the set contains both LPO and MP; the positive reductions cover each case. If the degree is not at most that of the set, then either the first coordinate fails, and the rule is LPO or EM while the set is contained in {MP}, or the second fails, and the rule is MP or EM while the set is contained in {LPO}. A rule that reduced to a subset would reduce to the larger set, and the four separations exclude each of these cases. The four degrees are four strengths: no rule; MP; LPO; and EM, which has the degree of LPO and MP together. □

Theorem 6.11 and Proposition 6.13 do not conflict: they concern different sets of permitted derivations. Induction on quantified formulas decides equality, the job that MP did in the remark after Theorem 6.10, and it derives every MP instance. Once the restricted rule costs nothing, the reduction of EM to LPO and MP becomes a reduction of EM to LPO, and the four strengths collapse to two. This is why the ledger records induction in an entry of its own: the price of a principle can depend on the induction available.

The empty ledger permits induction on quantifier-free formulas only. That much induction decides $x = 0$, by splitting into the zero and successor cases, but it does not decide equality in general, and the four strengths persist.

Proposition 6.14 (The price of each rule with quantifier-free induction)**.** *Consider only derivations whose induction formulas are all quantifier-free, that is, derivations whose ledger has a false induction entry. Then the reductions are exactly those of Proposition 6.13: EM reduces to LPO and MP together, each of LPO and MP reduces to EM, LPO does not reduce to MP, MP does not reduce to LPO, and EM reduces to neither of them alone. Two explicit formulas witness the separations from LPO: the MP instance*

$$\neg\neg\exists x(x + y = z) \to \exists x(x + y = z)$$

has no derivation whose ledger has false EM, MP and induction entries, even with LPO permitted, and therefore none with an empty ledger; nor has $\forall x\,\forall y(x = y \vee \neg(x = y))$*.*

Conditions and scope.

Base and premises

Derivations whose induction formulas are all quantifier-free, over the base rules of Chapter 5 and the rules EM, LPO and MP of (6.3)–(6.5), the MP rule restricted to quantifier-free bodies.

Conclusion

The reductions are exactly those of Proposition 6.13. With LPO permitted but no EM or MP rule and no induction on a formula with quantifiers, neither the MP instance $\neg\neg\exists x(x + y = z) \to \exists x(x + y = z)$ nor $\forall x\,\forall y(x = y \vee \neg(x = y))$ has a derivation.

Proof. The positive reductions are those of Proposition 6.13. Their derivations use no induction at all, so their ledgers have a false induction entry. The third assertion of Theorem 6.11 shows that neither LPO nor EM reduces to MP even when induction on every formula is permitted, so neither reduces to MP here. It remains to show that neither MP nor EM reduces to LPO, through the two displayed formulas. The structure C of Proposition 6.13 no longer serves, because quantifier-free induction proves $\forall x(x = 0 \vee \neg(x = 0))$, by the split into the zero and successor cases. We build another two-stage structure, again with a classical metatheory, in which the earlier stage also forces quantifier-free induction, and apply Theorem E.5 in its second form.

The later stage. Let P consist of the polynomials in t with integer coefficients whose leading coefficient is nonnegative; these are 0 and the polynomials with a positive leading coefficient. Its operations are 0, $p \mapsto p + 1$, and the sum and product of polynomials. For nonzero p, q in P the leading terms never cancel. If p has the larger degree, $p + q$ has the leading coefficient of p; if the degrees are equal, the leading coefficients add to a positive number. So $p + q$ lies in P and has the larger of the two degrees. The leading coefficient of pq is the product of the leading coefficients, which is positive, so pq lies in P and has degree $\deg p + \deg q$. Adding 0 or multiplying by 0 stays in P, and the successor is the sum with 1. The constant elements of P are the natural numbers. If p has positive degree, then for every natural number k the polynomial $p - k$ has the same degree and leading coefficient, so it lies in P and has positive degree; the elements $p - k$ are pairwise distinct, and the successor of $p - (k + 1)$ is $p - k$.

P satisfies the six arithmetic rules. If $p + 1 = 0$, then $p = -1$, whose leading coefficient is negative, so a successor is never 0. Adding 1 is injective. The four recursive equations, such as $p(q + 1) = pq + p$, are identities of polynomials.

Eventual constancy in P. Fix a quantifier-free formula ψ and an environment σ in P; the variable $x = x_0$ is singled out, and the others are parameters with the values σ gives them. For each term s let $s_\sigma(X)$ be the polynomial in a new variable X, with coefficients in the integer polynomials in t, obtained by writing X for x_0, the polynomial $\sigma(k)$ for x_{k+1}, and computing with 0, S, $+$ and $\cdot$ as polynomials. Induction on s shows that the value of s under $[w, \sigma]$ is $s_\sigma(w)$ for every w in P. So an equation $s = r$ holds under $[w, \sigma]$ exactly when w is a root of $s_\sigma - r_\sigma$.

Now let $w_0, w_1, w_2, \ldots$ be pairwise distinct elements of P. We claim that for each equation $s = r$ there is an N such that, for every $k \geq N$, the equation holds under $[w_k, \sigma]$ exactly when $s_\sigma = r_\sigma$ as polynomials in X. If $s_\sigma = r_\sigma$, it holds at every w. Otherwise $s_\sigma - r_\sigma$ is a nonzero polynomial whose coefficients lie in the integer polynomials in t, which have no zero divisors. Such a polynomial has at most as many roots as its degree. A root c splits off a factor: $s_\sigma - r_\sigma = (X - c) \cdot g$ with g of degree one less, by division by $X - c$; and every other root c' is a root of g, because $(c' - c)\, g(c') = 0$ and there are no zero divisors. Induction on the degree gives the bound. Since the w_k are distinct, only finitely many of them are roots; take N beyond those. Call the truth value obtained by giving each equation $s = r$ of ψ the value of $s_\sigma = r_\sigma$, and combining these by the truth tables of $\wedge$, $\vee$, $\to$ and $\bot$, the *generic value* of ψ at σ. Satisfaction of a quantifier-free formula is computed from its equations by the same truth tables, and ψ has finitely many equations. Taking the largest of their thresholds, we obtain an N such that ψ holds under $[w_k, \sigma]$, for every $k \geq N$, exactly when its generic value at σ is true.

Quantifier-free induction holds in P. Suppose $\psi(0)$ and $\forall x(\psi(x) \to \psi(S(x)))$ hold under σ. By Lemma 5.4, ψ holds under $[0, \sigma]$, and whenever it holds under $[w, \sigma]$ it holds under $[w + 1, \sigma]$. Ordinary induction gives ψ under $[n, \sigma]$ for every natural number n. The natural numbers are pairwise distinct elements of P, so the generic value of ψ at σ is true. Let w be any element of P. If w is constant, it is a natural number. Otherwise w has positive degree, and $w, w - 1, w - 2, \ldots$ are pairwise distinct elements of P; for large N, ψ holds under $[w - N, \sigma]$, because the generic value is true. Applying the step N times carries ψ up to $[w, \sigma]$. Thus $\forall x \psi(x)$ holds under σ, and P satisfies every quantifier-free induction instance.

The earlier stage. Let Q consist of the pairs (u, v) of elements of P that are equal or both of positive degree, with $0 = (0, 0)$ and the successor, sum and product taken in each coordinate. Every element of Q is either (n, n) for a natural number n or has both coordinates of positive degree. Q is closed under the operations. The successor keeps equal pairs equal and does not change degrees. A sum of two equal pairs is equal; otherwise one summand has both coordinates of positive degree, and since a sum in P has the larger degree of its summands, so does the sum. A product of two equal pairs is equal. Otherwise one factor has both coordinates of positive degree. If the other factor is $(0, 0)$, the product is $(0, 0)$. If not, both coordinates of the other factor are nonzero, because an element of Q with a zero coordinate is $(0, 0)$; degrees add, so both coordinates of the product have positive degree. The six arithmetic rules hold in each coordinate, hence in Q; in particular a successor $(u + 1, v + 1)$ is never $(0, 0)$. The passage $h(u, v) = u$ preserves 0, S, $+$ and $\cdot$, and it is onto, since $h(u, u) = u$. So Q, P and h form a two-stage structure.

Quantifier-free induction is forced at the earlier stage. For an environment ρ in Q write ρ^1 and ρ^2 for its two coordinate environments in P; thus $h\rho = \rho^1$. Since the operations act in each coordinate, the value of a term under ρ is the pair of its values under ρ^1 and ρ^2, and $\rho \Vdash s = r$ holds exactly when $s = r$ holds in P under ρ^1 and under ρ^2. For a quantifier-free

formula, induction on the formula shows that whether it is forced at ρ is determined by two assignments of truth values to its equations: the *earlier* assignment, which records which equations are forced at ρ, and the *later* one, which records which hold in P under $h\rho$. Equations are read from the earlier assignment, $\bot$ is false, $\wedge$ and $\vee$ combine their components, and an implication $\varphi \to \chi$ requires that forcing of φ give forcing of χ and that its truth table, read from the later assignment, be true.

Let ψ be quantifier-free and suppose $\rho \Vdash \psi(0)$ and $\rho \Vdash \forall x(\psi(x) \to \psi(S(x)))$. We show $\rho \Vdash \forall x\psi$, which has two parts. The later part asks that ψ hold in P under $[b, \rho^1]$ for every b in P. By persistence (Lemma E.3) both premises hold in P under ρ^1, and quantifier-free induction in P gives $\forall x\psi$ there. The earlier part asks that $[a, \rho] \Vdash \psi$ for every a in Q. By the binding lemma, $[(0,0), \rho] \Vdash \psi$, and the earlier clauses of the second premise show that $[a, \rho] \Vdash \psi$ implies $[S(a), \rho] \Vdash \psi$ for every a. So $[(n,n), \rho] \Vdash \psi$ for every natural number n. Now let $a = (u, v)$ have both coordinates of positive degree, and set $a_k = (u-k, v-k)$. These pairs lie in Q, $a_0 = a$, and $S(a_{k+1}) = a_k$. Along both sequences (k,k) and a_k the first coordinates are pairwise distinct, and so are the second coordinates. Apply eventual constancy to each equation $s = r$ of ψ, once with the parameters ρ^1 and once with ρ^2. For all large k, along either sequence, the equation is forced exactly when $s_{\rho^1} = r_{\rho^1}$ and $s_{\rho^2} = r_{\rho^2}$, and it holds after the passage exactly when $s_{\rho^1} = r_{\rho^1}$. These limiting assignments depend on ρ and ψ alone, not on the sequence. So there is an N such that, for every $k \geq N$, forcing of ψ at $[(k,k), \rho]$ and at $[a_k, \rho]$ have the same value, the one that the two-stage reading gives to the limiting assignments. Along (k,k) that value is true, so $[a_N, \rho] \Vdash \psi$, and N applications of the step carry it up to $[a_0, \rho] = [a, \rho]$.

Soundness. The two-stage structure (Q, P, h) satisfies the hypotheses of the second form of Theorem E.5. Hence every derivation whose ledger has false EM, MP and induction entries, and therefore whose only additional rules are LPO rules and whose induction formulas are quantifier-free, is forced at every environment that forces its context. In particular a formula derived from no hypotheses in this way is forced at every environment.

The MP instance fails. Let ρ send y to (t, t^2) and z to (t^2, t); both pairs lie in Q. Under $h\rho$ the variables have the values t and t^2, and $x = t^2 - t$, which lies in P with leading coefficient 1, satisfies $x + t = t^2$. So $\exists x(x + y = z)$ holds in P under $h\rho$, and $\neg\exists x(x + y = z)$ is false there. Consequently $\neg\exists x(x + y = z)$ is not forced at ρ, its later clause failing, and $\neg\neg\exists x(x + y = z)$ is forced: its earlier clause holds because $\neg\exists x(x + y = z)$ is not forced, and its later clause because $\exists x(x + y = z)$ holds in P. But no pair (a, b) in Q satisfies $(a, b) + (t, t^2) = (t^2, t)$, since the second coordinate would force $b = t - t^2$, whose leading coefficient is -1. So $\exists x(x + y = z)$ is not forced, the earlier clause of the implication fails, and the MP instance is not forced at ρ. It therefore has no derivation whose ledger has false EM, MP and induction entries, even with LPO permitted, and in particular none with an empty ledger.

Excluded middle fails. Let ρ send x to (t, t) and y to (t, t^2). The two pairs differ in the second coordinate, so $x = y$ is not forced. They have the same first coordinate, so $x = y$ holds in P under $h\rho$ and $\neg(x = y)$ is not forced either. So $x = y \vee \neg(x = y)$ is not forced at ρ, and neither is $\forall x \forall y(x = y \vee \neg(x = y))$, whose earlier clauses lead to this environment. Neither formula has a derivation whose ledger has false EM, MP and induction entries.

Thus MP and EM do not reduce to LPO at this level. With the positive reductions and the separations from MP, the comparison of degrees at the end of the proof of Proposition 6.13 applies word for word, and the reductions with quantifier-free induction are exactly those

without induction. □

The collapse to two strengths therefore needs induction on quantified formulas, the resource that the fourth entry of the ledger records.

What soundness needs

These theorems sharpen Theorem 6.6. That theorem assumes the metatheoretic MP for an MP entry and the metatheoretic EM for an EM entry. Neither assumption is needed in that form.

Corollary 6.15 (The metatheoretic price of the three rules)**.** *Let a derivation of $\Gamma \vdash \varphi$ have ledger O. If the EM or the LPO entry of O is true, assume the metatheoretic LPO of Definition 6.1 for the predicates $n \mapsto \big([n, \rho] \vDash \psi\big)$, one for each formula ψ and environment ρ; otherwise assume nothing. Every environment satisfying Γ then satisfies φ. This assumption is the least possible. If every derivation whose additional rules are all LPO rules is sound, or every derivation whose additional rules are all EM rules is sound, then LPO holds for these predicates; and for them it is equivalent to excluded middle for the propositions $\rho \vDash \psi$.*

Proof. Follow the proof of Theorem 6.6. The base cases and the LPO leaves are unchanged, and only the EM and MP leaves need new arguments. At an MP leaf, the second assertion of Theorem 6.9 gives the interpreted instance with no principle. At an EM leaf we need $(\rho \vDash \varphi) \vee \neg(\rho \vDash \varphi)$. The metatheoretic LPO supplies this for every formula, by the argument of Theorem 6.10 read in the metatheory, by induction on the formula and for every environment at once. Equations are decided by comparing values, and the connectives preserve decisions. For $\exists\psi$, apply LPO to the predicate $[n, \rho] \vDash \psi$, which the induction hypothesis decides at every n. For $\forall\psi$, apply it to $[n, \rho] \vDash \neg\psi$, and use the decision of each instance to pass from $\forall n\, \neg\neg\psi$ to $\forall n\, \psi$. Only predicates of the stated form occur, so LPO for them suffices, and the same argument shows that it gives excluded middle for every proposition $\rho \vDash \psi$.

For the converse, the LPO instance at ψ is a derivation from no hypotheses whose only additional rule is LPO. Its soundness at ρ is exactly LPO for the predicate $[n, \rho] \vDash \psi$. The EM instance at ψ gives, in the same way, $(\rho \vDash \psi) \vee \neg(\rho \vDash \psi)$; applied to $\exists\psi$, this excluded middle decides whether some n satisfies $[n, \rho] \vDash \psi$ or none does, which is LPO for that predicate. □

For the formulas of this language, then, interpreting a derivation never needs excluded middle for arbitrary propositions. What the derivations with an EM or LPO entry need, taken together, is exactly LPO for the predicates that formulas define, which is the same as excluded middle for the propositions that formulas express. Excluded middle for arbitrary propositions is not implied by LPO [4]; formulas of the arithmetic language are not arbitrary propositions.

The next chapter carries the two-direction test to a concrete structural question: which identifications can a reader of repeated records make? Supplying an explicit identified pair, asserting only that some pair must exist, supplying only a decision procedure and asking for a yes-or-no answer, the full alternative or the parity of the index, and asking for a classification with no decision procedure lead to different theorem statements, and their costs are proved in both directions. Those costs are stated with metatheoretic principles: those of Definition 6.1, applied to arbitrary decidable predicates, and the weaker omniscience principles of Definition 7.8. At that level Markov's principle is an assumption that the classification

genuinely needs: the classification implies it, and a model in Section 7.12 shows that intuitionistic second-order arithmetic proves neither. The restricted Markov rule of this chapter, the quantifier-free schema (6.5), by contrast costs nothing once induction on every formula is allowed. Theorem 7.38 shows that no two of the principles priced in the next chapter are equivalent.

Questions to work through

1. Write the two derivations of $(0 = 0) \vee \neg(0 = 0)$ and annotate each node with its ledger. What does their comparison establish, and what would examining only the EM proof fail to establish?

2. Reproduce the implication case of Lemma 6.2. Explain why deciding its finite components does not decide an arbitrary existential formula.

3. Why does the quantified-induction example have a nonempty ledger while remaining posit-free? Identify the tested formula rather than looking only at the conclusion.

4. In the proof of conditional soundness, identify the use of the MP rule's quantifier-free restriction. What premise of the metatheoretic principle does it supply?

5. For $\varphi(x)$ given by $x \cdot x = y + y$, find the coefficient lists and the bound B of Lemma 6.8. Carry out the search for $y = 8$. Why does the lemma fail for the formula $\exists z\,(x = z + z)$, which contains a quantifier?

6. Derive an instance of the LPO schema from the EM rule. Where is existential introduction used, and what is the ledger of the result?

7. Locate the inductions in the proof of Theorem 6.10. Show how one MP instance, at a formula under a quantifier whose variable does not occur in it, replaces them for the equation $x = 0$. What is the ledger of the result?

8. Explain why Theorem 6.11 and Proposition 6.13 are consistent. What does induction on quantified formulas supply that separates them, and why does Proposition 6.14 show that induction on quantifier-free formulas does not supply it?

Chapter 7

What can recognize the same record?

A tally distinguishes successive counts. A reader of a tally may retain less. Two different counts can receive the same reading. If the reader also respects addition, that loss of distinction cannot occur arbitrarily: an identification must remain valid after the same further count is added to both sides.

This requirement is strong enough to classify every possible pattern of identification. The answer has a simple shape. Either every count remains distinct, or an initial segment is followed by a repeating part. The mathematical content lies in proving that no other shape is possible.

There is also a logical question. What information have we been given about the reader, and what do we ask the classification to return? An actual pair of identified counts provides more than the assertion that the reader cannot distinguish everything. A way to decide each pair provides more than an arbitrary relation. Asking only whether the reader is faithful asks for less than its index and period. Keeping these differences visible leads to six precise versions of the classification. One needs no additional principle, and each of the other five is equivalent to exactly one named logical principle. The six principles, counting the empty one, are pairwise different over intuitionistic second-order arithmetic (Theorem 7.38), so no version sits at two of them.

We use natural-number coordinates for the orbit in this chapter. The round-trip maps of Chapter 1 preserve addition, so the results describe the same constructed arithmetic. No new carrier is being substituted for it.

7.1 Identifications that respect addition

Definition 7.1 (An additive congruence)**.** A relation $x \sim y$ on the natural numbers is an *additive congruence* if it is reflexive, symmetric and transitive, and satisfies

$$w \sim x \text{ and } y \sim z \quad \Longrightarrow \quad w + y \sim x + z.$$

In particular, $x \sim y$ implies $x + t \sim y + t$ for every t.

The final implication follows by combining $x \sim y$ with $t \sim t$. Its direction matters. A congruence permits us to add the same count to both sides. It need not permit cancellation. A reader can lose distinctions as the count advances. Section 7.8 identifies the congruences that do permit cancellation: they are exactly the ones that survive the passage to signed records.

For an addition-preserving reading r, define

$$x \sim_r y \quad \Longleftrightarrow \quad r(x) = r(y).$$

Equality of readings is an equivalence relation. Moreover, $r(w + y) = r(w) + r(y)$, so equal readings remain equal under addition. Thus the relation is an additive congruence. It is often called the *kernel* of the reading: it records exactly which inputs the reading identifies.

Definition 7.2 (The index–period relation)**.** Let i be a natural number and let $p > 0$. Define

$$x \sim_{i,p} y \quad \Longleftrightarrow \quad x = y \text{ or } \big(i \le x,\ i \le y,\ x \bmod p = y \bmod p\big). \tag{7.1}$$

The number i is the *index*; p is the *period*.

Before i, a count is identified only with itself. From i onward, counts with the same remainder modulo p are identified. For example, the definition gives the repeating chain

$$i \sim_{i,p} i + p \sim_{i,p} i + 2p \sim_{i,p} \cdots.$$

The displayed continuation describes repetitions of the same finite rule. It does not require a completed physical record of all those counts.

Proposition 7.3 (The family is well defined)**.** *For each i and $p > 0$, relation* (7.1) *is an additive congruence. Furthermore,*

$$n \sim_{i,p} n + p \quad \Longleftrightarrow \quad i \le n. \tag{7.2}$$

Proof. Reflexivity uses the equality alternative. Symmetry follows by reversing equality or equality of remainders. For transitivity, an equality alternative lets us replace one endpoint directly. If both relations use the second alternative, all necessary endpoints lie at or beyond i, and equality of remainders is transitive.

For addition, if both input relations are equalities, their sums are equal. If at least one uses the second alternative, both corresponding sums are at least i. Equality of remainders of the inputs gives equality of remainders of their sums, since the remainder of a sum is determined by the remainders of its summands. This proves compatibility with addition.

Finally n and $n + p$ are distinct because $p > 0$, and they have the same remainder modulo p. Their relation therefore holds exactly when n is at least i. □

7.2 How a period reaches an earlier collision

The difficult part of classification is to rule out irregular behaviour. We cannot simply cancel a large common addition in a congruence. Instead, we use an existing repetition to bring two chains together.

Say that a positive number d is a *period at x* when $x \sim x + d$. Addition compatibility and transitivity immediately give

$$x \sim x + kd \qquad (k \in \mathbb{N}).$$

The same period also holds at every later point: add $n - x$ to the relation when $n \ge x$.

Lemma 7.4 (Moving a period back to a collision)**.** *Suppose $d > 0$, $p > 0$, $x \sim x + d$, and $y \sim y + p$ with $y \geq x$. Then $x \sim x + p$.*

Proof. Choose a natural number k with $M = x+kd \geq y$. One explicit choice is $k = \lfloor (y-x)/d \rfloor + 1$. Repeating the first relation gives $x \sim M$. Translating the second relation from y to M gives $M \sim M + p$. Translating $x \sim M$ by p gives $x + p \sim M + p$. Symmetry and transitivity now combine the three relations:

$$x \sim M \sim M + p \sim x + p.$$

No cancellation of a congruence was used. □

Lemma 7.5 (A least period controls every collision)**.** *Suppose $p > 0$, $a \sim a + p$, and p is the least positive period at a. Every positive period at any point is a multiple of p. Also, if $x < y$ and $x \sim y$, then $x \sim x + p$.*

Proof. Let $e > 0$ be a period at some x. Translate that period to $a + x$, which lies at or beyond a. Apply Lemma 7.4, using the existing period p at a. The result is $a \sim a + e$.

Divide e by p: write $e = qp + r$ with $0 \leq r < p$. Repeating the p-period gives $a \sim a + qp$. After adding r, this becomes $a + r \sim a + e$. Together with $a \sim a + e$, it gives $a \sim a + r$. If $r > 0$, this contradicts minimality of p. Therefore $r = 0$, so p divides e.

For the final assertion, $y - x > 0$ is a period at x. Translate the p-period from a to $a + x$, and apply Lemma 7.4 with the existing positive period $y - x$ at x. It yields $x \sim x + p$. □

These two lemmas explain why an apparently local collision determines the shape of every later one. Their hypotheses contain the periods they use; neither proof searches for a period without evidence that one exists.

7.3 The constructive classification

Theorem 7.6 (The classification with an explicit collision)**.** *Let $\sim$ be an additive congruence. Suppose we have a decision procedure for each assertion $x \sim y$, and are given $a \sim b$ with $a \neq b$. Then there are unique natural numbers i and $p > 0$ such that $\sim$ is exactly $\sim_{i,p}$.*

The information in the hypothesis is concrete. The procedure decides individual pairs, and the supplied pair shows that at least one identification occurs. We will use two finite searches whose endpoints are supplied by that pair.

Construction and classification. Reverse a and b if necessary so that $a < b$. Search the integers $1, \ldots, b - a$ for the least p such that $a \sim a + p$. Every test is decidable, and the last candidate succeeds because $a + (b - a) = b$. Thus p exists, is positive and is the least positive period at a.

Next search $0, \ldots, a$ for the least i such that $i \sim i + p$. Again every test is decidable, and a succeeds. This i is also the least index among all natural numbers with that property: any smaller index would have occurred in the same search.

We prove equality of the two relations. Suppose first that $x \sim y$. If $x = y$, the equality alternative of (7.1) applies. If they differ, arrange $x < y$ by symmetry. Lemma 7.5 gives $x \sim x + p$, so minimality of i gives $i \le x \le y$. The positive gap $y - x$ is a period at x, hence a multiple of p. Consequently x and y have the same remainder modulo p. This is the second alternative of (7.1).

Conversely, equality is always a congruence relation. For the second alternative, arrange $x \le y$. Equal remainders mean $y - x = kp$ for some natural number k. The relation $i \sim i + p$ translates to a p-period at x because $i \le x$. Repeating it k times gives $x \sim x + kp = y$. Symmetry handles the opposite ordering. Thus the relations agree at every pair. □

Uniqueness. Suppose the same relation has two descriptions, with parameters (i, p) and (i', p'). The relation $i \sim i + p$, read in the second description, implies that p' divides p: its two unequal endpoints have equal remainders modulo p'. Reversing the descriptions shows that p divides p'. Positivity gives $p = p'$.

With the period fixed, equation (7.2) identifies the index. Since $i' \sim i' + p$, the first description gives $i \le i'$. The second description similarly gives $i' \le i$. Hence $i = i'$. □

The classification proof separates the search from the structural argument. Once a least positive period at a and the least index for that period are supplied, Lemma 7.5 and the two relation inclusions establish the answer. The decision procedure is used to find those values from the explicit collision.

7.4 What changes when the collision is not supplied

Now replace the displayed collision by a negative statement:

$$\neg\big[\forall x, y\,(x \sim y \implies x = y)\big]. \tag{7.3}$$

This says that the congruence is not equality. Constructively, it does not yet hand us a pair to start the two searches.

From here on, *decidable* means that a procedure giving a positive or negative decision is supplied. We use Markov's principle in the corresponding form: for a predicate with such pointwise decisions, $\neg\neg\exists n\, P(n)$ implies $\exists n\, P(n)$. This makes explicit the decision data behind the instance decisions discussed in Chapter 6.

This is the principle of Definition 6.1, applied to an arbitrary decidable predicate. It is not the arithmetic MP rule of Chapter 6. That rule applies only to quantifier-free formulas of the arithmetic language, and Theorem 6.9 shows that each of its instances is settled by a bounded search and, with induction on every formula permitted, is derivable from the base rules. A decidable predicate here is any predicate that comes with decisions, and at this level Markov's principle is genuinely needed. The reversal below shows that the classification implies it, and Section 7.12 gives a model of intuitionistic second-order arithmetic in which Markov's principle fails and the classification of the next theorem fails with it. That system therefore proves neither.

Theorem 7.7 (The classification from negative nontriviality)**.** *The following assertion is equivalent to Markov's principle, over the constructive mathematics retained here:*

For every decidable additive congruence satisfying (7.3)*, there exist i and $p > 0$ for which the congruence is $\sim_{i,p}$.*

Markov's principle suffices. Let $B(k)$ assert that some $x < k$ satisfies $x \sim k$. This is a finite search, so the given pairwise decisions decide $B(k)$. There cannot be no such k. Indeed, if none existed, any related pair x, y would have to be equal: if $x < y$, the count x would witness $B(y)$, and if $y < x$, symmetry would make y witness $B(x)$. This would contradict (7.3). We have therefore established $\neg\neg\exists k\, B(k)$.

Markov's principle gives a successful k, and hence an explicit distinct related pair. Theorem 7.6 applies. □

The converse is more informative. It shows how an arbitrary search question can be stored inside a congruence. Any procedure or principle that grants the stated classification must then be able to answer that question in the required sense.

The classification implies Markov's principle. Let $\theta(n)$ be any decidable predicate, and assume $\neg\neg\exists n\, \theta(n)$. Define

$$x \sim_\theta y \quad \Longleftrightarrow \quad x = y \text{ or } \exists k \le \min(x, y)\ \theta(k). \tag{7.4}$$

This relation is decidable by bounded search. It is reflexive and symmetric. For transitivity, equality alternatives are immediate. If $x \sim_\theta y$ and $y \sim_\theta z$ are both witnessed by successful indices, compare x and z. If $x \le z$, the first witness lies below both x and z; if $z < x$, the second does. Thus $x \sim_\theta z$. For addition compatibility, a successful witness below a related pair remains below the corresponding pair of sums. If both relations are equalities, the sums are equal. So this is an additive congruence.

It cannot be equality. If it were, any successful n would give $n \sim_\theta n+1$ and hence the impossible equation $n = n + 1$. That would refute $\exists n\, \theta(n)$, contradicting its double negation.

Apply the asserted classification to obtain i, p with $p > 0$. The period relation gives $i \sim_\theta i+p$. Its equality alternative is impossible. Its other alternative supplies a k with $\theta(k)$. We have obtained $\exists k\, \theta(k)$ from its double negation, for an arbitrary decidable predicate. That is Markov's principle. □

The theorem concerns the assertion for *every* congruence of the specified kind. It does not say that each particular classification needs MP. When an explicit collision is already available, the constructive proof applies directly.

7.5 What a decision procedure alone can buy

Keep the pairwise decision procedure, but supply neither a collision nor the assertion that the congruence is not equality. What may we then ask of the classification? Three questions are natural. Is the congruence equality? Which of the two alternatives holds: equality, or an

index–period description? And, more modestly, if there is a description, is its index odd or even?

Each question has its own exact price. The prices are principles about binary sequences, and no two of them are equivalent over intuitionistic second-order arithmetic (Theorem 7.38). We state them here; Chapter 12 meets them again on the continuum.

Definition 7.8 (Omniscience principles for binary sequences)**.** Let $\alpha : \mathbb{N} \to \{0,1\}$ be a binary sequence; its value at each specified index is decidable. The *weak limited principle of omniscience*, WLPO, states that every binary sequence satisfies

$$(\forall n,\ \alpha(n) = 0) \quad \text{or} \quad \neg(\forall n,\ \alpha(n) = 0).$$

The *limited principle of omniscience*, LPO, states that every binary sequence satisfies

$$(\forall n,\ \alpha(n) = 0) \quad \text{or} \quad (\exists n,\ \alpha(n) = 1).$$

The *lesser limited principle of omniscience*, LLPO, concerns sequences with at most one value equal to 1. For each such sequence it states

$$(\forall k,\ \alpha(2k) = 0) \quad \text{or} \quad (\forall k,\ \alpha(2k+1) = 0).$$

The binary form of Markov's principle states, for every binary sequence,

$$\mathrm{MP}_{\mathrm{bin}} : \qquad \neg(\forall n, \alpha(n) = 0) \implies \exists n, \alpha(n) = 1.$$

A decision procedure for a predicate on the natural numbers is the same information as the binary sequence of its answers. So the binary LPO is the predicate form of Definition 6.1 for predicates that come with decisions, and $\mathrm{MP}_{\mathrm{bin}}$ is equivalent to the form of Markov's principle used in Theorem 7.7, since $\neg(\forall n,\ \alpha(n) = 0)$ and $\neg\neg\exists n,\ \alpha(n) = 1$ imply each other. WLPO decides whether the all-zero assertion holds, without producing an index. LLPO, given at most one event, names a parity class free of events; it need not say whether an event occurs in the other class.

For a decidable congruence $\sim$, all three questions can be put to one sequence. Let

$$\beta_{\sim}(n) = 1 \quad \iff \quad \text{some } x < n \text{ satisfies } x \sim n. \tag{7.5}$$

Each value is a finite search, decided by the supplied procedure. The sequence is all zero exactly when $\sim$ is equality. If $\sim$ is equality, no $x < n$ satisfies $x \sim n$, because $x < n$ gives $x \neq n$. Conversely, let the sequence be all zero and $x \sim y$, and decide whether $x = y$. If $x \neq y$, then $x < y$ or $y < x$; by symmetry the smaller count is related to the larger, so $\beta_{\sim}(\max(x,y)) = 1$, which is excluded. Hence $x = y$. Only the decidability of equality and order between two counts is used. A value $\beta_{\sim}(n) = 1$ is itself an explicit collision: the search at n returns an $x < n$ with $x \sim n$.

In the other direction we reuse the congruence $\sim_\theta$ of (7.4), whose construction did not use the double-negation hypothesis. Given a binary sequence α, take $\theta(n)$ to be $\alpha(n) = 1$. Then $\sim_\theta$ is a decidable additive congruence, and

$$\sim_\theta \text{ is equality} \quad \iff \quad \forall n,\ \alpha(n) = 0. \tag{7.6}$$

An event at n relates n and $n+1$. Without events, only the equality alternative of (7.4) remains.

Theorem 7.9 (Three questions with a decision procedure)**.** *Over the retained constructive base:*

1. *The assertion that every decidable additive congruence is equality or is not equality is equivalent to WLPO.*
2. *The assertion that every decidable additive congruence is equality or equals some $\sim_{i,p}$ with $p > 0$ is equivalent to LPO.*
3. *The assertion that, for every decidable additive congruence, either every index–period description of it has odd index or every such description has even index, is equivalent to LLPO.*

Moreover, with no added principle, the assertion in (2) is equivalent to the conjunction of the assertion in (1) with the assertion of Theorem 7.7.

Equality has no index–period description, so both alternatives in (3) hold for it vacuously. The uniqueness argument of Theorem 7.6 uses neither the decision procedure nor the collision, so a congruence has at most one description, and (3) asks for one parity bit and nothing more.

The equality test is WLPO. Assume WLPO and apply it to $\beta_\sim$. If the sequence is all zero, $\sim$ is equality. If it is not all zero, $\sim$ cannot be equality, since equality would make it all zero. Conversely, given a binary sequence α, apply the assertion to $\sim_\theta$. By (7.6) its two alternatives are exactly the two alternatives of WLPO for α. □

The full alternative is LPO. Assume LPO and apply it to $\beta_\sim$. If the sequence is all zero, $\sim$ is equality. Otherwise LPO supplies k with $\beta_\sim(k) = 1$. The bounded search at k now produces an explicit pair $x \neq y$ with $x \sim y$, and Theorem 7.6 gives the description.

Conversely, apply the assertion to $\sim_\theta$. The equality alternative gives $\forall n,\ \alpha(n) = 0$ by (7.6). In the other alternative, $i \sim_\theta i + p$ with $p > 0$. These counts are unequal, so the definition of $\sim_\theta$ supplies $k \leq i$ with $\alpha(k) = 1$. Either way we have the conclusion of LPO.

For the final assertion, the equality test in (1) leaves two cases. The positive case is the first alternative of (2). In the negative case the congruence satisfies (7.3), and the assertion of Theorem 7.7 gives a description. Conversely, (2) gives (1) at once, because an index–period congruence is not equality. It also gives the assertion of Theorem 7.7, because for a congruence that is not equality its equality alternative is excluded. □

The last part is the catalogue's copy of Proposition 12.9: deciding the alternative is deciding whether there is anything to find, followed by finding it.

The parity of the index is LLPO. The forward direction needs a sequence with at most one event that records the parity. Call a pair $x < y$ the *first collision* of $\sim$ when $x \sim y$, no related pair $x' < y'$ has $y' < y$, and no $x' < x$ satisfies $x' \sim y$. Two first collisions must agree: each would otherwise violate a leastness condition of the other. Whether a given pair is the first collision is a finite check. For $b \in \{0, 1\}$ define

$$\gamma(2y + b) = 1 \quad \Longleftrightarrow \quad \text{some } x < y \text{ with } x \bmod 2 = b \text{ forms the first collision } (x, y).$$

Each value is decided by finite search, and uniqueness of the first collision gives at most one event.

Suppose $\sim$ equals $\sim_{i,p}$. A related pair $x < y$ satisfies $i \le x$ and $x + p \le y$, because the gap $y - x$ is then a positive multiple of p. Hence the first collision is $(i, i + p)$, and γ has its event at $2(i + p) + (i \bmod 2)$. Now apply LLPO to γ. If every even entry is zero, no description has even index, so every description has odd index. If every odd entry is zero, every description has even index.

Conversely, let α have at most one event. If $\alpha(k) = 1$, the congruence $\sim_\theta$ identifies two counts exactly when they are equal or both at least k; that is $\sim_{k,1}$. Apply the assertion to $\sim_\theta$. In its first alternative, an event at an even place $2j$ would give the description $\sim_{2j,1}$ with even index; so $\alpha(2j) \neq 1$, and since α is binary, $\alpha(2j) = 0$ for every j. The second alternative gives $\alpha(2j + 1) = 0$ for every j in the same way. These are the two alternatives of LLPO. □

The larger element of the first collision is the half y of the position $2y + b$, and the smaller element is then the least count related to y. That is why one parity bit is all the sequence needs to carry.

7.6 The unrestricted catalogue and excluded middle

Finally suppose no pairwise decision procedure is supplied. Ask for a catalogue that always returns one of two mathematical alternatives: either the congruence is equality, or it has an index–period description.

Theorem 7.10 (The full catalogue has exactly the strength of EM)**.** *The assertion*

$$\textit{every additive congruence is equality or some } \sim_{i,p} \textit{ with } p > 0$$

is equivalent to excluded middle over the retained constructive base.

Excluded middle suffices. Use EM to decide whether the congruence is equality. If so, take that alternative. Otherwise EM gives a distinct related pair: denying the existence of any such pair would make every related pair equal. Reverse the pair if needed to obtain $a < b$.

We need least numbers for predicates that may not have supplied decision procedures. EM supplies the following least-number argument. If $P(n)$ is known, use strong induction on n. EM either gives a $k < n$ with $P(k)$, in which case the induction hypothesis gives a least witness, or says no earlier witness exists, in which case n itself is least. Thus every inhabited natural-number predicate has a least witness under EM.

Apply this argument first to positive periods at a, using $b - a$ as a witness, and then to indices carrying that least period, using a as a witness. The structural argument in Theorem 7.6 now identifies the congruence as $\sim_{i,p}$. This proves the catalogue. □

The catalogue implies excluded middle. Let P be any proposition. Define

$$x \sim_P y \quad \Longleftrightarrow \quad x = y \text{ or } P. \tag{7.7}$$

This is an additive congruence without first deciding P. Reflexivity uses equality; symmetry and transitivity preserve an available proof of P or reduce to equality. For addition, if both input relations are equalities, their sums are equal; otherwise a proof of P already supplies the conclusion.

Apply the catalogue. In its equality branch, P would imply $0 \sim_P 1$, and hence $0 = 1$. Therefore $\neg P$. In its index–period branch, $i \sim_P i + p$ with $p > 0$. These numbers are unequal, so definition (7.7) gives P. Either branch supplies a side of $P \vee \neg P$. Since P was arbitrary, excluded middle follows. □

This proof does not turn EM into an executable decision procedure for every proposition. It establishes an equivalence between mathematical assertions in the metatheory. The forward proof keeps its least-witness claims at that level. The version with supplied pairwise procedures and an explicit collision has the more concrete bounded searches. Between the two lies the version of Section 7.5: the same alternative, asked of a congruence that comes with a decision procedure but no collision, costs exactly LPO.

7.7 What the classification tells us about a reader

Return to an addition-preserving reading r from the orbit into an additive commutative monoid V. Its kernel, $x \sim_r y$ exactly when $r(x) = r(y)$, is an additive congruence, and r is injective exactly when its kernel is equality. A question about the reader is therefore a question about a congruence, and the prices follow it.

The only new ingredient is the information carried by the target. If equality of values in V can be decided, the kernel is a decidable congruence. Conversely, every additive congruence $\sim$ is the kernel of a reading: send x to its class in the quotient $\mathbb{N}/\sim$, whose addition $[x] + [y] = [x + y]$ is well defined because $\sim$ respects addition. Two classes are equal exactly when their representatives are related, so equality of classes is decidable when $\sim$ is.

Theorem 7.11 (The recognition dichotomy and its prices)**.** *Consider readings that preserve zero and addition from the orbit into additive commutative monoids.*

1. *If equality in the target of r is decidable and $r(a) = r(b)$ for given $a \neq b$, then the kernel of r is $\sim_{i,p}$ for unique i and $p > 0$. No added principle is used.*
2. *For readings into targets with decidable equality, each of the following assertions about every such reading is equivalent to the principle named after it:*
   (a) *the reading is injective or not injective: WLPO;*
   (b) *the reading is injective or its kernel is some $\sim_{i,p}$ with $p > 0$: LPO;*
   (c) *if the reading is not injective, its kernel is some $\sim_{i,p}$ with $p > 0$: MP;*
   (d) *every index–period description of the kernel has odd index, or every one has even index: LLPO.*
3. *The assertion that every such reading, into an arbitrary additive commutative monoid, is injective or has an index–period kernel is equivalent to EM.*

Proof. For (1), the kernel is a decidable congruence with the exhibited collision $a \sim_r b$; apply Theorem 7.6.

For (2) and (3), compare each assertion with the catalogue assertion of the same price. A reading supplies its kernel, which is decidable when equality in the target is, and injectivity of the reading corresponds to the kernel being equality. A congruence supplies its quotient reading $x \mapsto [x]$, whose kernel is the congruence itself, and whose target has decidable equality when the congruence is decidable. These two translations carry each reading assertion to the corresponding catalogue assertion and back, with no added principle. Theorems 7.7, 7.9 and 7.10 now give the prices. □

The classical statement of the dichotomy, for arbitrary targets, therefore costs exactly excluded middle. A reader whose outputs can be compared pays only LPO for the same dichotomy, and nothing at all once a single collision has been observed.

The result concerns the reading's identifications. It does not assert that every target object is reached, that every physical device has this form, or that addition preservation can be omitted. Those are different hypotheses. Chapter 8 will make the relationship between a quotient and the range of a reading precise.

7.8 Signed records keep only the pure periods

A congruence permits adding the same count to both sides; it need not permit removing one. The signed records of Chapter 4 show exactly when it does. An *additive congruence* on $\mathbb{Z}_\delta$ is defined as in Definition 7.1, with signed records in place of counts. Reading a count n as the signed record $[n, 0]$, such a congruence $\approx$ restricts to the relation $x \sim y$ defined by $[x, 0] \approx [y, 0]$. Call an additive congruence on the natural numbers *cancellative* when $x + z \sim y + z$ implies $x \sim y$.

Theorem 7.12 (Congruences of the signed records)**.** *Restriction is a bijection from the additive congruences of $\mathbb{Z}_\delta$ onto the cancellative additive congruences of the natural numbers. A cancellative congruence $\sim$ extends by*

$$[a, b] \approx [c, d] \quad \Longleftrightarrow \quad a + d \sim c + b, \tag{7.8}$$

and this is its only extension. Among the index–period congruences, $\sim_{i,p}$ is cancellative exactly when $i = 0$.

Proof. A restricted relation is an additive congruence because $[x + y, 0] = [x, 0] + [y, 0]$. It is cancellative because $\mathbb{Z}_\delta$ has negatives: adding $[0, z]$ to both sides of $[x + z, 0] \approx [y + z, 0]$ gives $[x, 0] \approx [y, 0]$.

Now let $\sim$ be cancellative. Relation (7.8) does not depend on representatives. If (a, b) is replaced by a balanced pair (a', b'), so that $a + b' = a' + b$, add b' to both sides of $a + d \sim c + b$. The left side becomes $(a' + d) + b$, so $(a' + d) + b \sim (c + b') + b$, and cancellation removes b. The same argument handles the second pair and the reverse direction. Reflexivity and symmetry are immediate. For transitivity, add f to $a + d \sim c + b$ and b to $c + f \sim e + d$; the two results chain to $(a + f) + d \sim (e + b) + d$, and cancellation removes d. Adding two instances of (7.8) gives the instance for the sums, so the extension respects addition.

The extension restricts to $\sim$, since $[x,0] \approx [y,0]$ means $x+0 \sim y+0$. Conversely, let $\approx'$ be any congruence on $\mathbb{Z}_\delta$ restricting to $\sim$. Adding $[b+d,0]$ to both sides turns $[a,b] \approx' [c,d]$ into $[a+d,0] \approx' [c+b,0]$, and adding $[0,b+d]$ reverses the step. So $\approx'$ is relation (7.8). This proves the bijection and the uniqueness of the extension.

Finally, if $i > 0$ then $0 + i \sim_{i,p} p + i$, since both sums are at least i and have the same remainder modulo p, while 0 and p are different and $0 < i$, so they are not related. If $i = 0$, equal remainders of $x + z$ and $y + z$ give equal remainders of x and y. □

Passing to signed records therefore erases the index. A congruence with index $i > 0$, which keeps the counts below i apart, has no counterpart on the signed records; only the pure periods survive. The prices do not change, provided the parity question is asked of the period: every description now has index zero, so the parity of the index costs nothing, while the parity of the period costs exactly LLPO.

Corollary 7.13 (The signed catalogue)**.** *Let $\approx$ be a decidable additive congruence on $\mathbb{Z}_\delta$ with an exhibited pair of distinct related records. Then there is exactly one $p > 0$ such that*

$$[a,b] \approx [c,d] \quad \Longleftrightarrow \quad (a+d) \bmod p = (c+b) \bmod p.$$

No added principle is used. For congruences on $\mathbb{Z}_\delta$, each of the following assertions is equivalent to the principle named after it:

(a) every decidable congruence that is only known not to be equality has this form: MP;

(b) for every decidable congruence, either every period p describing it in this form is odd, or every such period is even: LLPO;

(c) every decidable congruence is equality or is not equality: WLPO;

(d) every decidable congruence is equality or has this form: LPO;

(e) every congruence, with no decision procedure, is equality or has this form: EM.

The parity of the index, asked as in Theorem 7.9, costs nothing here: every index–period description of the restriction of a congruence on $\mathbb{Z}_\delta$ has index 0.

Proof. Restriction carries a decision procedure for $\approx$ to one for $\sim$, and (7.8) carries one back. Distinct related records $[a,b] \approx [c,d]$ give the collision $a+d \sim c+b$, with $a+d \neq c+b$ because the records are distinct. Theorem 7.6 describes $\sim$ as $\sim_{i,p}$, cancellation forces $i = 0$, and (7.8) gives the displayed relation. The period is unique because the description is.

For assertions (a), (c), (d) and (e), the forward directions follow in the same way from Theorems 7.7, 7.9 and 7.10 applied to the restriction. By (7.8), $\approx$ is equality exactly when $\sim$ is: if $\sim$ is equality, $[a,b] \approx [c,d]$ says $a + d = c + b$, which is equality of the two records, and if $\approx$ is equality, so is its restriction.

The reversals cannot simply reuse $\sim_\theta$: when the first witness of θ is positive, $\sim_\theta$ has a positive index and is not cancellative. Read a signed record through the faithful integer reading I of Proposition 4.6, and for a decidable θ put

$$u \approx_\theta v \quad \Longleftrightarrow \quad u = v, \text{ or } \theta \text{ has a least witness } n \text{ and } (n+1)! \text{ divides } I(v) - I(u).$$

This relation is decidable: when $u \neq v$ the difference $I(v) - I(u)$ is nonzero, and a witness n with $(n+1)!$ dividing it satisfies $n < (n+1)! \leq |I(v) - I(u)|$, so the search is bounded. A least witness is unique, so any two uses of the second alternative involve the same factorial; this makes $\approx_\theta$ reflexive, symmetric and transitive, and it respects addition. If $\approx_\theta$ is equality, θ has no witness, since a witness gives a least one n by bounded search and then relates $[0,0]$ to the distinct record $[(n+1)!, 0]$. If $\approx_\theta$ has a period $p > 0$, it relates $[0,0]$ to $[p,0]$, which needs a witness. These two facts give MP from (a) and LPO from (d), exactly as in the proofs of Theorems 7.7 and 7.9. Without a witness only the alternative $u = v$ remains, so $\approx_\theta$ is equality exactly when θ has no witness. For $\theta(n)$ given by $\alpha(n) = 1$, the two alternatives of (c) at $\approx_\theta$ are therefore the two alternatives of WLPO for α. For EM, take any proposition P and let $u \approx_P v$ hold when $u = v$, or when P holds and 2 divides $I(v) - I(u)$. Its equality alternative refutes P, because P would relate $[0,0]$ and $[2,0]$; a period $p > 0$ relates $[0,0]$ and $[p,0]$, which requires P.

The parity question needs its own sequence, because the index of a restriction carries no information. For (b), let $\gamma(2y + b) = 1$ exactly when y is the least positive count with $[0,0] \approx [y,0]$ and b is the remainder of y modulo 2. Each value is a bounded search, and the least such count is unique, so γ has at most one event. If $\approx$ is described by the period p, the least such count is p, and the event sits at $2p + (p \bmod 2)$, which has the parity of p. Apply LLPO to γ. If every even entry is zero, no describing period is even; if every odd entry is zero, none is odd.

Conversely, let α have at most one event. Put $q(n) = 2n + 1$ when n is even and $q(n) = 2n + 2$ when n is odd, so that $q(n) > n$ and $q(n)$ has the parity of $n + 1$. Let $u \approx_\alpha v$ hold when $u = v$, or when $\alpha(n) = 1$ for some n such that $q(n)$ divides $I(v) - I(u)$. A witness n for a nonzero difference d satisfies $n < q(n) \leq |d|$, so each pair is decided by bounded search. Since there is at most one event, any two uses of the second alternative involve the same n; hence $\approx_\alpha$ is an additive congruence. It is equality when α has no event, and it is described by the period $q(n)$ when $\alpha(n) = 1$. An event at an even place gives an odd period, and an event at an odd place an even one. So the first alternative of (b), every period odd, gives $\alpha(2j + 1) = 0$ for every j, and the second gives $\alpha(2j) = 0$ for every j. These are the two alternatives of LLPO.

Finally, the restriction of a congruence on $\mathbb{Z}_\delta$ is cancellative, so by Theorem 7.12 every index–period description of it has index 0. The alternative "every description has even index" therefore holds for every congruence, with no principle at all. □

7.9 One classification, six prices

We have also learned how to read a logical price correctly. One classification, of one kind of object, has six exact prices. The price is fixed by what is supplied and by what is asked for:

Supplied	Asked for	Exact price
decisions and a collision	the description	none
decisions, and "not equality"	the description	MP
decisions	the parity of the index	LLPO
decisions	equality or not	WLPO
decisions	equality or the description	LPO
nothing	equality or the description	EM

Theorems 7.6, 7.7, 7.9 and 7.10 prove the rows. Theorem 7.11 gives the same table for readers, and Corollary 7.13 all six rows for signed records, the parity row read on the period. The reversals, rather than the presence of a label on one proof, establish these exact equivalences. Each reversal stores an arbitrary sequence or proposition inside a congruence, so any principle that grants the classification must answer that question.

The equivalences place each form exactly at its principle, and the principles themselves are different. No two of the six are equivalent, so no version of the classification is equivalent to two of them. Each separation is a model of intuitionistic second-order arithmetic in which one principle holds and the other fails. Three take their truth values in the open sets of a space: the one-point compactification of an uncountable discrete set (Markov's principle holds, LLPO fails), the remainder $\beta\mathbb{N} \setminus \mathbb{N}$ (LLPO holds, WLPO fails), and $\beta\mathbb{N}$ itself (WLPO holds, MP and LPO fail). The fourth takes its truth values in a chain (LPO holds, EM fails). Each equivalence of the table is also a derivation in that system, so in every model, these four included, each version of the classification has exactly the truth value of its principle. Section 7.10 states the system, Section 7.11 derives the six equivalences inside it, Section 7.12 builds the models, and Section 7.13 shows that the six prices are not all the prices.

7.10 A system and its models of truth values

An equivalence is proved by two constructions. A difference between two principles needs something of another kind: a precise system of reasoning, and an interpretation of that system in which every derivable sentence is true while one principle holds and the other fails. We supply both. We also write each of the six versions of the classification as a sentence of the system and derive, inside the system, its equivalence with its principle (Theorem 7.33). An interpretation of the system then gives each version exactly the value of its principle, for the same reason that it makes every derivable sentence true: no separate computation inside the model is needed. Interpretations of this kind are standard in constructive mathematics [4, 5]; the work particular to this chapter is the derivation of the six equivalences. Chapter 16 builds a system of the same kind for δ's own objects, points, functions and compact sets included, and shows that the system of this section translates into it.

Definition 7.14 (Intuitionistic second-order arithmetic)**.** The language has two kinds of variable: $x, y, \ldots$ for numbers and $X, Y, \ldots$ for sets of numbers. Terms are built from number variables with 0, S, $+$ and $\cdot$; the atomic formulas are equations $t = u$ and memberships $t \in X$; formulas are built from these with $\bot$, $\wedge$, $\vee$, $\to$ and quantifiers over both kinds of variable. We write $\neg\varphi$ for $\varphi \to \bot$ and $\varphi \leftrightarrow \psi$ for $(\varphi \to \psi) \wedge (\psi \to \varphi)$.

A derivation is a finite tree of judgments $\Gamma \vdash \varphi$, where Γ is a finite list of formulas, built from the following rules.

(i) The rules of Chapter 5 for hypotheses, for reflexivity and substitution of equals, for the connectives and for the number quantifiers, and its six arithmetic rules as axioms: $\neg(S(t) = 0)$, $S(t) = S(u) \to t = u$, $t + 0 = t$, $t + S(u) = S(t + u)$, $t \cdot 0 = 0$ and $t \cdot S(u) = t \cdot u + t$. The substitution rule may substitute into any formula of the present language. In Chapter 5 variables are positions and a fresh variable is made by lifting. With the named variables of this chapter the lifting conditions are the usual eigenvariable conditions: universal introduction derives $\varphi(x)$ from Γ for a number variable x not free in Γ and concludes $\forall x\, \varphi(x)$, and existential elimination concludes ψ from $\exists x\, \varphi(x)$ and a derivation of ψ from $\Gamma, \varphi(x)$, where x is free neither in Γ nor in ψ.

(ii) The same four rules for the set quantifiers. Universal introduction proves $\varphi(X)$ for a set variable X not free in Γ and concludes $\forall X\, \varphi(X)$; universal elimination passes from $\forall X\, \varphi(X)$ to $\varphi(Y)$ for any set variable Y; existential introduction passes from $\varphi(Y)$ to $\exists X\, \varphi(X)$; existential elimination concludes ψ from $\exists X\, \varphi(X)$ and a derivation of ψ from $\Gamma, \varphi(X)$, where X is free neither in Γ nor in ψ.

(iii) The induction axiom

$$\forall X \Big(0 \in X \to \forall x \big(x \in X \to S(x) \in X \big) \to \forall x (x \in X) \Big).$$

(iv) The comprehension axiom $\exists X \forall x (x \in X \leftrightarrow \varphi)$ for every formula φ in which X is not free. The formula φ may contain other free variables of both kinds; they are the parameters of the set it describes.

This system is usually called HAS [4, 5]. A *derivation in HAS* of a sentence is a derivation of it from the empty list of hypotheses.

A derivation of $\Gamma \vdash \varphi$ gives a derivation of $\Gamma' \vdash \varphi$ whenever every formula of Γ occurs in Γ': by induction on the derivation, after renaming each eigenvariable that is free in Γ' to a fresh variable. We use this without comment whenever a derived statement is applied inside a longer argument.

The induction rule (5.2) of Chapter 5 is not among the rules. It is derived.

Lemma 7.15 (Induction for every formula)**.** *For every formula $\varphi(x)$, possibly with parameters of both kinds, HAS derives*

$$\varphi(0) \to \forall x \big(\varphi(x) \to \varphi(S(x)) \big) \to \forall x\, \varphi(x).$$

Consequently the induction rule (5.2) *is a derived rule of HAS, for formulas of the present language.*

Proof. Assume $\varphi(0)$ and $\forall x (\varphi(x) \to \varphi(S(x)))$. Comprehension gives a set X with $x \in X \leftrightarrow \varphi(x)$ for every x; we use it by existential elimination, with a set variable X that occurs neither in the hypotheses nor in the conclusion $\forall x\, \varphi(x)$. Then $0 \in X$, and $x \in X$ gives $\varphi(x)$, hence $\varphi(S(x))$, hence $S(x) \in X$. The induction axiom at X gives $\forall x (x \in X)$, and so $\forall x\, \varphi(x)$. Discharging the two hypotheses gives the displayed sentence. Moving it into the context Γ of the two premises of (5.2) and applying it to them gives the rule. □

Lemma 7.16 (Heyting arithmetic inside HAS)**.** *Every posit-free derivation of Chapter 6, that is, every derivation from the base rules of Chapter 5 with induction on every formula and with no EM, LPO or MP rule, becomes a derivation in HAS of the same judgment, when its formulas are read as formulas of the present language without set variables. In particular, every theorem of Heyting arithmetic is derivable in HAS.*

Proof. By induction on the derivation. Every base rule other than induction and injectivity is a rule of HAS by clause (i) of Definition 7.14, with the same premises and conclusion; the injectivity rule, from $S(t) = S(u)$ to $t = u$, is the axiom $S(t) = S(u) \to t = u$ followed by implication elimination. The lifting conditions of Chapter 5 become the eigenvariable conditions of clause (i). An induction rule is replaced by the derived rule of Lemma 7.15. The second sentence is the first applied to the posit-free derivations, which prove exactly the theorems of Heyting arithmetic (Remark 6.12). □

Order is written with existential quantifiers:

$$x \le y \;:\equiv\; \exists d\,(x + d = y), \qquad x < y \;:\equiv\; \exists d\,\big(x + S(d) = y\big). \tag{7.9}$$

We use the pairing

$$J(x, y) = (x + y) \cdot (x + y) + x. \tag{7.10}$$

Lemma 7.17 (Arithmetic used in the derivations)**.** *HAS derives the universal closures of the following formulas.*

(a) $x = y \lor \neg(x = y)$.

(b) $x \le y \lor y < x$; $x < y \lor x = y \lor y < x$.

(c) $\neg(x < 0)$; $x < S(y) \leftrightarrow x \le y$; $x \le y \land \neg(x = y) \to x < y$; $x < y \to \neg(y \le x)$; $x \le y \to y \le z \to x \le z$; $x < y \to y \le z \to x < z$; $x \le x + y$; $\neg(p = 0) \to x < x + p$; $x < y \to x \le y$; $x \le y \to y < z \to x < z$; $x \le y \to x + z \le y + z$.

(d) $\neg(d = 0) \to y \le x + d \cdot y$.

(e) $\neg(p = 0) \to \exists q\, \exists r\big(r < p \land e = q \cdot p + r\big)$.

(f) $\exists h\,(x = h + h) \lor \exists h\,\big(x = S(h + h)\big)$; $\neg(h + h = S(k + k))$; $h + h = k + k \to h = k$.

(g) $x + z = y + z \to x = y$, *together with the commutative semiring laws for* $+$ *and* $\cdot$.

(h) $J(x, y) = J(x', y') \to x = x' \land y = y'$.

Proof. By Lemma 7.16 it is enough that each formula is a theorem of Heyting arithmetic, and each is proved there by induction from the six arithmetic rules. The semiring laws and cancellation in (g) are the derivations of Chapter 3 written in the language, as in Section 5.7. For (a), induct on x for the formula $\forall y(x = y \lor \neg(x = y))$: every y is 0 or a successor (a one-step induction), $S(x) \neq 0$, and $S(x) = S(y)$ holds exactly when $x = y$. For (b), induct on x for $\forall y(x \le y \lor y < x)$, using that $y = 0$ or $y = S(y')$; the second form follows with (a). The

formulas in (c) follow from the definitions (7.9) by cancellation, the rule $\neg(S(t) = 0)$ and the fact that every number is 0 or a successor. For (d), write $d = S(d')$; then $x+d\cdot y = (x+d'\cdot y)+y$. For (e), induct on e: for $e = 0$ take $q = r = 0$, and $0 < p$ since $p \neq 0$; from $e = qp + r$ with $r < p$, either $S(r) < p$, and $S(e) = qp + S(r)$, or $S(r) = p$, and $S(e) = (q + 1)p + 0$. For the first part of (f), induct on x: $0 = 0 + 0$; $x = h + h$ gives $S(x) = S(h + h)$; and $x = S(h + h)$ gives $S(x) = S(h) + S(h)$. For the second part, induct on h for $\forall k\neg(h + h = S(k + k))$: $0 \neq S(k + k)$, and $S(h) + S(h) = S(k + k)$ forces $k = S(k')$ and then $h + h = S(k' + k')$. For the third part, $h < k$ would give $h + h < k + k$, and $k < h$ symmetrically, so (b) gives $h = k$. For (h), put $s = x + y$ and $s' = x' + y'$. If $s < s'$ then $J(x, y) \leq s\cdot s + s < (s + 1)\cdot(s + 1) \leq s'\cdot s' \leq J(x', y')$, using that $u \leq v$ gives $u\cdot u \leq v\cdot v$, and symmetrically if $s' < s$; so (b) gives $s = s'$, cancellation in $J(x, y) = J(x', y')$ gives $x = x'$, and cancellation in $x + y = x + y'$ gives $y = y'$. □

The objects of this chapter now become sets. A binary sequence is a set X with $n \in X \vee \neg\, n \in X$ for every n, read as $\alpha(n) = 1$ exactly when $n \in X$. A relation on counts is a set R read through the pairing: we write $x \sim y$, or $x \sim_R y$ when R must be named, for $J(x, y) \in R$. By Lemma 7.17(h) distinct pairs have distinct codes, so every relation on counts arises in this way from a set of numbers.

Definition 7.18 (The principles and the versions as sentences)**.** For a set X and a set R write

$$\begin{aligned}
\mathrm{Dec}(X) &:\equiv \forall n\,(n \in X \vee \neg\, n \in X), & \mathrm{Dec}_2(R) &:\equiv \forall x\,\forall y(x \sim y \vee \neg\, x \sim y),\\
\mathrm{Z}(X) &:\equiv \forall n\,\neg\, n \in X, & \mathrm{E}(X) &:\equiv \exists n\,(n \in X),\\
\mathrm{A}(X) &:\equiv \forall m\,\forall n\,(m \in X \to n \in X \to m = n), & \mathrm{Eq}(R) &:\equiv \forall x\,\forall y(x \sim y \to x = y),\\
\mathrm{Ev}(X) &:\equiv \forall k\,\neg\,(k + k) \in X, & \mathrm{Od}(X) &:\equiv \forall k\,\neg\, S(k + k) \in X.
\end{aligned}$$

$\mathrm{Cong}(R)$ is the conjunction of

$$\forall x(x \sim x), \qquad \forall x\,\forall y(x \sim y \to y \sim x), \qquad \forall x\,\forall y\,\forall z(x \sim y \to y \sim z \to x \sim z),$$
$$\forall w\,\forall x\,\forall y\,\forall z(w \sim x \to y \sim z \to w + y \sim x + z).$$

The relation (7.1) and a description are

$$\begin{aligned}
x \equiv y\,(\mathrm{mod}\ p) &:\equiv \exists d\big(x = y + p\cdot d \ \vee\ y = x + p\cdot d\big),\\
x \sim_{i,p} y &:\equiv x = y \ \vee\ \big(i \leq x \wedge i \leq y \wedge x \equiv y\,(\mathrm{mod}\ p)\big),\\
\mathrm{Desc}_R(i, p) &:\equiv \forall x\,\forall y\big(x \sim y \leftrightarrow x \sim_{i,p} y\big),\\
\mathrm{D}(R) &:\equiv \exists i\,\exists p\,\big(\neg(p = 0) \wedge \mathrm{Desc}_R(i, p)\big),
\end{aligned}$$

and the two parity assertions are

$$\begin{aligned}
\mathrm{Odd}(R) &:\equiv \forall i\,\forall p\,\big(\neg(p = 0) \to \mathrm{Desc}_R(i, p) \to \exists h\,(i = S(h + h))\big),\\
\mathrm{Even}(R) &:\equiv \forall i\,\forall p\,\big(\neg(p = 0) \to \mathrm{Desc}_R(i, p) \to \exists h\,(i = h + h)\big).
\end{aligned}$$

The principles of Definition 7.8 and excluded middle are the sentences

$$\begin{aligned}
\mathrm{MP} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \neg\mathrm{Z}(X) \to \mathrm{E}(X)\big),\\
\mathrm{LLPO} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{A}(X) \to \mathrm{Ev}(X) \vee \mathrm{Od}(X)\big),\\
\mathrm{WLPO} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{Z}(X) \vee \neg\mathrm{Z}(X)\big),\\
\mathrm{LPO} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{Z}(X) \vee \mathrm{E}(X)\big),\\
\mathrm{EM} &:\equiv \forall X(0 \in X \vee \neg\, 0 \in X),
\end{aligned}$$

and the empty principle is the sentence $\bot \to \bot$. The six versions of the classification are

$$\begin{aligned}
\mathsf{V}_{\mathrm{none}} &:\equiv \forall R\,\big(\mathrm{Dec}_2(R) \to \mathrm{Cong}(R) \to \forall x \forall y(\neg(x = y) \to x \sim y \to \mathrm{D}(R))\big),\\
\mathsf{V}_{\mathrm{MP}} &:\equiv \forall R\,\big(\mathrm{Dec}_2(R) \to \mathrm{Cong}(R) \to \neg\mathrm{Eq}(R) \to \mathrm{D}(R)\big),\\
\mathsf{V}_{\mathrm{LLPO}} &:\equiv \forall R\,\big(\mathrm{Dec}_2(R) \to \mathrm{Cong}(R) \to \mathrm{Odd}(R) \vee \mathrm{Even}(R)\big),\\
\mathsf{V}_{\mathrm{WLPO}} &:\equiv \forall R\,\big(\mathrm{Dec}_2(R) \to \mathrm{Cong}(R) \to \mathrm{Eq}(R) \vee \neg\mathrm{Eq}(R)\big),\\
\mathsf{V}_{\mathrm{LPO}} &:\equiv \forall R\,\big(\mathrm{Dec}_2(R) \to \mathrm{Cong}(R) \to \mathrm{Eq}(R) \vee \mathrm{D}(R)\big),\\
\mathsf{V}_{\mathrm{EM}} &:\equiv \forall R\,\big(\mathrm{Cong}(R) \to \mathrm{Eq}(R) \vee \mathrm{D}(R)\big).
\end{aligned} \tag{7.11}$$

The six sentences (7.11) state in this language exactly what the six rows of the table in Section 7.9 assert: $\mathsf{V}_{\mathrm{none}}$ is the existence assertion of Theorem 7.6, V_{MP} the assertion of Theorem 7.7, $\mathsf{V}_{\mathrm{WLPO}}$, $\mathsf{V}_{\mathrm{LPO}}$ and $\mathsf{V}_{\mathrm{LLPO}}$ the assertions (1), (2) and (3) of Theorem 7.9, and V_{EM} the assertion of Theorem 7.10. A decision procedure for a relation is Dec_2, and a description by i and $p > 0$ is $\neg(p = 0) \wedge \mathrm{Desc}_R(i, p)$. Excluded middle is stated for the single proposition $0 \in X$; through comprehension it gives every instance $\varphi \vee \neg\varphi$, since a set X with $\forall x(x \in X \leftrightarrow \varphi)$, where x is not free in φ, has $0 \in X \leftrightarrow \varphi$.

Definition 7.19 (Models of truth values)**.** A *system of truth values* is a set H ordered by strength, with a meet and a join for every family of elements and an implication $\Rightarrow$ satisfying

$$a \wedge c \le b \quad \Longleftrightarrow \quad c \le (a \Rightarrow b).$$

Its least and greatest elements are $\bot$ and $\top$, and $\neg a$ is $a \Rightarrow \bot$. A formula of Definition 7.14 receives a value in H under an assignment to its free variables. Numbers range over $\mathbb{N}$, and an equation has the value $\top$ when it holds there and $\bot$ otherwise. Sets range over all assignments $A : \mathbb{N} \to H$, and $t \in X$ has the value $A(t)$. The connectives $\wedge$, $\vee$ and $\to$ are meet, join and $\Rightarrow$; a universal quantifier is the meet of the values of its instances, and an existential quantifier their join.

We write $[\![\varphi]\!]_{\rho,\sigma}$ for the value of φ under the assignment ρ of numbers to number variables and σ of maps $\mathbb{N} \to H$ to set variables, and $\rho[x \mapsto n]$, $\sigma[X \mapsto A]$ for the assignments changed at one variable. A number term t has the value $t^{\rho} \in \mathbb{N}$ computed in $\mathbb{N}$. In such a model a relation read through the pairing is an assignment of a truth value to each pair of counts, and every such assignment arises, since J is injective.

The open sets of a topological space form such a system. Meet and join of two open sets are intersection and union, the join of a family is its union, the meet of a family is the interior of its intersection, and $U \Rightarrow V$ is the interior of the union of V with the complement of U. So $\neg U$ is the largest open set disjoint from U. A chain with a meet and a join for every family is another example. For $0 < 1 < 2 < \cdots < \infty$, the implication $a \Rightarrow b$ is $\top$ when $a \le b$ and b otherwise.

Three properties of a system of truth values carry the proof below. First, $a \wedge (a \Rightarrow b) \le b$, which is the defining equivalence at $c = a \Rightarrow b$. Second, meeting with a fixed element distributes over every join,

$$a \wedge \bigvee_j b_j = \bigvee_j (a \wedge b_j), \tag{7.12}$$

because $\bigvee_j (a \wedge b_j) \le c$ means $b_j \le (a \Rightarrow c)$ for every j, hence $\bigvee_j b_j \le (a \Rightarrow c)$, hence $a \wedge \bigvee_j b_j \le c$. Taking $c = \bigvee_j (a \wedge b_j)$ gives one inequality, and the other holds because each $a \wedge b_j$ lies below

$a \wedge \bigvee_j b_j$. Third, $(a \wedge b) \Rightarrow c$ and $a \Rightarrow (b \Rightarrow c)$ are equal, since an element lies below either exactly when its meet with $a \wedge b$ lies below c.

Lemma 7.20 (Values respect substitution)**.** *For every formula φ, number variable x, term t and set variables X, Y: $[\![\varphi(t)]\!]_{\rho,\sigma} = [\![\varphi(x)]\!]_{\rho[x \mapsto t^{\rho}],\sigma}$ and $[\![\varphi(Y)]\!]_{\rho,\sigma} = [\![\varphi(X)]\!]_{\rho,\sigma[X \mapsto \sigma(Y)]}$, where the substitutions rename bound variables as usual; and the value of φ depends only on the values of its free variables.*

Proof. By induction on φ. For an atomic formula the value of a term after substitution is the value of the term at the changed assignment, by induction on the term. The connectives commute with substitution and with the operations of H. At a quantifier, the substitution passes under the binder with its bound variable renamed away from t (or Y), and the induction hypothesis applies to each instance before the meet or join is taken. The last assertion is proved in the same induction. These are the identities of Lemma 5.4, with values in H in place of satisfaction and with set variables carried along; the proof is the same. □

Lemma 7.21 (Derivable sentences are true in every model)**.** *If a sentence of Definition 7.14 has a derivation, its value in every system of truth values is $\top$.*

Proof. For a list $\Gamma = \varphi_1, \dots, \varphi_k$ write $[\![\Gamma]\!]_{\rho,\sigma} = [\![\varphi_1]\!]_{\rho,\sigma} \wedge \cdots \wedge [\![\varphi_k]\!]_{\rho,\sigma}$, which is $\top$ for the empty list. We prove, by induction on derivations, that a derivation of $\Gamma \vdash \varphi$ gives

$$[\![\Gamma]\!]_{\rho,\sigma} \leq [\![\varphi]\!]_{\rho,\sigma} \qquad \text{for every assignment } \rho, \sigma.$$

For a sentence derived from no hypotheses this says $\top \leq [\![\varphi]\!]$, which is the lemma. We fix ρ, σ in each case, abbreviate $g = [\![\Gamma]\!]_{\rho,\sigma}$ and drop the subscripts when they are unchanged.

Hypotheses and absurdity. A member of Γ lies above the meet g. If $g \leq [\![\bot]\!] = \bot$, then $g \leq [\![\varphi]\!]$ for every φ.

Conjunction and disjunction. The rules for $\wedge$ are the facts that $g \leq a \wedge b$ exactly when $g \leq a$ and $g \leq b$. Disjunction introduction uses $a \leq a \vee b$ and $b \leq a \vee b$. For disjunction elimination, the premises give $g \leq a \vee b$, $g \wedge a \leq c$ and $g \wedge b \leq c$, where a, b, c are the values of the two cases and of the conclusion. By (7.12), $g = g \wedge (a \vee b) = (g \wedge a) \vee (g \wedge b) \leq c$.

Implication. Introduction turns $g \wedge a \leq b$ into $g \leq (a \Rightarrow b)$ by the defining equivalence. Elimination turns $g \leq (a \Rightarrow b)$ and $g \leq a$ into $g \leq a \wedge (a \Rightarrow b) \leq b$.

Number quantifiers. Universal introduction has the premise $\Gamma \vdash \varphi(x)$ with x not free in Γ. For each $n \in \mathbb{N}$ the induction hypothesis at $\rho[x \mapsto n]$ gives $[\![\Gamma]\!]_{\rho[x \mapsto n],\sigma} \leq [\![\varphi(x)]\!]_{\rho[x \mapsto n],\sigma}$, and the left side is g by Lemma 7.20, because x is not free in Γ. Hence g lies below the meet of these values, which is $[\![\forall x \varphi(x)]\!]$. Universal elimination uses that this meet lies below its instance at $n = t^{\rho}$, which is $[\![\varphi(t)]\!]$ by Lemma 7.20. Existential introduction uses that $[\![\varphi(t)]\!]$ is one of the values whose join is $[\![\exists x \varphi(x)]\!]$. For existential elimination, the second premise derives ψ from $\Gamma, \varphi(x)$ with x free neither in Γ nor in ψ. At $\rho[x \mapsto n]$ it gives $g \wedge [\![\varphi(x)]\!]_{\rho[x \mapsto n],\sigma} \leq [\![\psi]\!]$ for every n, and the first premise gives $g \leq \bigvee_n [\![\varphi(x)]\!]_{\rho[x \mapsto n],\sigma}$. By (7.12),

$$g = g \wedge \bigvee_n [\![\varphi(x)]\!]_{\rho[x \mapsto n],\sigma} = \bigvee_n \big(g \wedge [\![\varphi(x)]\!]_{\rho[x \mapsto n],\sigma}\big) \leq [\![\psi]\!].$$

This is the step at which joins of arbitrary families, and their distributivity, are needed.

Set quantifiers. The four cases are the same, with the assignments $\sigma[X \mapsto A]$, for all $A : \mathbb{N} \to H$, in place of $\rho[x \mapsto n]$. Universal elimination at a set variable Y uses the instance $A = \sigma(Y)$, and existential introduction from $\varphi(Y)$ the same instance, both through Lemma 7.20.

Equality. An equation $t = t$ has the value $\top$. For substitution of equals, the premises give $g \le [\![t = s]\!]$ and $g \le [\![\varphi(t)]\!]$. If $t^\rho = s^\rho$, then $[\![\varphi(t)]\!] = [\![\varphi(x)]\!]_{\rho[x \mapsto t^\rho],\sigma} = [\![\varphi(s)]\!]$ by Lemma 7.20. Otherwise $[\![t = s]\!] = \bot$, so $g = \bot$.

Arithmetic axioms. The four equations hold in $\mathbb{N}$ at every assignment, so they have the value $\top$. The equation $S(t) = 0$ fails in $\mathbb{N}$, so its negation has the value $\bot \Rightarrow \bot = \top$. If $S(t) = S(u)$ holds in $\mathbb{N}$ then so does $t = u$, and the implication has the value $\top \Rightarrow \top$; otherwise its antecedent has the value $\bot$. Either way the value is $\top$.

Induction axiom. Fix $A : \mathbb{N} \to H$ and put $c = A(0) \wedge \bigwedge_n \big(A(n) \Rightarrow A(n+1)\big)$. By induction on m, $c \le A(m)$: for $m = 0$ this is a meetand of c, and $c \le A(m)$ together with $c \le (A(m) \Rightarrow A(m+1))$ gives $c \le A(m+1)$. So $c \le \bigwedge_m A(m)$, and by the third property above $A(0) \Rightarrow \big(\bigwedge_n (A(n) \Rightarrow A(n+1)) \Rightarrow \bigwedge_m A(m)\big) = c \Rightarrow \bigwedge_m A(m) = \top$. The axiom is the meet of these values over all A.

Comprehension. Let X not be free in φ and put $A(n) = [\![\varphi]\!]_{\rho[x \mapsto n],\sigma}$. At the assignment $\sigma[X \mapsto A]$, the formula $x \in X$ has the value $A(n)$ at $\rho[x \mapsto n]$, and so does φ, because X is not free in it. So each instance of $x \in X \leftrightarrow \varphi$ has the value $(A(n) \Rightarrow A(n)) \wedge (A(n) \Rightarrow A(n)) = \top$, their meet is $\top$, and the join over all set assignments, which is the value of the axiom, is $\top$. $\square$

7.11 The six equivalences inside the system

We now derive in HAS each version's equivalence with its principle. The arguments are those of Lemmas 7.4 and 7.5 and of the proofs of Theorems 7.6, 7.7, 7.9 and 7.10, written so that every step is a rule of Definition 7.14 or one of the derived rules proved here. Three features of those arguments need care when they are carried out inside a formal system. Every finite search becomes a set given by comprehension, and its decidability is derived by induction. Every least witness comes from the least-number principle for decidable sets, derived in the same way. Every encoding of a sequence or a proposition in a congruence is a set given by comprehension, and its defining property is derived through the injectivity of the pairing.

We reason informally, under three conventions that make each step an inference of HAS. A case distinction is made only on a disjunction that has already been derived: usually a decision from Lemma 7.17, or from a hypothesis $\mathrm{Dec}(X)$ or $\mathrm{Dec}_2(R)$. A set is introduced only by a comprehension instance, displayed with its defining formula; its parameters are the other free variables of that formula. A least element is taken only of a decidable set, by Lemma 7.22. A case that has been refuted closes by the rule for an impossible case, so its conclusion is whatever the argument needs. Throughout, R is a set variable and $x \sim y$ means $J(x, y) \in R$; Lemma 7.17 is used without further mention for order, cancellation, division with remainder and parity.

Lemma 7.22 (Bounded search and least numbers)**.** *For every set X, HAS derives from* $\mathrm{Dec}(X)$*:*

(a) for every n: either some $k < n$ has $k \in X$ and $\neg\, j \in X$ for all $j < k$, or $\neg\, k \in X$ for all $k < n$;

(b) for every n: $\exists k\,(k < n \wedge k \in X) \vee \neg\exists k\,(k < n \wedge k \in X)$;

(c) if $n \in X$, then some $k \in X$ has $\neg\, j \in X$ for all $j < k$.

Proof. For (a), induct on n (Lemma 7.15, with X as a parameter). For $n = 0$ the second alternative holds, since no k satisfies $k < 0$. Suppose the assertion holds at n. In its first alternative, the same k serves at $S(n)$, since $k < n$ gives $k < S(n)$. In its second alternative, decide $n \in X$. If $n \in X$, then $k = n$ gives the first alternative at $S(n)$: $n < S(n)$, and every $j < n$ has $\neg\, j \in X$. If $\neg\, n \in X$, the second alternative holds at $S(n)$: from $k < S(n)$ we get $k \leq n$, so either $k < n$ or $k = n$, and both are excluded.

Part (b) is a weakening of (a). For (c), apply (a) at $S(n)$. Its second alternative is refuted by $n < S(n)$ and $n \in X$, and its first alternative is the conclusion. □

Part (c) is the least-number principle for decidable sets. Every search of this chapter is an application of it to a set given by comprehension.

Lemma 7.23 (Congruence laws)**.** *HAS derives from* $\mathrm{Cong}(R)$*, for all numbers:*

(a) $x \sim y \to x + t \sim y + t$;

(b) $x \sim x + d \to x \sim x + d \cdot k$;

(c) if $z \sim z + p$ and $z \leq w$, then $w \sim w + p$;

(d) (period transfer) if $\neg(d = 0)$, $x \sim x + d$, $x \leq y$ and $y \sim y + p$, then $x \sim x + p$.

Proof. For (a), combine $x \sim y$ with $t \sim t$ by addition compatibility. For (b), induct on k. At $k = 0$, $x \sim x$ by reflexivity, and $x + d \cdot 0 = x$. If $x \sim x + d \cdot k$, translate $x \sim x + d$ by $d \cdot k$ using (a): $x + d \cdot k \sim x + d + d \cdot k = x + d \cdot S(k)$. Transitivity gives $x \sim x + d \cdot S(k)$. For (c), write $w = z + c$ and translate by c.

For (d), put $M = x + d \cdot y$. Since $d \neq 0$, Lemma 7.17(d) gives $y \leq M$; write $M = y + c$. By (b), $x \sim M$. Translating $y \sim y + p$ by c gives $M \sim M + p$, and translating $x \sim M$ by p gives $x + p \sim M + p$. Symmetry and transitivity give $x \sim M \sim M + p \sim x + p$. This is Lemma 7.4, with the explicit choice $k = y$ in place of $\lfloor (y - x)/d \rfloor + 1$. With this choice the hypothesis $x \leq y$ is not used; we keep it so that the statement is that of Lemma 7.4. □

Lemma 7.24 (The structure with a least period and a least index)**.** *HAS derives the following from* $\mathrm{Cong}(R)$*,* $\neg(p = 0)$*,* $a \sim a + p$*,*

$$\forall d\big(d < p \to \neg(d = 0) \to \neg\,(a \sim a + d)\big), \qquad i \sim i + p, \qquad \forall z\,\big(z < i \to \neg\,(z \sim z + p)\big).$$

(a) If $x < y$ and $x \sim y$, then $i \leq x$, $i \leq y$ and $x \equiv y \pmod{p}$.

(b) $\mathrm{Desc}_R(i, p)$*.*

Proof. (a) Write $y = x + e$ with $e = S(e')$, so $e \neq 0$. Translating $a \sim a + p$ by x gives $(a + x) \sim (a + x) + p$. Since $x \leq a + x$ and $x \sim x + e$, period transfer (Lemma 7.23(d)) gives $x \sim x + p$. Decide $i \leq x$ or $x < i$; the second case contradicts the leastness of i at $z = x$. So $i \leq x$, and $i \leq y$ because $x \leq y$.

Next, translating $x \sim x + e$ by a gives $(a + x) \sim (a + x) + e$, and period transfer from the period $p \neq 0$ at a, with $a \leq a + x$, gives $a \sim a + e$. Divide: $e = q \cdot p + r$ with $r < p$. By Lemma 7.23(b), $a \sim a + p \cdot q$; translating by r gives $a + r \sim a + e$. With $a \sim a + e$, symmetry and transitivity give $a \sim a + r$. Decide $r = 0$. If $r \neq 0$, the leastness of p at $d = r$ refutes $a \sim a + r$. So $r = 0$, $y = x + p \cdot q$, and $x \equiv y \pmod{p}$ with $d = q$ in its second alternative.

(b) Let $x \sim y$. Decide $x = y$; equality is the first alternative of $x \sim_{i,p} y$. Otherwise $x < y$ or $y < x$. If $x < y$, part (a) gives the second alternative. If $y < x$, symmetry gives $y \sim x$, part (a) gives $i \leq y$, $i \leq x$ and $y \equiv x \pmod{p}$, and exchanging the two alternatives in the definition of the congruence gives $x \equiv y \pmod{p}$.

Conversely let $x \sim_{i,p} y$. If $x = y$, reflexivity gives $x \sim y$. Otherwise $i \leq x$, $i \leq y$, and $y = x + p \cdot d$ or $x = y + p \cdot d$. In the first case, $i \sim i + p$ and $i \leq x$ give $x \sim x + p$ by Lemma 7.23(c), and then $x \sim x + p \cdot d = y$ by (b) of that lemma. The second case gives $y \sim x$ in the same way, and symmetry gives $x \sim y$. □

Part (a) combines the two assertions of Lemma 7.5 at the pair (x, y) with the leastness of i, and part (b) is the structural half of Theorem 7.6. Neither uses a decision procedure for $\sim$.

Proposition 7.25 (The classification with an explicit collision)**.** *HAS derives* V_{none}.

Proof. Let R satisfy $\mathrm{Dec}_2(R)$ and $\mathrm{Cong}(R)$, and let $\neg(a = b)$ and $a \sim b$. Then $a < b$ or $b < a$. In the second case, symmetry gives $b \sim a$, and the argument below applies with a and b exchanged; so let $a < b$, and write $b = a + e$ with $e \neq 0$.

The least period. Comprehension gives a set P_a with

$$\forall d \big(d \in P_a \leftrightarrow \neg(d = 0) \wedge a \sim a + d \big),$$

with parameters a and R. It is decidable: $d = 0$ is decided by Lemma 7.17(a), $a \sim a + d$ by $\mathrm{Dec}_2(R)$, and a conjunction of two decided formulas is decided. Since $e \in P_a$, Lemma 7.22(c) gives $p \in P_a$ with no member of P_a below it: $p \neq 0$, $a \sim a + p$, and $\neg(a \sim a + d)$ for every $d < p$ with $d \neq 0$.

The least index. Comprehension gives a set I_p with $\forall z (z \in I_p \leftrightarrow z \sim z + p)$. It is decidable by $\mathrm{Dec}_2(R)$, and $a \in I_p$. Lemma 7.22(c) gives $i \sim i + p$ with $\neg(z \sim z + p)$ for every $z < i$.

Lemma 7.24(b) now gives $\mathrm{Desc}_R(i, p)$, and with $p \neq 0$ this is $\mathrm{D}(R)$. □

The two searches of the proof of Theorem 7.6 ran over $1, \ldots, b - a$ and $0, \ldots, a$. Here they are the least members of the sets P_a and I_p, which contain $e = b - a$ and a; the bounds are the same.

Lemma 7.26 (The collision search as a set)**.** *Let R satisfy* $\mathrm{Dec}_2(R)$ *and* $\mathrm{Cong}(R)$*. Comprehension gives a set B with*

$$\forall n \big(n \in B \leftrightarrow \exists x (x < n \wedge x \sim n)\big),$$

the set of the collision search $\beta_\sim$ of (7.5)*. HAS derives:*

(a) $\mathrm{Dec}(B)$*;*

(b) $\mathrm{Z}(B) \to \mathrm{Eq}(R)$*;*

(c) $\mathrm{Eq}(R) \to \mathrm{Z}(B)$*;*

(d) $\mathrm{E}(B) \to \mathrm{D}(R)$*.*

Proof. (a) Fix n. Comprehension gives a set C with $\forall x (x \in C \leftrightarrow x \sim n)$, with parameter n; it is decidable by $\mathrm{Dec}_2(R)$. Lemma 7.22(b) at the bound n decides $\exists x (x < n \wedge x \in C)$, which is $n \in B$.

(b) Assume $\mathrm{Z}(B)$ and $x \sim y$. Decide $x = y$. Otherwise $x < y$ or $y < x$. If $x < y$, then x witnesses $y \in B$, against $\mathrm{Z}(B)$. If $y < x$, symmetry gives $y \sim x$, and y witnesses $x \in B$. Both cases are refuted, so $x = y$.

(c) Assume $\mathrm{Eq}(R)$ and $n \in B$, with $x < n$ and $x \sim n$. Then $x = n$, which contradicts $x < n$. So $\neg\, n \in B$ for every n.

(d) From $n \in B$ we obtain $x < n$ with $x \sim n$, so $x \neq n$, and Proposition 7.25 gives $\mathrm{D}(R)$. □

Proposition 7.27 (The forward directions)**.** *HAS derives* $\mathrm{MP} \to \mathsf{V}_{\mathrm{MP}}$, $\mathrm{WLPO} \to \mathsf{V}_{\mathrm{WLPO}}$, $\mathrm{LPO} \to \mathsf{V}_{\mathrm{LPO}}$ *and* $\mathrm{EM} \to \mathsf{V}_{\mathrm{EM}}$.

Proof. For the first three, let R satisfy $\mathrm{Dec}_2(R)$ and $\mathrm{Cong}(R)$, and let B be its collision set (Lemma 7.26), which is decidable.

MP. Assume $\neg\mathrm{Eq}(R)$. By part (b) of the lemma, $\mathrm{Z}(B)$ would give $\mathrm{Eq}(R)$, so $\neg\mathrm{Z}(B)$. MP at B gives $\mathrm{E}(B)$, and part (d) gives $\mathrm{D}(R)$.

WLPO. WLPO at B gives $\mathrm{Z}(B) \vee \neg\mathrm{Z}(B)$. The first case gives $\mathrm{Eq}(R)$ by part (b). In the second, $\mathrm{Eq}(R)$ would give $\mathrm{Z}(B)$ by part (c), so $\neg\mathrm{Eq}(R)$.

LPO. LPO at B gives $\mathrm{Z}(B) \vee \mathrm{E}(B)$, hence $\mathrm{Eq}(R)$ by part (b) or $\mathrm{D}(R)$ by part (d).

EM. Now R satisfies only $\mathrm{Cong}(R)$. First, EM decides the relation. For numbers x and y, comprehension gives a set Y with $\forall z (z \in Y \leftrightarrow x \sim y)$, where z is a variable not occurring in $x \sim y$; EM at Y gives $0 \in Y \vee \neg\, 0 \in Y$, that is, $x \sim y \vee \neg\, x \sim y$. So $\mathrm{Dec}_2(R)$ holds, and the collision set B exists and is decidable. Comprehension gives a set Y' with $\forall z (z \in Y' \leftrightarrow \mathrm{E}(B))$, and EM at Y' gives $\mathrm{E}(B) \vee \neg\mathrm{E}(B)$. The first case gives $\mathrm{D}(R)$. In the second, $n \in B$ would give $\mathrm{E}(B)$, so $\mathrm{Z}(B)$, and $\mathrm{Eq}(R)$ follows. □

The proof of Theorem 7.10 took least witnesses for arbitrary predicates from EM. The derivation above uses EM only twice: to decide the relation, after which the least witnesses come

from the decidable searches, and to decide whether the collision set is inhabited. Either argument proves the forward direction; the second is the shorter one inside HAS.

For the reversals, a set is stored inside a congruence. For a set X, put

$$\theta_X(x,y) \;:\equiv\; x = y \;\vee\; \exists k\,(k \le x \wedge k \le y \wedge k \in X),$$

the relation (7.4) with $\theta(k)$ read as $k \in X$.

Lemma 7.28 (The congruence of a set)**.** *For every set X, comprehension gives a set T_X with*

$$\forall z\Big(z \in T_X \leftrightarrow \exists x\,\exists y\big(z = J(x,y) \wedge \theta_X(x,y)\big)\Big).$$

Write $x \sim_\theta y$ for $J(x,y) \in T_X$. HAS derives:

(a) $x \sim_\theta y \leftrightarrow \theta_X(x,y)$*;*

(b) $\mathrm{Cong}(T_X)$*;*

(c) $\mathrm{Dec}(X) \to \mathrm{Dec}_2(T_X)$*;*

(d) $\mathrm{Eq}(T_X) \to \mathrm{Z}(X)$ *and* $\mathrm{Z}(X) \to \mathrm{Eq}(T_X)$*;*

(e) $\mathrm{D}(T_X) \to \mathrm{E}(X)$*;*

(f) if $\mathrm{A}(X)$ *and* $k \in X$*, then* $\mathrm{Desc}_{T_X}(k,1)$*.*

Proof. (a) From right to left, x and y themselves witness the existential. From left to right, $J(x,y) = J(x',y')$ with $\theta_X(x',y')$ gives $x = x'$ and $y = y'$ by Lemma 7.17(h), and substitution of equals gives $\theta_X(x,y)$. By (a), the remaining parts are statements about θ_X.

(b) Reflexivity uses $x = x$, and symmetry exchanges the roles of x and y in each alternative. For transitivity, let $\theta_X(x,y)$ and $\theta_X(y,z)$. If either uses the equation, substitute it into the other. Otherwise there are $k \le x$, $k \le y$ with $k \in X$, and $k' \le y$, $k' \le z$ with $k' \in X$. Decide $x \le z$ or $z < x$. If $x \le z$, then $k \le z$, and k witnesses $\theta_X(x,z)$; if $z < x$, then $k' \le x$, and k' witnesses it. For addition, let $\theta_X(w,x)$ and $\theta_X(y,z)$. If both use equations, $w + y = x + z$. If the first uses a witness $k \le w$, $k \le x$, then $k \le w + y$ and $k \le x + z$, so k witnesses $\theta_X(w+y, x+z)$; if only the second uses a witness $k \le y$, $k \le z$, then again $k \le w + y$ and $k \le x + z$.

(c) Given x and y, decide $x = y$. For the second alternative, decide $x \le y$ or $y < x$ and let m be the smaller number. Then $\exists k\,(k \le x \wedge k \le y \wedge k \in X)$ is equivalent to $\exists k\,(k < S(m) \wedge k \in X)$, which Lemma 7.22(b) decides. A disjunction of two decided formulas is decided, so (a) gives $x \sim_\theta y \vee \neg\, x \sim_\theta y$.

(d) Assume $\mathrm{Eq}(T_X)$ and $k \in X$. Since $k \le k$ and $k \le S(k)$, we have $\theta_X(k, S(k))$, so $k \sim_\theta S(k)$ and $k = S(k)$, which is impossible. So $\neg\, k \in X$ for every k. Conversely, assume $\mathrm{Z}(X)$ and $x \sim_\theta y$. The witness alternative of $\theta_X(x,y)$ would give a member of X, so $x = y$.

(e) Let $p \neq 0$ and $\mathrm{Desc}_{T_X}(i,p)$. We have $i \sim_{i,p} i + p$: indeed $i \le i$, $i \le i + p$, and $i + p = i + p \cdot 1$. So $i \sim_\theta i + p$, that is, $\theta_X(i, i+p)$. Its first alternative $i = i + p$ is impossible because $i < i + p$, and its second gives a member of X.

(f) Let $\mathrm{A}(X)$ and $k \in X$. If $x \sim_\theta y$, either $x = y$, the first alternative of $x \sim_{k,1} y$, or some $k' \in X$ has $k' \le x$ and $k' \le y$; then $k' = k$ by $\mathrm{A}(X)$, so $k \le x$ and $k \le y$. Moreover $x \equiv y \pmod 1$: decide $x \le y$ or $y < x$, and write $y = x + 1 \cdot d$ or $x = y + 1 \cdot d$. Conversely, $x \sim_{k,1} y$ gives either $x = y$ or $k \le x$, $k \le y$ with $k \in X$, and both give $\theta_X(x, y)$. □

Lemma 7.29 (The congruence of a proposition)**.** *For every set X, write P for $0 \in X$. Comprehension gives a set Q_X with*

$$\forall z \Big(z \in Q_X \leftrightarrow \exists x \exists y \big(z = J(x, y) \wedge (x = y \vee P) \big) \Big).$$

Write $x \sim_P y$ for $J(x, y) \in Q_X$. HAS derives $x \sim_P y \leftrightarrow (x = y \vee P)$, $\mathrm{Cong}(Q_X)$, $\mathrm{Eq}(Q_X) \to \neg P$ and $\mathrm{D}(Q_X) \to P$.

Proof. The first assertion follows from injectivity of the pairing, as in Lemma 7.28(a). This is the relation (7.7). Reflexivity and symmetry are immediate. For transitivity and addition, if any premise uses the alternative P, the conclusion uses it too; otherwise the premises are equations and so is the conclusion. If $\mathrm{Eq}(Q_X)$ and P, then $0 \sim_P 1$, so $0 = 1$, which contradicts $\neg(S(0) = 0)$. If $p \neq 0$ and $\mathrm{Desc}_{Q_X}(i, p)$, then $i \sim_P i + p$ as in Lemma 7.28(e), and $i \neq i + p$, so P. □

Proposition 7.30 (The reversals)**.** *HAS derives $\mathsf{V}_{\mathrm{MP}} \to \mathrm{MP}$, $\mathsf{V}_{\mathrm{WLPO}} \to \mathrm{WLPO}$, $\mathsf{V}_{\mathrm{LPO}} \to \mathrm{LPO}$, $\mathsf{V}_{\mathrm{LLPO}} \to \mathrm{LLPO}$ and $\mathsf{V}_{\mathrm{EM}} \to \mathrm{EM}$.*

Proof. For the first four, let X satisfy $\mathrm{Dec}(X)$ and let T_X be the set of Lemma 7.28. By parts (b) and (c), T_X is a decidable congruence, so each version applies to it.

MP. Assume $\neg\mathrm{Z}(X)$. Then $\neg\mathrm{Eq}(T_X)$, since $\mathrm{Eq}(T_X)$ would give $\mathrm{Z}(X)$ by part (d). V_{MP} gives $\mathrm{D}(T_X)$, and part (e) gives $\mathrm{E}(X)$.

WLPO. $\mathsf{V}_{\mathrm{WLPO}}$ gives $\mathrm{Eq}(T_X) \vee \neg\mathrm{Eq}(T_X)$. By part (d), the first case gives $\mathrm{Z}(X)$, and in the second, $\mathrm{Z}(X)$ would give $\mathrm{Eq}(T_X)$, so $\neg\mathrm{Z}(X)$.

LPO. $\mathsf{V}_{\mathrm{LPO}}$ gives $\mathrm{Eq}(T_X) \vee \mathrm{D}(T_X)$, hence $\mathrm{Z}(X)$ by part (d) or $\mathrm{E}(X)$ by part (e).

LLPO. Assume also $\mathrm{A}(X)$. $\mathsf{V}_{\mathrm{LLPO}}$ gives $\mathrm{Odd}(T_X) \vee \mathrm{Even}(T_X)$. Suppose $\mathrm{Odd}(T_X)$, and let $k + k \in X$. Part (f) gives $\mathrm{Desc}_{T_X}(k + k, 1)$, and $1 \neq 0$, so $\mathrm{Odd}(T_X)$ gives h with $k + k = S(h + h)$, which Lemma 7.17(f) refutes. So $\mathrm{Ev}(X)$. Suppose $\mathrm{Even}(T_X)$, and let $S(k + k) \in X$. Then $\mathrm{Desc}_{T_X}(S(k + k), 1)$ gives h with $S(k + k) = h + h$, which is refuted in the same way. So $\mathrm{Od}(X)$.

EM. Let X be any set and let Q_X be the set of Lemma 7.29, a congruence. V_{EM} gives $\mathrm{Eq}(Q_X) \vee \mathrm{D}(Q_X)$, hence $\neg P$ or P, where P is $0 \in X$. □

The forward direction for LLPO needs the first collision. For a set B and a relation R put

$$\begin{aligned} \mathrm{LB}(c) &:\equiv c \in B \wedge \forall c' \, (c' < c \to \neg\, c' \in B), \\ \mathrm{LP}(x, c) &:\equiv x < c \wedge x \sim c \wedge \forall x' \, (x' < x \to \neg\, x' \sim c). \end{aligned}$$

When B is the collision set of R, $\mathrm{LB}(c)$ says that c is the least count with a smaller partner, and $\mathrm{LP}(x, c)$ that x is its least partner. The pair (x, c) is then the first collision of the proof of Theorem 7.9(3).

Lemma 7.31 (The first collision as a sequence). *Let R satisfy $\mathrm{Dec}_2(R)$ and $\mathrm{Cong}(R)$, and let B be its collision set. Comprehension gives a set G with*

$$\forall m \Big(m \in G \leftrightarrow \exists c \exists x \big(\mathrm{LB}(c) \wedge \mathrm{LP}(x,c) \wedge \big((m = c + c \wedge \exists h\,(x = h + h)) \\ \vee\, (m = S(c+c) \wedge \exists h\,(x = S(h+h))) \big) \big) \Big),$$

the set of the sequence γ with $\gamma(2c + b) = 1$ exactly when (x, c) is the first collision and b is the remainder of x modulo 2. HAS derives:

(a) $\mathrm{LB}(c) \wedge \mathrm{LB}(c') \to c = c'$ *and* $\mathrm{LP}(x,c) \wedge \mathrm{LP}(x',c) \to x = x'$*;*

(b) $\mathrm{A}(G)$*;*

(c) $\mathrm{Dec}(G)$*;*

(d) if $p \neq 0$ and $\mathrm{Desc}_R(i,p)$, then $\mathrm{LB}(i+p)$ and $\mathrm{LP}(i, i+p)$; hence $(i+p)+(i+p) \in G$ when i is even, and $S((i+p)+(i+p)) \in G$ when i is odd.

Proof. (a) Decide $c = c'$. Otherwise $c < c'$ or $c' < c$, and the leastness in $\mathrm{LB}(c')$, respectively $\mathrm{LB}(c)$, refutes $c \in B$, respectively $c' \in B$. The same argument, with the leastness clause of LP, gives $x = x'$.

(b) Let $m, m' \in G$, through (c, x) and (c', x'). By (a), $c = c'$ and $x = x'$. If both use the same alternative, $m = m'$. If they use different alternatives, x is both even and odd, which Lemma 7.17(f) refutes.

(c) Fix m. Lemma 7.17(f) gives c with $m = c + c$ or $m = S(c + c)$. If $m \in G$ through a pair (c'', x''), then $c'' = c$: the equations $c + c = c'' + c''$ and $S(c + c) = S(c'' + c'')$ each give $c = c''$, by injectivity of the step and Lemma 7.17(f), and the mixed equations $c + c = S(c'' + c'')$ and $S(c + c) = c'' + c''$ are refuted by Lemma 7.17(f).

Decide $\mathrm{LB}(c)$: $c \in B$ is decided by Lemma 7.26(a), and $\exists c'\,(c' < c \wedge c' \in B)$ by Lemma 7.22(b). If $\neg\mathrm{LB}(c)$, then $\neg\, m \in G$, since a pair (c'', x'') through which $m \in G$ has $c'' = c$ and $\mathrm{LB}(c'')$.

If $\mathrm{LB}(c)$, then $c \in B$ gives $x_0 < c$ with $x_0 \sim c$. The set $\{x : x \sim c\}$, given by comprehension, is decidable and contains x_0, so Lemma 7.22(c) gives $x \sim c$ with $\neg(x' \sim c)$ for all $x' < x$. Then $x \leq x_0$, since $x_0 < x$ would contradict leastness, so $x < c$ and $\mathrm{LP}(x, c)$. Decide whether x is even or odd. If $m = c + c$ and x is even, or $m = S(c + c)$ and x is odd, then (c, x) witnesses $m \in G$. In the two other combinations $\neg\, m \in G$: a witness (c'', x'') would have $c'' = c$, $x'' = x$ by (a), and its alternative would make x both even and odd, or $c + c = S(c + c)$.

(d) Let $p \neq 0$ and $\mathrm{Desc}_R(i, p)$. As in Lemma 7.28(e), $i \sim i + p$, and $i < i + p$, so $i + p \in B$. Suppose $c' < i + p$ and $c' \in B$, with $x' < c'$ and $x' \sim c'$. The description gives $x' \sim_{i,p} c'$. Its equality alternative is refuted by $x' < c'$, so $i \leq x'$ and $x' \equiv c' \pmod p$. The form $x' = c' + p \cdot d$ is refuted by $x' < c'$. In the form $c' = x' + p \cdot d$ we have $d \neq 0$, since $d = 0$ would give $c' = x'$; writing $d = S(d')$ gives $c' = x' + p + p \cdot d' \geq i + p$, which contradicts $c' < i + p$. So $\mathrm{LB}(i + p)$. Next, $i < i + p$ and $i \sim i + p$; if $x' < i$ and $x' \sim i + p$, the description gives $x' \sim_{i,p} i + p$, whose equality alternative is refuted by $x' < i < i + p$ and whose other alternative gives $i \leq x'$, against $x' < i$. So $\mathrm{LP}(i, i + p)$. The last assertion is the definition of G at $c = i + p$, $x = i$. □

Proposition 7.32 (The forward direction for LLPO)**.** *HAS derives* $\mathrm{LLPO} \to \mathsf{V}_{\mathrm{LLPO}}$.

Proof. Let R satisfy $\mathrm{Dec}_2(R)$ and $\mathrm{Cong}(R)$, with collision set B and first-collision set G. By Lemma 7.31(b) and (c), LLPO applies to G and gives $\mathrm{Ev}(G) \vee \mathrm{Od}(G)$.

Suppose $\mathrm{Ev}(G)$, and let $p \neq 0$ and $\mathrm{Desc}_R(i, p)$. Decide whether i is even or odd. If i is even, part (d) of the lemma puts $(i + p) + (i + p)$ in G, against $\mathrm{Ev}(G)$; so i is odd. This is $\mathrm{Odd}(R)$. Suppose $\mathrm{Od}(G)$. If i is odd, part (d) puts $S((i + p) + (i + p))$ in G, against $\mathrm{Od}(G)$; so i is even. This is $\mathrm{Even}(R)$. □

Theorem 7.33 (The six equivalences are derivable)**.** *HAS derives* $\mathsf{V}_{\mathrm{none}}$ *and the five biconditionals*

$$\mathsf{V}_{\mathrm{MP}} \leftrightarrow \mathrm{MP}, \quad \mathsf{V}_{\mathrm{LLPO}} \leftrightarrow \mathrm{LLPO}, \quad \mathsf{V}_{\mathrm{WLPO}} \leftrightarrow \mathrm{WLPO}, \quad \mathsf{V}_{\mathrm{LPO}} \leftrightarrow \mathrm{LPO}, \quad \mathsf{V}_{\mathrm{EM}} \leftrightarrow \mathrm{EM}.$$

Equivalently, for each of the six versions V *and its principle* P*, with* $\bot \to \bot$ *as the empty principle, HAS derives* $\mathsf{V} \leftrightarrow P$.

Conditions and scope.

Base and premises
HAS (Definition 7.14), intuitionistic second-order arithmetic with the induction axiom and comprehension for every formula; no further axiom. The versions are the sentences (7.11) and the principles those of Definition 7.18.

Conclusion
Derivations in HAS of $\mathsf{V}_{\mathrm{none}}$ and of $\mathsf{V}_P \leftrightarrow P$ for each of MP, LLPO, WLPO, LPO and EM.

Proof. Proposition 7.25 derives $\mathsf{V}_{\mathrm{none}}$, and so $\mathsf{V}_{\mathrm{none}} \leftrightarrow (\bot \to \bot)$, since both sides are derivable. The forward directions are Propositions 7.27 and 7.32, the reversals Proposition 7.30. □

Corollary 7.34 (Each version has the value of its principle)**.** *In every system of truth values, each of the six sentences* $\mathsf{V}_{\mathrm{none}}, \ldots, \mathsf{V}_{\mathrm{EM}}$ *has the same value as its principle; in particular* $\mathsf{V}_{\mathrm{none}}$ *has the value* $\top$.

Proof. Let v and q be the values of a version and of its principle; both are sentences, so the values do not depend on an assignment. By Theorem 7.33 and Lemma 7.21, $(v \Rightarrow q) \wedge (q \Rightarrow v) = \top$. So $\top \leq (v \Rightarrow q)$, which gives $v \leq q$ by the defining property of implication, and likewise $q \leq v$. Hence $v = q$. The empty principle $\bot \to \bot$ has the value $\top$. □

No argument of the chapter has to be rerun inside a model. The arguments run once, inside HAS, and soundness carries their conclusions into every model, including models in which a relation takes intermediate truth values and the searches of the proofs are not decided at every point.

Table 7.1 lists every encoding the chapter uses: each finite search, each way of storing a sequence or a proposition inside a congruence, and the translations to readers and to signed records. For the six versions of the classification, every encoding is a set given by

Encoding	Where it is defined	What it serves	Interpreted in HAS by
least positive period at a; least index for that period	proof of Theorem 7.6	the version with a collision (no principle)	the sets P_a and I_p of Proposition 7.25; decided by $\mathrm{Dec}_2(R)$; least members by Lemma 7.22(c); the description by Lemma 7.24
collision search $\beta_\sim$	(7.5); the search $B(k)$ in the proof of Theorem 7.7	forward directions for MP, WLPO, LPO and EM	the set B of Lemma 7.26: decidable; empty exactly when the relation is equality; a member is a collision and gives a description
first-collision sequence γ	proof of Theorem 7.9(3)	forward direction for LLPO	the set G of Lemma 7.31: decidable; at most one member; for a description by (i, p) its member is $2(i + p) + (i \bmod 2)$
$\sim_\theta$	(7.4), (7.6)	reversals to MP, WLPO, LPO and LLPO	the set T_X of Lemma 7.28: a congruence; decidable when the sequence is; equality exactly when the sequence is all zero; a description yields an event; with at most one event, at k, it is $\sim_{k,1}$
$\sim_P$	(7.7)	reversal to EM	the set Q_X of Lemma 7.29: a congruence; equality refutes P; a description proves P
least witnesses under EM	proof of Theorem 7.10	forward direction for EM	not needed: in Proposition 7.27 EM decides the relation and whether the collision set B is inhabited, and the decidable searches supply the least witnesses
kernel $\sim_r$ of a reading; quotient reading $x \mapsto [x]$	Section 7.7	Theorem 7.11	not used by Theorem 7.38
restriction to counts; extension (7.8)	Theorem 7.12	Corollary 7.13	not used by Theorem 7.38
$\approx_\theta$, $\approx_P$, $\approx_\alpha$; least positive count related to $[0, 0]$	proof of Corollary 7.13	the signed rows	not used by Theorem 7.38

Table 7.1. Every encoding of the chapter and where it is interpreted. The rows above the middle rule are the encodings of the six versions; each is a set given by comprehension, and the properties listed are derived in HAS. The rows below it serve the readers and the signed records.

comprehension, and every property the proofs use is derived in HAS; soundness then interprets the encoding, with all those properties, in every model at once. The last three rows serve Theorem 7.11 and Corollary 7.13. Their equivalences are proved in the constructive base of this chapter, and Theorem 7.38 makes no claim about them in the models, so none of them needs an interpretation there.

7.12 Four models, and why the six prices are different

A principle whose value is not $\top$ in some model has no derivation, by Lemma 7.21. If one sentence has the value $\top$ and another does not, the implication from the first to the second has the value of the second and has no derivation either. One model in which P holds and Q fails therefore shows that P and Q are not equivalent.

The principles decrease in strength along EM, LPO, WLPO, LLPO, and LPO is WLPO and MP together. These are derivations in HAS, so they hold in every model, and they let one check in a model settle several entries of the table below.

Proposition 7.35 (The order of strength)**.** *HAS derives* EM $\to$ LPO, LPO $\to$ WLPO, LPO $\to$ MP, WLPO $\to$ LLPO *and* WLPO $\to$ (MP $\to$ LPO).

Proof. Let X satisfy $\mathrm{Dec}(X)$. Each principle is applied at X, or at a set given by comprehension from X.

EM gives LPO. Comprehension gives a set Y with $\forall z\,(z \in Y \leftrightarrow \mathrm{E}(X))$, and EM at Y gives $\mathrm{E}(X) \vee \neg\mathrm{E}(X)$. In the second case a member of X would give $\mathrm{E}(X)$, so $\mathrm{Z}(X)$.

LPO gives WLPO and MP. LPO gives $\mathrm{Z}(X) \vee \mathrm{E}(X)$. A member of X refutes $\mathrm{Z}(X)$, so the second alternative gives $\neg\mathrm{Z}(X)$, and $\mathrm{Z}(X) \vee \neg\mathrm{Z}(X)$ follows. Under the hypothesis $\neg\mathrm{Z}(X)$ of MP, the first alternative is refuted and the second is the conclusion $\mathrm{E}(X)$.

WLPO and MP give LPO. WLPO gives $\mathrm{Z}(X) \vee \neg\mathrm{Z}(X)$, and in the second case MP gives $\mathrm{E}(X)$.

WLPO gives LLPO. Let also $\mathrm{A}(X)$ hold. Comprehension gives Y with $\forall k\,(k \in Y \leftrightarrow k + k \in X)$, which is decidable because X is, and $\mathrm{Z}(Y)$ is $\mathrm{Ev}(X)$. WLPO at Y gives $\mathrm{Z}(Y) \vee \neg\mathrm{Z}(Y)$. In the second case we derive $\mathrm{Od}(X)$: if $S(k + k) \in X$, then every j with $j \in Y$ gives $j + j \in X$, and $\mathrm{A}(X)$ gives $S(k + k) = j + j$, which Lemma 7.17(f) refutes; so $\mathrm{Z}(Y)$, against $\neg\mathrm{Z}(Y)$. Hence $\neg\, S(k + k) \in X$ for every k. □

Corollary 7.36 (Implications valid in every model)**.** *In every system of truth values,* $[\![\mathrm{EM}]\!] \le [\![\mathrm{LPO}]\!]$, $[\![\mathrm{LPO}]\!] \le [\![\mathrm{MP}]\!]$, $[\![\mathrm{LPO}]\!] \le [\![\mathrm{WLPO}]\!]$ *and* $[\![\mathrm{WLPO}]\!] \le [\![\mathrm{LLPO}]\!]$.

Proof. By Lemma 7.21, a derivable implication $P \to Q$ between sentences has the value $\top$, that is, $\top \le ([\![P]\!] \Rightarrow [\![Q]\!])$, which says $[\![P]\!] \le [\![Q]\!]$. Apply this to Proposition 7.35. □

In the open sets of a space, a binary sequence is a sequence of sets $A_0, A_1, \ldots$ that are both open and closed, since $A_n \vee \neg A_n = \top$ says exactly that the complement of A_n is open. At a point x the sequence reads $\alpha(n) = 1$ when $x \in A_n$, so it varies continuously with the point. Write O

for the union of the sets A_n. The value of $\exists n\, \alpha(n) = 1$ is O, and the value of $\forall n\, \alpha(n) = 0$ is $\neg O$. At this sequence the principles say:

LPO:	O is closed;	
WLPO:	the closure of O is open;	
MP:	O is the interior of its closure;	(7.13)
LLPO:	if the A_n are disjoint, the union of the even-indexed ones and the union of the odd-indexed ones have disjoint closures.	

Excluded middle says that every open set is closed. To refute a principle it is enough to find one sequence at which its condition fails. To verify one, the condition must hold for every sequence, and also, inside each open part of the space, for the sequences decided only on that part. When the space has a base of sets that are both open and closed, the second task reduces to the first.

Lemma 7.37 (Reduction to sequences of open and closed sets)**.** *Let T be a topological space with a base of sets that are both open and closed, and let its open sets be the truth values. Then each of LPO, WLPO and MP has the value T exactly when its condition in* (7.13) *holds for every sequence of sets that are both open and closed, and LLPO has the value T exactly when its condition holds for every such sequence of pairwise disjoint sets.*

Proof. First let every A_n be both open and closed. Then the value d of $\mathrm{Dec}(X)$ is T, the value e of $\mathrm{E}(X)$ is O, the value of $\mathrm{Z}(X)$ is $T \setminus \overline{O}$, its negation is the interior of $\overline{O}$, the value of $\mathrm{A}(X)$ is T exactly when the A_n are pairwise disjoint, and the values of $\mathrm{Ev}(X)$ and $\mathrm{Od}(X)$ are the complements of the closures of the even and of the odd union. So the instance of LPO at this sequence is T exactly when $(T \setminus \overline{O}) \cup O = T$, that is, when O is closed. The instance of WLPO is T exactly when $(T \setminus \overline{O}) \cup \operatorname{int} \overline{O} = T$, that is, when $\overline{O}$ is open. The instance of MP is T exactly when $\operatorname{int} \overline{O} \subseteq O$; since O is open and so lies in $\operatorname{int} \overline{O}$, this says $O = \operatorname{int} \overline{O}$. For a disjoint sequence the instance of LLPO is T exactly when the two closures are disjoint. A principle is the meet of its instances, so if its value is T, each condition holds.

Conversely, assume the conditions, let $A : \mathbb{N} \to H$ be any sequence of open sets, and let W be the value of the hypotheses of an instance: d, met with the value of $\neg\mathrm{Z}(X)$ for MP and with the value of $\mathrm{A}(X)$ for LLPO. Let $x \in W$, and choose V, both open and closed, with $x \in V \subseteq W$. Put $A'_n = A_n \cap V$. Each A'_n is open, and it is closed: its complement is $(T \setminus V) \cup (V \cap \neg A_n)$, because $V \subseteq d \subseteq A_n \cup \neg A_n$, and both pieces are open. Let $O' = \bigcup_n A'_n = O \cap V$. Two facts are used repeatedly. An open set disjoint from every A_n lies in the value of $\mathrm{Z}(X)$, which is the interior of $\bigcap_n (T \setminus A_n)$. And a point of V that lies in some A_n lies in O'; so an open subset of V that misses O' misses every A_n. We show that the conclusion of the instance contains V, hence x.

For LPO, the condition at A' makes O' closed, so $V \setminus O'$ is open; it misses every A_n and lies in the value of $\mathrm{Z}(X)$, while $V \cap O'$ lies in O, the value of $\mathrm{E}(X)$. For WLPO, the condition makes $\overline{O'}$ open, so $V \setminus \overline{O'}$ is open and lies in the value of $\mathrm{Z}(X)$; and $V \cap \overline{O'}$ is an open set that misses the value of $\mathrm{Z}(X)$, since that value is an open set disjoint from O' and hence from $\overline{O'}$, so $V \cap \overline{O'}$ lies in the value of $\neg\mathrm{Z}(X)$. For MP, every point y of V lies in $\overline{O'}$: otherwise some open $U \ni y$ misses O', the open set $U \cap V$ misses every A_n and lies in the value of $\mathrm{Z}(X)$; it also lies in V, inside the value of $\neg\mathrm{Z}(X)$; these two values are disjoint, and $U \cap V$ contains y. So the open

set V lies in $\operatorname{int}\overline{O'}$, which the condition puts inside $O' \subseteq O$, the value of $\mathrm{E}(X)$. For LLPO, the sets A'_n are pairwise disjoint, since V lies in the value of $\mathrm{A}(X)$, which is disjoint from $A_m \cap A_n$ when $m \neq n$. The condition makes the closures of $O'_{\mathrm{ev}} = \bigcup_k A'_{2k}$ and $O'_{\mathrm{od}} = \bigcup_k A'_{2k+1}$ disjoint, so the open sets $V \setminus \overline{O'_{\mathrm{ev}}}$ and $V \setminus \overline{O'_{\mathrm{od}}}$ cover V. The first misses every A_{2k}, so it lies in the value of $\mathrm{Ev}(X)$; the second lies in the value of $\mathrm{Od}(X)$ in the same way.

In each case the hypotheses of the instance at A lie below its conclusion, so the instance has the value T, and so does the principle. □

The models are built in ordinary classical mathematics, with the axiom of choice supplying the ultrafilters. That is the usual setting of an independence proof. The question is what a specified system derives, and the answer is established about that system from outside it.

The one-point compactification of an uncountable set

Let S be an uncountable set, for example the set of all sets of natural numbers, and add one point ∞. The open sets are all subsets of S, together with the sets that contain ∞ and omit only finitely many points of S. The sets both open and closed are the finite subsets of S and their complements, and they form a base: each point of S is isolated, and the complements of finite subsets of S are a base at ∞.

Markov's principle holds. By Lemma 7.37 it is enough to check that a countable union O of sets both open and closed is the interior of its closure. If one of them contains ∞, the complement of O is a finite subset of S, which is open, so O is closed and equals the interior of its closure. Otherwise O is a countable subset of S. Each point of S is isolated, so the closure of O adds at most ∞, and ∞ is not interior to it: every neighbourhood of ∞ contains uncountably many points of S, hence points outside O and outside its closure. Again O is the interior of its closure. LLPO fails. Choose distinct points $s_0, s_1, \ldots$ of S and put $A_n = \{s_n\}$. These sets are disjoint, the even-indexed and the odd-indexed points form two infinite subsets of S, and ∞ lies in the closure of both.

The remainder $\beta\mathbb{N} \setminus \mathbb{N}$

The points are the non-principal ultrafilters on $\mathbb{N}$. For $B \subseteq \mathbb{N}$ let B^* be the set of those that contain B. These sets are open and closed and form a base, and by compactness every set both open and closed has this form; Walker [18] develops these facts about ultrafilters. Moreover $B^* \cap C^* = (B \cap C)^*$, and B^* is empty exactly when B is finite.

LLPO holds. By Lemma 7.37 it is enough to separate the closures for a disjoint sequence of sets both open and closed. Let the sets be $A_n = B_n^*$, so that $B_m \cap B_n$ is finite when $m \neq n$. Let B be the union, over k, of B_{2k} with its finitely many points in $B_1 \cup B_3 \cup \cdots \cup B_{2k+1}$ removed. Then only finitely many points of each B_{2k} lie outside B, and each B_{2m+1} meets B only in its finite overlaps with $B_0, B_2, \ldots, B_{2m-2}$. Hence every even-indexed A_n lies in B^* and every odd-indexed one in $(\mathbb{N} \setminus B)^*$. These two sets are closed and disjoint, so they separate the closures of the two unions.

WLPO fails. Split $\mathbb{N}$ into infinitely many infinite sets $B_0, B_1, \ldots$, put $A_n = B_n^*$, and let O be their union. If the closure of O were open, it would be open and closed, hence equal to B^* for some

B, and each B_n would lie in B apart from finitely many points. Choose one point b_n of $B \cap B_n$ for each n. The set $C = \{b_0, b_1, \ldots\}$ is infinite, lies in B, and meets each B_n in a single point. So C^* is a nonempty open subset of the closure of O that meets no A_n, and so misses O. That is impossible.

The space $\beta\mathbb{N}$

Now take all ultrafilters on $\mathbb{N}$. The principal ultrafilter at n is an isolated point, which we write n. The sets $\overline{B}$ of ultrafilters containing B are open and closed, they form a base, and $\overline{B}$ is the closure of B. An open set U meets $\mathbb{N}$ in a set B that is dense in U, so the closure of U is $\overline{B}$, which is open. WLPO holds, by Lemma 7.37. For Markov's principle and LPO, take $A_n = \{n\}$. Then $O = \mathbb{N}$, whose closure is the whole space. So O is neither closed nor the interior of its closure, and both principles fail.

The chain $0 < 1 < 2 < \cdots < \infty$

In a chain, $\neg a = \bot$ for every $a \neq \bot$, so $a \vee \neg a = \top$ only when a is $\bot$ or $\top$. For a map A, let d be the value of $\mathrm{Dec}(X)$. If $d = \bot$ the instance of LPO at A is $\top$. Otherwise $A(n) \vee \neg A(n) \geq d$ gives, at each n, either $A(n) = \bot$ or $A(n) \geq d$. The classical mathematics in which the model is built either finds an n with $A(n) \neq \bot$, and then the value of $\mathrm{E}(X)$ is at least d, or shows that $A(n) = \bot$ for every n, and then the value of $\mathrm{Z}(X)$ is $\top$. Either way the instance has the value $\top$. LPO holds. Excluded middle fails at the value 1, since $1 \vee \neg 1 = 1$.

Theorem 7.38 (The six principles are different)**.** *Over intuitionistic second-order arithmetic:*

1. *none of MP, LLPO, WLPO, LPO and EM is derivable, and no two of the six principles none, MP, LLPO, WLPO, LPO and EM are equivalent;*
2. *each of the six versions of the classification in the table of Section 7.9, written as the sentences* (7.11)*, is derivably equivalent to its principle as written in Definition 7.18, so in every system of truth values it has the same value as its principle;*
3. *consequently no version of the classification is equivalent to any principle other than its own.*

Conditions and scope.

Base and premises

HAS (Definition 7.14), with the principles and versions written as the sentences of Definition 7.18 and (7.11). The non-derivations are read off from four systems of truth values, built in classical mathematics with the axiom of choice supplying ultrafilters.

Conclusion

HAS derives none of MP, LLPO, WLPO, LPO and EM and no equivalence between two of the six principles. It derives each version's equivalence with its own principle, and no equivalence of a version with another principle.

Proof. (1) Lemma 7.21 turns a model in which a sentence does not have the value $\top$ into the fact that the sentence has no derivation. The one-point compactification refutes LLPO, WLPO, LPO and EM, and $\beta\mathbb{N}$ refutes MP (Table 7.2), so none of the five priced principles is derivable.

For two different principles P and Q, a model in which P has the value $\top$ and Q does not gives $P \leftrightarrow Q$ the value $(\top \Rightarrow q) \wedge (q \Rightarrow \top) = q \neq \top$, where q is the value of Q; so $P \leftrightarrow Q$ has no derivation. Table 7.2 supplies such a model for each of the fifteen pairs. The empty principle has the value $\top$ everywhere, so the five pairs containing it are separated by the models just named. The one-point compactification separates MP from LLPO, WLPO, LPO and EM; the remainder $\beta\mathbb{N} \setminus \mathbb{N}$ separates LLPO from WLPO, LPO and EM; $\beta\mathbb{N}$ separates WLPO from LPO and EM; and the chain separates LPO from EM. That is $5 + 4 + 3 + 2 + 1 = 15$ pairs.

(2) Theorem 7.33 derives each version's equivalence with its principle, and Corollary 7.34 gives the equality of values in every system of truth values. Table 7.3 lists the resulting value of each version in each of the four models.

(3) Let a version V have the principle P, and let Q be a different principle. If $\mathsf{V} \leftrightarrow Q$ had a derivation, then, with the derivation of $\mathsf{V} \leftrightarrow P$ from (2), the two implications $P \to \mathsf{V} \to Q$ and $Q \to \mathsf{V} \to P$ would give a derivation of $P \leftrightarrow Q$, which (1) excludes. Equivalently: in a model that separates P from Q, the version has the value of P, so $\mathsf{V} \leftrightarrow Q$ does not have the value $\top$ there. □

Model	Holds	Fails
one-point compactification	MP	LLPO, WLPO, LPO, EM
$\beta\mathbb{N} \setminus \mathbb{N}$	LLPO, MP (Theorem 7.42)	WLPO, LPO, EM
$\beta\mathbb{N}$	WLPO, LLPO	MP, LPO, EM
chain $0 < 1 < \cdots < \infty$	LPO, MP, WLPO, LLPO	EM

Table 7.2. Four models of intuitionistic second-order arithmetic. In the first three the truth values are the open sets of the space named. Each entry not checked in the text follows from Corollary 7.36: in every model EM implies LPO, LPO implies MP and WLPO, and WLPO implies LLPO.

Version	one-point	$\beta\mathbb{N} \setminus \mathbb{N}$	$\beta\mathbb{N}$	chain
V_{none}	$\top$	$\top$	$\top$	$\top$
V_{MP}	$\top^{\text{t}}$	$\top^{\text{p}}$	$\neq \top^{\text{t}}$	$\top^{\text{c}}$
V_{LLPO}	$\neq \top^{\text{t}}$	$\top^{\text{t}}$	$\top^{\text{c}}$	$\top^{\text{c}}$
V_{WLPO}	$\neq \top^{\text{c}}$	$\neq \top^{\text{t}}$	$\top^{\text{t}}$	$\top^{\text{c}}$
V_{LPO}	$\neq \top^{\text{c}}$	$\neq \top^{\text{c}}$	$\neq \top^{\text{t}}$	$\top^{\text{t}}$
V_{EM}	$\neq \top^{\text{c}}$	$\neq \top^{\text{c}}$	$\neq \top^{\text{c}}$	$\neq \top^{\text{t}}$

Table 7.3. The value of each version (7.11) in each model of Table 7.2: $\top$, or a value other than $\top$. By Corollary 7.34 a version has the value of its principle. A mark t means that the principle's value is computed in this section, and c that it follows from those computations by Corollary 7.36; the empty principle has the value $\top$ in every model. The mark p means that the value is computed in Theorem 7.42; Theorem 7.38 does not use it.

Two consequences follow. Markov's principle is genuinely needed for the classification from negative nontriviality: the system proves neither the principle nor that version. And the six prices do not form a single ladder. EM, LPO, WLPO and LLPO decrease strictly in strength: each derives the next by Proposition 7.35, and no converse is derivable by (1). LPO is WLPO and MP together, by the same proposition; with Theorem 7.33, HAS also derives $\mathsf{V}_{\mathrm{LPO}} \leftrightarrow (\mathsf{V}_{\mathrm{WLPO}} \wedge \mathsf{V}_{\mathrm{MP}})$, the form inside the system of the last assertion of Theorem 7.9. But Markov's principle is comparable with neither WLPO nor LLPO. The one-point compactification satisfies MP and refutes LLPO, and $\beta\mathbb{N}$ satisfies WLPO and refutes MP.

7.13 Prices between the six

Take a binary sequence with at most one entry 1, known not to be all zero. Which parity class is free of entries? Markov's principle answers, since the entry it finds has a parity; so does LLPO, without the extra knowledge. Is this a seventh price? It is, and not the only one: every gap of the chart of Section 7.12 contains further prices (Figure 7.1). As there, derivations are derivations in HAS, and the models are built in classical mathematics, with the axiom of choice supplying ultrafilters and chosen points.

Definition 7.39 (Further principles as sentences)**.** With the abbreviations of Definition 7.18, and with $\bar{n}$ the numeral of n, put

$$\begin{aligned}
\mathrm{MP}^{\vee} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{A}(X) \to \neg \mathrm{Z}(X) \to \mathrm{Ev}(X) \vee \mathrm{Od}(X)\big),\\
\mathrm{W}(X) &:\equiv \forall Y\Big(\mathrm{Dec}(Y) \to \neg\neg \mathrm{E}(Y) \vee \neg\neg \exists n\,\big(n \in X \wedge \neg\, n \in Y\big)\Big),\\
\mathrm{WMP} &:\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{W}(X) \to \mathrm{E}(X)\big),\\
\mathrm{WEM} &:\equiv \forall X\big(\neg\, 0 \in X \vee \neg\neg\, 0 \in X\big).
\end{aligned}$$

For $n \geq 1$ and $i < n$ let $\mathrm{C}_i^n(X) :\equiv \forall j \neg\, (\bar{n} \cdot j + \bar{\imath}) \in X$, and put

$$\mathrm{LLPO}_n :\equiv \forall X\big(\mathrm{Dec}(X) \to \mathrm{A}(X) \to \mathrm{C}_0^n(X) \vee \mathrm{C}_1^n(X) \vee \cdots \vee \mathrm{C}_{n-1}^n(X)\big).$$

For binary sequences, $\mathrm{MP}^{\vee}$ is LLPO restricted to sequences known not to be all zero: the disjunctive Markov principle of Definition 14.18, which Chapter 14 meets as the price of the weak sign of a nonzero point. WMP is Ishihara's weak Markov principle [60, 43]: if, for every decidable Y, either Y cannot be empty or the part of X outside Y cannot be empty, then X has a member. WEM, weak excluded middle, decides of every proposition whether it is refuted. LLPO_n says that a decidable set with at most one member misses one of the n residue classes modulo n; for $n = 2$ its alternatives say what $\mathrm{Ev}(X)$ and $\mathrm{Od}(X)$ say. These weakenings of LLPO were introduced by Richman [73, Section 8.1]. For $n = 1$ the only class is all of $\mathbb{N}$, so LLPO_1 says that a decidable set with at most one member is empty, which the set $\{0\}$ refutes; the family therefore starts at $n = 2$.

Remark 7.40 (The two halves of Markov's principle)**.** Read for binary sequences, WMP says that $\exists n\, \alpha(n) = 1$ whenever every binary β has $\neg\neg \exists n\, \beta(n) = 1$ or $\neg\neg \exists n\, (\alpha(n) = 1 \wedge \beta(n) = 0)$. In this form $\mathrm{MP}_{\mathrm{bin}}$ is equivalent to WMP and $\mathrm{MP}^{\vee}$ together, with no choice principle [43]. MP gives both, as in Lemma 7.41 below. Conversely, if α is not all zero, so is the sequence α' that keeps only its first entry 1, and for a binary β so is the sequence with $\alpha'(n)\beta(n)$ at $2n$ and

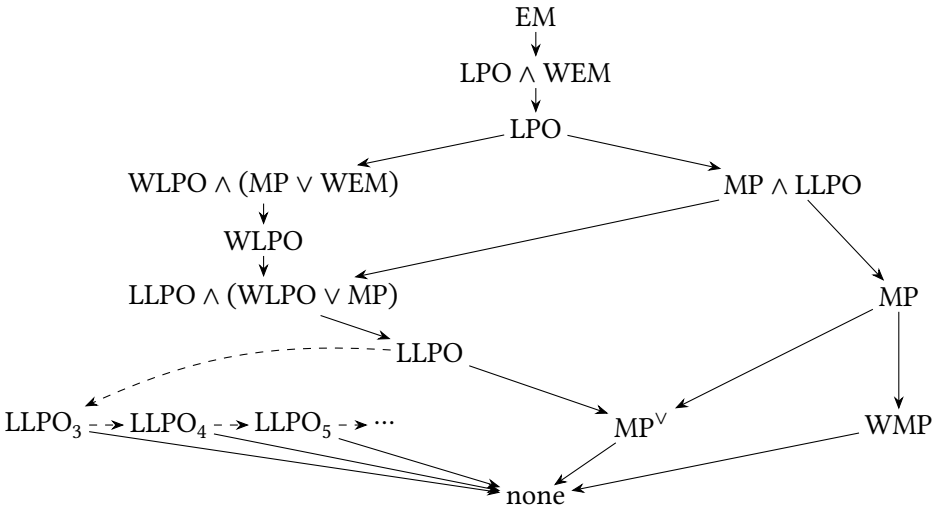

Figure 7.1. The chart of prices over intuitionistic second-order arithmetic. A solid arrow is a derivation; a dashed arrow is an inequality of values in every system of truth values. No arrow can be reversed. The principles $\mathrm{LLPO}, \mathrm{LLPO}_3, \mathrm{LLPO}_4, \ldots$ form a strictly descending chain: each value lies below the next, and for $m \geq 3$, LLPO_m derives neither LLPO nor LLPO_n for $2 \leq n < m$. Each LLPO_n with $n \geq 3$, and WMP, is incomparable with $\mathrm{MP}^\vee$; WMP is also incomparable with LLPO and WLPO, and $\mathrm{MP} \wedge \mathrm{LLPO}$ with WLPO.

$\alpha'(n)(1 - \beta(n))$ at $2n + 1$, which has at most one entry 1. $\mathrm{MP}^\vee$ empties its even places, giving $\neg\neg\exists n\,(\alpha'(n) = 1 \wedge \beta(n) = 0)$, or its odd places, giving $\neg\neg\exists n\,\beta(n) = 1$; so WMP finds an entry 1 of α', hence of α. Over HAS neither half derives the other or MP (Theorem 7.45). Kohlenbach showed that WMP is not derivable even in intuitionistic arithmetic in all finite types with the axiom of choice [75].

Lemma 7.41 (What the six principles derive)**.**

1. *HAS derives* $\mathrm{MP} \to \mathrm{MP}^\vee$, $\mathrm{MP} \to \mathrm{WMP}$, $\mathrm{LLPO} \to \mathrm{MP}^\vee$ *and* $\mathrm{LPO} \to \mathrm{MP} \wedge \mathrm{LLPO}$.
2. *HAS derives* $\mathrm{WLPO} \to \mathrm{LLPO} \wedge (\mathrm{WLPO} \vee \mathrm{MP})$, $\mathrm{LPO} \to \mathrm{WLPO} \wedge (\mathrm{MP} \vee \mathrm{WEM})$ *and* $\mathrm{EM} \to \mathrm{LPO} \wedge \mathrm{WEM}$*, and each of these three conjunctions derives its first conjunct. It also derives* $\mathrm{MP} \wedge \mathrm{LLPO} \to \mathrm{MP}$ *and* $\mathrm{MP} \wedge \mathrm{LLPO} \to \mathrm{LLPO} \wedge (\mathrm{WLPO} \vee \mathrm{MP})$.
3. *For* $2 \leq n \leq m$*, in every system of truth values* $[\![\mathrm{LLPO}]\!] \leq [\![\mathrm{LLPO}_n]\!] \leq [\![\mathrm{LLPO}_m]\!]$.

Proof. (1) Let $\mathrm{Dec}(X)$. For $\mathrm{MP} \to \mathrm{MP}^\vee$ assume also $\mathrm{A}(X)$ and $\neg\mathrm{Z}(X)$. MP gives some $n \in X$, and by Lemma 7.17(f), $n = h + h$ or $n = S(h + h)$. In the first case $\mathrm{Od}(X)$ holds: a member $S(k + k)$ of X would give $h + h = S(k + k)$ by $\mathrm{A}(X)$, which Lemma 7.17(f) refutes. The second case gives $\mathrm{Ev}(X)$ in the same way. For $\mathrm{MP} \to \mathrm{WMP}$ assume $\mathrm{W}(X)$ and apply it at $Y := X$. Its second alternative, $\neg\neg\exists n\,(n \in X \wedge \neg\, n \in X)$, is absurd; its first, $\neg\neg\mathrm{E}(X)$, gives $\neg\mathrm{Z}(X)$, since $\mathrm{Z}(X)$ refutes $\mathrm{E}(X)$. So MP gives $\mathrm{E}(X)$. LLPO gives $\mathrm{MP}^\vee$ directly. Proposition 7.35 gives $\mathrm{LPO} \to \mathrm{MP}$ and $\mathrm{LPO} \to \mathrm{WLPO} \to \mathrm{LLPO}$.

(2) Use Proposition 7.35 and disjunction introduction; EM gives WEM, since $0 \in X$ gives $\neg\neg\, 0 \in X$. That each of the three conjunctions derives its first conjunct is conjunction

elimination. MP $\wedge$ LLPO gives MP by conjunction elimination, and LLPO $\wedge$ (WLPO $\vee$ MP) by conjunction elimination and disjunction introduction.

(3) Fix $2 \le n \le m$ and $A : \mathbb{N} \to H$. Put $g(j) = m\lfloor j/n \rfloor + (j \bmod n)$ and $B_j = A_{g(j)}$; the map g is injective, since $j \bmod n < n \le m$, and sends $nk + i$ to $mk + i$ for $i < n$. The values of $\mathrm{Dec}(X)$ and $\mathrm{A}(X)$ at B are meets over some of the meetands of their values at A, hence at least those values: for $j \neq j'$ the meetand $B_j \Rightarrow (B_{j'} \Rightarrow \bot)$ is that of A at $g(j) \neq g(j')$. For $i < n$ the value of $\mathrm{C}_i^n(X)$ at B is $\bigwedge_k \neg A_{mk+i}$, the value of $\mathrm{C}_i^m(X)$ at A; for $n = 2$ the values of $\mathrm{Ev}(X)$ and $\mathrm{Od}(X)$ at B are those of $\mathrm{C}_0^2(X)$ and $\mathrm{C}_1^2(X)$, since $k + k$ and $2k$ have the same value. So the conclusion of LLPO_n at B, and for $n = 2$ that of LLPO, a join of the values of $\mathrm{C}_i^m(X)$ at A over $i < n$, lies below the conclusion of LLPO_m at A, the join over all $i < m$. Since $a \Rightarrow b$ grows when a shrinks or b grows, the instance of LLPO_n at B, and for $n = 2$ that of LLPO, lies below the instance of LLPO_m at A. The value of a principle lies below each of its instances, and the value of LLPO_m is the meet of its instances over all A. This gives $[\![\mathrm{LLPO}_n]\!] \le [\![\mathrm{LLPO}_m]\!]$, and, with $n = 2$, $[\![\mathrm{LLPO}]\!] \le [\![\mathrm{LLPO}_m]\!]$ for every $m \ge 2$. □

Three models for the halves of Markov's principle

Section 7.12 computes every entry of Table 7.3 but one, which we compute first.

Theorem 7.42 (Markov's principle in the remainder)**.** *In the open sets of $\beta\mathbb{N} \setminus \mathbb{N}$, Markov's principle has the value $\top$. Hence MP and LLPO both hold there, while WLPO and LPO fail.*

Proof. We use the sets B^* of Section 7.12. By Lemma 7.37 it is enough to show that a union O of sets $A_n = B_n^*$ is the interior of its closure. It lies in that interior, being open. Suppose a point p of the interior is not in O, and choose C^* with $p \in C^* \subseteq \overline{O}$. For each n, $p \notin B_n^*$, so $B_n \notin p$, and since an ultrafilter contains a finite union only if it contains one of its members, $D_n = C \setminus (B_0 \cup \cdots \cup B_n)$ belongs to p. Each D_n is infinite, because p contains no finite set. Choose $e_0 \in D_0$, and $e_{k+1} \in D_{k+1}$ with $e_{k+1} > e_k$. The set $E = \{e_0, e_1, \ldots\}$ is infinite and lies in C, and it meets B_n only among $e_0, \ldots, e_{n-1}$, because $e_k \in D_k$ misses B_n for $k \ge n$. So E^* is nonempty, lies in $C^* \subseteq \overline{O}$, and misses every A_n, since $E^* \cap B_n^* = (E \cap B_n)^*$ is empty. A nonempty open subset of $\overline{O}$ that misses O is impossible. LLPO holds and WLPO and LPO fail by Section 7.12. □

With S^+ the one-point compactification of an uncountable set of Section 7.12, the next model compactifies $\mathbb{N}$: let $\widehat{\mathbb{N}} = \mathbb{N} \cup \{\infty\}$, and call a set open when it omits ∞ or contains ∞ and all but finitely many natural numbers, so that $0, 1, 2, \ldots$ converges to ∞. Each natural number is isolated, so for an open set U and a natural number m we have $m \in \neg U$ exactly when $m \notin U$, and $m \in \neg\neg U$ exactly when $m \in U$.

Proposition 7.43 (The convergent sequence)**.** *In the open sets of $\widehat{\mathbb{N}}$,* WMP *has the value $\top$ and* $\mathrm{MP}^\vee$ *does not. Consequently MP, LLPO, WLPO and LPO fail there.*

Proof. WMP holds. Let $A : \mathbb{N} \to H$, let $O = \bigcup_n A_n$, the value of $\mathrm{E}(X)$, and let x lie in the values of $\mathrm{Dec}(X)$ and $\mathrm{W}(X)$. We show $x \in O$. The value of $\mathrm{W}(X)$ lies below its instance at the constant map $\bot$, whose value is $\neg\neg O$; so if x is a natural number, it lies in O. Let $x = \infty$ and suppose $\infty \notin O$. Since ∞ lies in $A_n \cup \neg A_n$, it lies in $\neg A_n$ for every n. Let B_n be the

set of even natural numbers in A_n; it is open. The value of $\mathrm{Dec}(Y)$ at B is the whole space: $\infty \in \neg A_n \subseteq \neg B_n$, and each natural number lies in B_n or, being isolated, in $\neg B_n$. So the instance of $\mathrm{W}(X)$ at B puts ∞ in $\neg\neg U$ or in $\neg\neg V$, where $U = \bigcup_n B_n$ and $V = \bigcup_n (A_n \cap \neg B_n)$. Both are impossible. The open set $\neg\neg U$ would contain ∞, hence every large natural number, among them an odd number $2N+1$; but $2N+1$ is outside U, hence in $\neg U$ and not in $\neg\neg U$. Likewise $\neg\neg V$ would contain a large even number $2N+2$; but $2N+2$ lies in no $A_n \cap \neg B_n$, since an even member of A_n is in B_n, so it is in $\neg V$ and not in $\neg\neg V$.

$\mathrm{MP}^\vee$ *fails.* Take $A_n = \{n\}$. Its complement is open, so the value of $\mathrm{Dec}(X)$ is the whole space, and the sets are disjoint, so that of $\mathrm{A}(X)$ is too. An open set disjoint from every $\{n\}$ is empty; so $\neg\mathrm{Z}(X)$ has the value of the whole space. The instance of $\mathrm{MP}^\vee$ at A therefore has the value of $\mathrm{Ev}(X) \vee \mathrm{Od}(X)$. It misses ∞: an open set containing ∞ contains an even number $2k$, so it is not inside $\neg\{2k\}$, and it contains an odd number, so the same holds for the odd places. By Lemmas 7.41 and 7.21, the values of MP and LLPO lie below that of $\mathrm{MP}^\vee$, and by Corollary 7.36 those of WLPO and LPO lie below that of LLPO. □

Proposition 7.44 (Weak Markov fails in $\beta\mathbb{N}$)**.** *In the open sets of* $\beta\mathbb{N}$, WMP *does not have the value* $\top$.

Proof. Use the notation of Section 7.12 and take $A_n = \{n\}$, the isolated principal points. Then $\mathrm{Dec}(X)$ has the value $\top$ and $\mathrm{E}(X)$ the value $\mathbb{N}$, which is not the whole space. We show that $\mathrm{W}(X)$ has the value $\top$; then the instance of WMP at A has the value $\mathbb{N}$. First, if every point n of a set $E \subseteq \mathbb{N}$ lies in an open set U, then $\overline{E} \subseteq \neg\neg U$. Indeed $\overline{E}$ is open, and it misses $\neg U$: a point v of $\overline{E}$ in $\neg U$ would have a basic neighbourhood $\bar{t} \subseteq \neg U$, and $\bar{t}$ meets E, because $t \cap E \in v$, at a point that lies in both U and $\neg U$. Now let $B : \mathbb{N} \to H$ and let u lie in the value of $\mathrm{Dec}(Y)$; choose $s \in u$ with $\bar{s}$ inside that value. For $n \in s$, the point n lies in B_n or in $\neg B_n$. Let E be the set of $n \in s$ with $n \in B_n$. If $E \in u$, then $u \in \overline{E} \subseteq \neg\neg \bigcup_n B_n$. Otherwise $s \setminus E \in u$, and each $n \in s \setminus E$ lies in $A_n \cap \neg B_n$, so $u \in \neg\neg \bigcup_n (A_n \cap \neg B_n)$. Either way u lies in the value of the disjunction in $\mathrm{W}(X)$. So the instance of $\mathrm{W}(X)$ at B has the value $\top$ for every B, and so has $\mathrm{W}(X)$. □

Theorem 7.45 (The two halves of Markov's principle, and MP with LLPO)**.** *Over intuitionistic second-order arithmetic:*

1. $\mathrm{MP} \to \mathrm{MP}^\vee$ *is derivable, while* $\mathrm{MP}^\vee$ *and* $\mathrm{MP}^\vee \to \mathrm{MP}$ *are not;*
2. $\mathrm{MP} \to \mathrm{WMP}$ *is derivable, while* WMP *and* $\mathrm{WMP} \to \mathrm{MP}$ *are not;*
3. $\mathrm{LLPO} \to \mathrm{MP}^\vee$ *is derivable, while* $\mathrm{MP}^\vee \to \mathrm{LLPO}$ *is not;*
4. *none of the six implications between* WMP *and each of* $\mathrm{MP}^\vee$*, LLPO and WLPO, in either direction, is derivable;*
5. $\mathrm{LPO} \to \mathrm{MP} \wedge \mathrm{LLPO}$ *is derivable, while none of* $\mathrm{MP} \wedge \mathrm{LLPO} \to \mathrm{LPO}$, $\mathrm{MP} \to \mathrm{MP} \wedge \mathrm{LLPO}$, $\mathrm{LLPO} \to \mathrm{MP} \wedge \mathrm{LLPO}$, $\mathrm{MP} \wedge \mathrm{LLPO} \to \mathrm{WLPO}$ *and* $\mathrm{WLPO} \to \mathrm{MP} \wedge \mathrm{LLPO}$ *is derivable.*

So LPO is WLPO and MP together (Proposition 7.35), but not LLPO and MP.

Table 7.4. The two halves of Markov's principle and four of the six principles in five models.

Proof. The derivations are Lemma 7.41. The non-derivations are read off from models as in Section 7.12, a conjunction having the meet of the two values; Table 7.4 collects the values. The rows come from Proposition 7.43, Section 7.12 (S^+, $\beta\mathbb{N}$, the chain), Theorem 7.42 and Proposition 7.44, the other entries from Lemma 7.41 with Lemma 7.21, and from Corollary 7.36. Now read off: (1) $\widehat{\mathbb{N}}$ refutes $\mathrm{MP}^\vee$, and $\beta\mathbb{N}$ has $\mathrm{MP}^\vee$ without MP; (2) $\beta\mathbb{N}$ refutes WMP, and $\widehat{\mathbb{N}}$ has WMP without MP; (3) S^+ has $\mathrm{MP}^\vee$ without LLPO; (4) $\widehat{\mathbb{N}}$ has WMP without $\mathrm{MP}^\vee$, LLPO or WLPO, and $\beta\mathbb{N}$ has all three without WMP; (5) $\beta\mathbb{N}\setminus\mathbb{N}$ has MP $\wedge$ LLPO without LPO or WLPO, S^+ has MP without LLPO, and $\beta\mathbb{N}$ has LLPO and WLPO without MP. □

Hendtlass and Lubarsky separate many fragments of weak excluded middle, LPO and Markov's principle, WMP among them, by Kripke and topological models [74]; the models used here are topological.

Infinitely many prices below LLPO

For the family LLPO_n we need models in which the neighbourhoods of one extra point are prescribed by finitely many ultrafilters. For $k\geq 1$ and $l<k$, let $U_{k,l}$ be a nonprincipal ultrafilter on $\mathbb{N}$ that contains the residue class of l modulo k, and let F_k be the family of sets that belong to all of $U_{k,0},\dots,U_{k,k-1}$. Let $X_k=\mathbb{N}\cup\{\infty\}$, with a set W open when $\infty\in W$ implies that the natural numbers in W form a member of F_k. Natural numbers are isolated, and the complement of $\{m\}$ is open, because a nonprincipal ultrafilter contains every cofinite set.

Proposition 7.46 (A family of principles below LLPO)**.**

1. *For $n\geq 2$, the value of LLPO lies below that of LLPO_n in every system of truth values.*
2. *No LLPO_n with $n\geq 2$ is derivable in HAS.*
3. *For $n\geq 3$, neither $\mathrm{LLPO}_n\to\mathrm{LLPO}$ nor $\mathrm{LLPO}_n\to\mathrm{MP}^\vee$ is derivable, and for $n\geq 2$ neither is $\mathrm{MP}^\vee\to\mathrm{LLPO}_n$.*
4. *For $2\leq n<m$, $\mathrm{LLPO}_m\to\mathrm{LLPO}_n$ is not derivable.*

Proof. Part 1 is Lemma 7.41(3). In each model below, an open set disjoint from every A_{nj+i} lies in the value of $\mathrm{C}_i^n(X)$.

LLPO_k *fails in X_k.* Take $A_m=\{m\}$; the values of $\mathrm{Dec}(X)$ and $\mathrm{A}(X)$ are the whole space. If ∞ lay in the value of $\mathrm{C}_l^k(X)$, an open set inside it would contain ∞ and a member T of $F_k\subseteq U_{k,l}$

of natural numbers. The set T meets the residue class of l, at some $m = kj + l$, and m would lie in $\neg\{m\}$.

LLPO_m *holds in* X_k *for* $m > k$. Let $A : \mathbb{N} \to H$ and let x lie in the values of $\mathrm{Dec}(X)$ and of $\mathrm{A}(X)$; call the latter M. We find $i < m$ with x in the value of $\mathrm{C}_i^m(X)$. If $x \in A_a$ for some a, choose $i < m$ different from a mod m. A point of the open set $A_a \cap M$ that lay in some A_{mj+i} would give $a = mj + i$ by $\mathrm{A}(X)$, which is impossible; so $A_a \cap M$ is disjoint from every A_{mj+i} and contains x. If x is a natural number in no A_a, the open set $\{x\}$ serves for $i = 0$. Finally let $x = \infty$ lie in no A_a. The natural numbers of M form a set $T \in F_k$. For $i < m$ let O_i be the set of natural numbers lying in some A_{mj+i}. For $i \neq i'$, the set $O_i \cap O_{i'} \cap T$ is empty, by $\mathrm{A}(X)$. If every O_i belonged to one of the k ultrafilters, two of the $m > k$ classes would belong to the same $U_{k,l}$, together with T, and their empty intersection would belong to it. So some O_i belongs to none of them, its complement belongs to all, and $\{\infty\} \cup (\mathbb{N} \setminus O_i)$ is an open set containing ∞ and disjoint from every A_{mj+i}.

$\mathrm{MP}^\vee$ *fails in* X_2. With $A_m = \{m\}$, an open set containing ∞ contains a member of $U_{2,0}$, hence an even number p, which is not in $\neg\{p\}$; so ∞ is not in the value of $\mathrm{Ev}(X)$, nor of $\mathrm{Z}(X)$, and by $U_{2,1}$ not in that of $\mathrm{Od}(X)$. Natural numbers are not in the value of $\mathrm{Z}(X)$ either, so $\neg\mathrm{Z}(X)$ has the value $\top$, and the instance of $\mathrm{MP}^\vee$ at A misses ∞.

Every LLPO_n *fails in* S^+. With distinct points $s_0, s_1, \ldots$ of S and $A_m = \{s_m\}$, every open set containing ∞ contains some s_{nj+i}, so ∞ lies in no value $\mathrm{C}_i^n(X)$. MP, and with it $\mathrm{MP}^\vee$, holds in S^+.

Now read off: S^+ refutes LLPO_n and validates $\mathrm{MP}^\vee$, which gives part 2 and the last claim of part 3. For $n \geq 3$, X_2 validates LLPO_n and refutes $\mathrm{MP}^\vee$ and LLPO_2, hence LLPO by part 1. For $n < m$, X_n validates LLPO_m and refutes LLPO_n. □

With Lemma 7.41(3), parts 3 and 4 make LLPO, LLPO_3, LLPO_4, … a strictly descending chain. Diener shows that each LLPO_n fails in the topological model over any metric space with an accumulation point [73, Proposition 8.1.5]; for separations of this kind see also [74].

Between LLPO and WLPO, and between WLPO and LPO

The candidates are $\mathrm{LLPO} \wedge (\mathrm{WLPO} \vee \mathrm{MP})$ and $\mathrm{WLPO} \wedge (\mathrm{MP} \vee \mathrm{WEM})$. That each lies between its neighbours is Lemma 7.41(2), and the upper steps are strict by models we have: $\beta\mathbb{N} \setminus \mathbb{N}$ validates LLPO and MP but not WLPO, and $\beta\mathbb{N}$ validates WLPO and WEM but not LPO. WEM holds in $\beta\mathbb{N}$ because the closure of an open set U is open (Section 7.12): then $\neg U$ is the complement of $\overline{U}$, $\neg\neg U$ is $\overline{U}$, and the two cover the space. The lower steps need a model in which the lower principle holds and both alternatives of the disjunction fail at one point. For a set Y and a family $\mathscr{B}$ of its subsets we give a space of ultrafilters on Y the topology with basic open sets $\langle s\rangle$, the ultrafilters containing s, for $s \in \mathscr{B}$. Then $\langle s\rangle \cap \langle t\rangle = \langle s \cap t\rangle$ and the complement of $\langle s\rangle$ is $\langle Y \setminus s\rangle$, so whenever $\mathscr{B}$ is closed under finite intersections and complements the basic sets are open and closed and form a base, and every closed set is an intersection of basic sets.

The model K. Let $Y = \mathbb{N} \times \mathbb{N}$. A point (n, k) lies in column n, and we read k through a fixed bijection $k \mapsto (r(k), q(k))$ of $\mathbb{N}$ onto $\mathbb{N} \times \mathbb{N}$ with $r(k) \leq k$ as a row $r(k)$ and a place $q(k)$. A set is *column-finite* when it meets each column in finitely many points. Let K be the space of

ultrafilters on Y that contain the complement of every column-finite set, with $\mathscr{B}$ all subsets of Y. A basic set $\langle s\rangle$ is empty exactly when s is column-finite: otherwise s meets a column infinitely often, so s and the complements of the column-finite sets have the finite intersection property and lie in a common ultrafilter. The same argument shows that K is compact: if finitely many of the sets $\langle s_i\rangle$ always meet, then no finite intersection of the s_i is column-finite, and one ultrafilter in K contains all of them. So every set both open and closed, being compact, is a finite union of basic sets, hence basic.

The model L. Let $Z = \{0,1\} \times \mathscr{P}(\mathbb{N})$ and $Y = \mathbb{N} \times Z$. Each half $\{b\} \times \mathscr{P}(\mathbb{N})$ of Z is uncountable. Let $\mathscr{B}$ consist of the sets $s \subseteq Y$ whose column sections $s_n = \{z : (n,z) \in s\}$ are each countable or have countable complement in Z. This family is closed under complements and countable unions: the section at n of a union is the union of the sections at n, which is countable when all of them are and otherwise contains a set with countable complement. Let L be the space of all ultrafilters on Y, with this $\mathscr{B}$. The principal ultrafilter x_p at $p \in Y$ lies in $\langle s\rangle$ exactly when $p \in s$, so a basic set $\langle s\rangle$ is nonempty exactly when s is. L is compact by the argument used for K, and every set both open and closed is $\langle b\rangle$ for some $b \in \mathscr{B}$.

Theorem 7.47 (Two further intermediate prices)**.** *Over intuitionistic second-order arithmetic, the four implications of the chains*

$$\mathrm{WLPO} \to \mathrm{LLPO} \wedge (\mathrm{WLPO} \vee \mathrm{MP}) \to \mathrm{LLPO} \quad \textit{and} \quad \mathrm{LPO} \to \mathrm{WLPO} \wedge (\mathrm{MP} \vee \mathrm{WEM}) \to \mathrm{WLPO}$$

are derivable, and none of the four reverse implications is. More precisely, LLPO has the value $\top$ in K while $\mathrm{WLPO} \vee \mathrm{MP}$ *does not, and WLPO has the value $\top$ in L while* $\mathrm{MP} \vee \mathrm{WEM}$ *does not.*

Proof. The derivations and the upper steps were shown above. A model in which P has the value $\top$ and D does not gives $P \to P \wedge D$ the value of D; so it remains to check the two models, where Lemma 7.37 applies.

LLPO holds in K. Let $A_n = \langle b_n\rangle$ be pairwise disjoint, so that $b_m \cap b_n$ is column-finite for $m \neq n$. Put

$$s = \bigcup_k \big(b_{2k+1} \setminus (b_0 \cup b_2 \cup \cdots \cup b_{2k})\big).$$

Then $s \cap b_{2m}$ lies in the union of the sets $b_{2k+1} \cap b_{2m}$ with $k < m$, and $b_{2k+1} \setminus s$ in the union of the sets $b_{2k+1} \cap b_{2j}$ with $j \leq k$; both are column-finite. So every even-indexed A_n lies in $\langle Y \setminus s\rangle$ and every odd-indexed one in $\langle s\rangle$, two disjoint closed sets that separate the closures of the two unions.

The point x_1 of K. For $N \in \mathbb{N}$, $f : \mathbb{N} \to \mathbb{N}$ and $g : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, the tail $T(N,f,g)$ is the set of (n,k) with $n \geq N$, $r(k) \geq f(n)$ and $q(k) \geq g(n, r(k))$. Two tails contain a third, and no tail is empty, so some ultrafilter x_1 contains every tail. It lies in K: if c is column-finite, choose $f(n)$ above every position of c in column n; since $r(k) \leq k$, the tail $T(0,f,0)$ misses c.

MP fails at x_1. Let $A_n = \langle \{n\} \times \mathbb{N}\rangle$, the columns. A nonempty basic $\langle s\rangle$ has s meeting some column n infinitely often, so it meets A_n; hence $\mathrm{Z}(X)$ has the value $\varnothing$ and $\neg\mathrm{Z}(X)$ the value K. But x_1 contains no column, since $T(n+1,0,0)$ misses column n, so x_1 is not in the value $\bigcup_n A_n$ of $\mathrm{E}(X)$.

WLPO fails at x_1. Let $A_m = \langle R_m\rangle$, where R_m is the set of points in row m, across all columns. Suppose a basic $\langle s\rangle \ni x_1$ lies in the value of $\mathrm{Z}(X)$. If s met each cell (column n, row m) in

finitely many points, with places below $G(n,m)$, then s would miss the tail $T(0,0,G)$; so s meets some cell infinitely often, $s \cap R_m$ is not column-finite, and $\langle s\rangle$ meets A_m, which is impossible. Suppose instead that $\langle s\rangle \ni x_1$ lies in the value of $\neg\mathrm{Z}(X)$. If s met each column in boundedly many rows, with rows below $F(n)$, it would miss $T(0,F,0)$; so in some column n it meets infinitely many rows. Let s' be the set of points of s that have the least position k among the points of s in their cell. Then s' meets each row in at most one point per column, so $\langle s'\rangle \cap A_m = \langle s' \cap R_m\rangle$ is empty for every m, and $\langle s'\rangle$ lies in the value of $\mathrm{Z}(X)$. But s' has infinitely many points in column n, so $\langle s'\rangle$ is a nonempty open subset of $\langle s\rangle$, inside the values of both $\mathrm{Z}(X)$ and its negation. So x_1 lies in neither value, the instance of WLPO at A misses x_1, and x_1 is in neither $[\![\mathrm{WLPO}]\!]$ nor $[\![\mathrm{MP}]\!]$.

WLPO holds in L. Let $A_n = \langle b_n\rangle$ with $b_n \in \mathscr{B}$, and let $t = \bigcup_n b_n$, a member of $\mathscr{B}$. The set $\langle t\rangle$ is closed and contains every A_n. Each of its points x lies in the closure of their union: for a basic $\langle c\rangle \ni x$, the set $c \cap t \in x$ has a point p, in some b_n, and $x_p \in \langle c\rangle \cap A_n$. So the closure of the union is $\langle t\rangle$, which is open.

The point x_0 of L. The tails $\{(n,z) : n \geq N,\ z \notin C\}$, for $N \in \mathbb{N}$ and countable $C \subseteq Z$, are nonempty and directed, so some ultrafilter x_0 contains all of them. It contains no column $\{n\} \times Z$, since the tail for $N = n+1$ misses it. Every $s \in \mathscr{B}$ with $s \in x_0$ meets both halves $\mathbb{N} \times \{b\} \times \mathscr{P}(\mathbb{N})$: if s missed the half of b, no section of s could have countable complement, since that half of Z is uncountable; so all sections would be countable, their union C would be countable, and the tail for $N = 0$ and C would miss s.

MP fails at x_0. The columns lie in $\mathscr{B}$. With A_n the basic set of column n, the value of $\mathrm{Dec}(X)$ is L, and every nonempty basic set contains a principal point, which lies in some A_n; so $\neg\mathrm{Z}(X)$ has the value L, while x_0 is not in $\bigcup_n A_n$.

WEM fails at x_0. For $z \in Z$ the row $\mathbb{N} \times \{z\}$ lies in $\mathscr{B}$. Let P be the union of the basic sets of the rows with z in the half of 1, and Q that of the rows with z in the half of 0. Distinct rows are disjoint, so $Q \subseteq \neg P$. If a basic $\langle s\rangle \ni x_0$ lay in $\neg P$, then s would meet the half of 1 at a point p, and x_p would lie in $\langle s\rangle$ and in P. If it lay in $\neg\neg P$, then s would meet the half of 0 at p, and x_p would lie in $\langle s\rangle$ and in $Q \subseteq \neg P$. So x_0 is not in $\neg P \cup \neg\neg P$, the instance of WEM at the constant map P, and x_0 is in neither $[\![\mathrm{MP}]\!]$ nor $[\![\mathrm{WEM}]\!]$. □

Above LPO

Proposition 7.48 (Excluded middle for decidable sets and its levels)**.**

1. *Let φ be a formula without set quantifiers, possibly with number parameters. If HAS derives, from a list Γ, LPO and $\mathrm{Dec}(X)$ for each set variable X free in φ, then it derives $\varphi \vee \neg\varphi$ from Γ.*

2. *Consequently HAS derives $\mathrm{LPO} \to \forall X\big(\mathrm{Dec}(X) \to \varphi \vee \neg\varphi\big)$ for every such φ whose only set variable is X, whatever its quantifier prefix; and it derives $\forall X\big(\mathrm{Dec}(X) \to \mathrm{E}(X) \vee \neg\mathrm{E}(X)\big) \to \mathrm{LPO}$.*

3. *$\mathrm{EM} \to \mathrm{LPO} \wedge \mathrm{WEM}$ and $\mathrm{LPO} \wedge \mathrm{WEM} \to \mathrm{LPO}$ are derivable, and none of $\mathrm{LPO} \wedge \mathrm{WEM} \to \mathrm{EM}$, $\mathrm{LPO} \to \mathrm{LPO} \wedge \mathrm{WEM}$, $\mathrm{LPO} \to \mathrm{WEM}$ and $\mathrm{WEM} \to \mathrm{LPO}$ is.*

Proof. (1) Induction on φ. Equations are decided by Lemma 7.17(a), memberships $t \in X$ by the hypothesis $\mathrm{Dec}(X)$ at t, and $\bot$ is refuted. Decisions of two formulas decide their conjunction, disjunction and implication. For $\exists n\,\psi$, the induction hypothesis, applied with n fresh, gives $\forall n\,(\psi \vee \neg\psi)$. Comprehension gives a set Y with $\forall n\,(n \in Y \leftrightarrow \psi)$, and Y is decidable. LPO at Y gives $\mathrm{Z}(Y)$, hence $\neg\exists n\,\psi$, or $\mathrm{E}(Y)$, hence $\exists n\,\psi$. For $\forall n\,\psi$, LPO at the set of n with $\neg\psi$ gives $\forall n\,\neg\neg\psi$, hence $\forall n\,\psi$ by the decisions, or a counterexample, hence $\neg\forall n\,\psi$. This is the argument of Theorem 6.10, with comprehension supplying the sets.

(2) The first claim is part 1 with Γ the hypotheses LPO and $\mathrm{Dec}(X)$. For the second, let $\mathrm{Dec}(X)$; the hypothesis gives $\mathrm{E}(X)$ or $\neg\mathrm{E}(X)$, and the second gives $\mathrm{Z}(X)$.

(3) The derivations are Lemma 7.41(2). The chain $0 < 1 < 2 < \cdots < \infty$ validates LPO (Section 7.12) and WEM, because in a chain $\neg a$ is $\top$ for $a = \bot$ and $\bot$ otherwise, so $\neg a \vee \neg\neg a = \top$; EM fails there. The *cone* has three points, two open points a, b and a focal point c whose only open neighbourhood is the whole space. Let $A : \mathbb{N} \to H$. The open point a lies in some A_n, hence in the value of $\mathrm{E}(X)$, or in none, and then the open set $\{a\}$ lies in the value of $\mathrm{Z}(X)$; the same holds for b. If c lies in the value of $\mathrm{Dec}(X)$, then for each n it lies in A_n, which is then the whole space, or in $\neg A_n$, which is then the whole space, so that A_n is empty; so c lies in the value of $\mathrm{E}(X)$, or $\mathrm{Z}(X)$ has the value $\top$. Hence LPO has the value $\top$. WEM fails at c: for $A_0 = \{a\}$, $\neg A_0 = \{b\}$ and $\neg\neg A_0 = \{a\}$, and their union misses c. So the cone refutes $\mathrm{LPO} \to \mathrm{WEM}$ and $\mathrm{LPO} \to \mathrm{LPO} \wedge \mathrm{WEM}$. Finally $\beta\mathbb{N}$ validates WEM and refutes LPO. □

Corollary 7.49 (The six prices are not all the prices)**.** *Between each of the following pairs of principles, HAS has a sentence that is derivable from the stronger, derives the weaker, and is equivalent to neither: none and MP (*$\mathrm{MP}^{\vee}$ *and* WMP*); none and LLPO (*$\mathrm{MP}^{\vee}$*); MP and LPO, and also LLPO and LPO (*$\mathrm{MP} \wedge \mathrm{LLPO}$*); LLPO and WLPO (*$\mathrm{LLPO} \wedge (\mathrm{WLPO} \vee \mathrm{MP})$*); WLPO and LPO (*$\mathrm{WLPO} \wedge (\mathrm{MP} \vee \mathrm{WEM})$*); LPO and EM (*$\mathrm{LPO} \wedge \mathrm{WEM}$*).*

Proof. Lemma 7.41 and conjunction elimination give the derivations (every sentence derives $\bot \to \bot$); Theorems 7.45 and 7.47 and Proposition 7.48 give the rest. □

The chart of prices is therefore neither a ladder nor a finite list. Not every candidate is new: Markov's principle for quantifier-free formulas of arithmetic is derivable in HAS (Theorem 6.9(3) and Lemma 7.16).

7.14 One halting question, priced instance by instance

Fix one program question: does program e return a value on input 0? The halting matrix $\theta(e, x)$ of Lemma E.11 says that it does so within allowance x. Each principle of this chapter then has one instance at θ, a single sentence of first-order arithmetic. The WLPO instance says that for every e the search for a halting time either fails everywhere or does not fail everywhere; the LPO instance says that it fails everywhere or finds a time. Does the first sentence derive the second in the calculus of Chapter 6?

The question is finer than the ones answered so far. Theorem 6.11 prices the three rules of Chapter 6 as schemas, and Theorems 7.38, 7.45 and 7.47 separate the principles of this chapter as schemas over all sets of intuitionistic second-order arithmetic. A separation of schemas

may use a different set at each step. Here the instance is fixed, the sentences have no set variables, and the derivations are those of Chapter 6, with their ledgers and every tier of induction. The answer is that the familiar separations survive instance by instance: WLPO gives neither LPO nor Markov's principle at θ, the bit principles give neither, LLPO gives neither WLPO nor LPO, and Markov's principle proper, unlike the quantifier-free rule of Theorem 6.9, has a price. Every separation is a model and a check; at the halting matrix the models are realizability interpretations, and each check ends with a program that cannot exist: one that decides whether programs halt [21], one that separates the programs returning 0 from those returning 1, or one that picks a halting program from every pair of which one halts. The section closes with the order of the weak arithmetic principles over HAS.

As in Section 7.12, the separations are theorems about a specified calculus, proved from outside it in classical mathematics.

Instances and letters

Definition 7.50 (Instances at a matrix)**.** Let $\varphi(e, x)$ be a formula of the arithmetic language whose free variables are among e and x. Its instances are the sentences

$$\begin{aligned}
\mathrm{MP}_\varphi &:\equiv \forall e\,\big(\neg\neg\exists x\,\varphi \to \exists x\,\varphi\big),\\
\mathrm{LPO}_\varphi &:\equiv \forall e\,\big(\forall x(\varphi \vee \neg\varphi) \to \exists x\,\varphi \vee \forall x\,\neg\varphi\big),\\
\mathrm{WLPO}_\varphi &:\equiv \forall e\,\big(\forall x(\varphi \vee \neg\varphi) \to \forall x\,\neg\varphi \vee \neg\forall x\,\neg\varphi\big),\\
\mathrm{LLPO}_\varphi &:\equiv \forall e\Big(\forall x(\varphi \vee \neg\varphi) \to \forall x\,\forall y\big(\varphi(e,x) \wedge \varphi(e,y) \to x = y\big)\\
&\qquad\qquad \to \forall x\,\neg\varphi(e, x + x) \vee \forall x\,\neg\varphi(e, S(x + x))\Big),\\
\mathrm{MP}^{\vee}_\varphi &:\equiv \forall e_1\,\forall e_2\,\Big(\neg\big(\neg\exists x\,\varphi(e_1,x) \wedge \neg\exists x\,\varphi(e_2,x)\big)\\
&\qquad\qquad \to \neg\neg\exists x\,\varphi(e_1,x) \vee \neg\neg\exists x\,\varphi(e_2,x)\Big).
\end{aligned}$$

The LPO instance is the universal closure of the LPO rule (6.4) at φ; $\mathrm{MP}^{\vee}_\varphi$ is the disjunctive Markov principle of Definition 7.39, read for two programs.

Two matrices carry the section. The first is the halting matrix θ. The second records the output. Let $\mathrm{out}_b(e, K)$ say, as $\theta(e, K)$ does, that some justified table claims a value at the cell $(K, e, 0)$, and that the value is b. Put

$$\begin{aligned}
\lambda(e,x) :\equiv \exists K\Big[&\big(K = 0 \vee \exists K'\,(K = S(K') \wedge \neg\theta(e,K'))\big)\\
&\wedge \big((x = K + K \wedge \mathrm{out}_0(e,K)) \vee (x = S(K + K) \wedge \mathrm{out}_1(e,K))\big)\Big].
\end{aligned}$$

By the proof of Lemma E.11, $\lambda(e, x)$ is true exactly when $x = 2K + b$, where K is the least allowance within which program e returns a value on input 0 and $b \in \{0, 1\}$ is that value. So $\lambda(e, \cdot)$ has at most one witness; it has an even one exactly when program e returns 0, and an odd one exactly when it returns 1. Its truth at (e, x) is decided by a program, which also computes a realizer when it is true. These are the two sets A_0, A_1 of programs that no program separates (proof of Theorem 12.22).

Definition 7.51 (Letters and Σ_1 formulas)**.** A *letter* of a principle P among MP, LPO, WLPO and LLPO is a sentence $\forall z_1 \cdots \forall z_n\, \psi$ where ψ is the body of the instance P_φ (the formula under $\forall e$, or under $\forall e_1 \forall e_2$) at some formula φ; the variables z_i close all its parameters. A Σ_1 *formula* is one built from equations and $\bot$ by $\wedge$, $\vee$, $\exists$ and bounded universal quantifiers $\forall y\big(\exists z\,(b + z = y) \vee \chi\big)$, with b a term free of y and z; such a formula contains no implication, hence no negation. The halting matrix θ is a Σ_1 formula: its bounded universal statements have exactly this form (Lemma E.11). A derivation *from letters* is a derivation of Chapter 6 whose context is a finite list of letters.

So MP_θ is an MP letter at a Σ_1 formula, and an LLPO or WLPO letter may sit at any formula at all. The rules of Chapter 6 add three facts that every proof below uses.

Lemma 7.52 (Three tools)**.**

1. *A derivation from letters whose EM and LPO entries are false can be rebuilt, with the same conclusion and context, as a derivation from the same letters with no added rule; the rebuilt derivation may use induction on formulas with quantifiers.*
2. *A derivation with no added rule is, read in the two-sorted language, a derivation in the theory of Theorem 12.22, from the same hypotheses.*
3. *Kleene realizability, modified realizability and Lifschitz realizability each carry realizers of the hypotheses of such a derivation to a realizer of its conclusion, by one program built along the derivation.*

Proof. (1) Each MP rule is at a quantifier-free body, and by Theorem 6.9(3) it has a derivation with no added rule; replace each MP leaf by that derivation, with the leaf's hypotheses added, as in Section 6.7. (2) The rules of Chapter 5, with induction on every formula, are rules of that theory for formulas without sequence variables, and its arithmetic axioms are the six arithmetic rules. (3) For Kleene realizability this is Theorem E.9; for modified realizability it is the construction in the proof of Theorem 12.22; for Lifschitz realizability it is Lemma 12.69. □

Markov's principle proper has a price

Theorem 6.9 showed that the Markov rule of Chapter 6, restricted to quantifier-free bodies, costs nothing once induction on quantified formulas is allowed: such a body is eventually constant, so its search is bounded in advance. At the halting matrix the search is not bounded, and the price returns.

Theorem 7.53 (Markov's principle at the halting matrix)**.**

1. MP_θ *has no derivation whose EM and LPO entries are false, whatever its induction; in particular none with false EM, LPO and MP entries.*
2. *Read in the two-sorted language,* MP_θ *is not a theorem of the theory of Theorem 12.22, intuitionistic arithmetic with sequences and countable choice for numbers and for sequences.*
3. *Every MP letter at a* Σ_1 *formula,* MP_θ *among them, has a derivation whose ledger is exactly* {EM}*: one EM rule and no induction on a formula with quantifiers.*

Conditions and scope.

Base and premises

The calculus of Chapter 6 with its ledger; the halting matrix θ; for part 2, the theory of Theorem 12.22. Parts 1 and 2 are proved in classical mathematics about these systems.

Conclusion

In the levels of Theorem 6.11, MP_θ sits at level 1 exactly: every derivation of it has a true EM or LPO entry, whatever its induction; one EM rule suffices; countable choice does not supply it. As a hypothesis it stays strictly below EM (Theorem 7.54).

Proof. (3) Let the letter be $\forall \vec{z}\,(\neg\neg\exists x\,\varphi \to \exists x\,\varphi)$. Assume $\neg\neg\exists x\,\varphi$. The EM rule at $\exists x\,\varphi$ gives $\exists x\,\varphi$ or $\neg\exists x\,\varphi$; the second meets the assumption and yields $\bot$, hence $\exists x\,\varphi$. Implication and universal introduction add no rule.

(1) and (2). By Lemma 7.52(1) and (2), a derivation as in (1) gives a theorem of the theory of Theorem 12.22, so it suffices to prove (2): every theorem of that theory has a modified realizer, and we show that MP_θ has none. The argument is the one that refutes $\mathrm{MP}_{\mathrm{bin}}$ there, at θ. Suppose r realizes MP_θ. Then $\{r\}(e)$ lies in the type of $\neg\neg\exists x\,\theta \to \exists x\,\theta$, and 0 lies in every type, so $m(e) = (\{\{r\}(e)\}(0))_0$ is a total computable function of e. If program e halts on input 0, then $\exists x\,\theta(e,x)$ is true; a realizer of θ makes it true, since θ has no implication (Lemma E.8), so $\neg\exists x\,\theta(e,x)$ has no realizer and every element of its type, 0 included, realizes $\neg\neg\exists x\,\theta(e,x)$. Then $\{\{r\}(e)\}(0)$ realizes $\exists x\,\theta(e,x)$, and $\theta(e,m(e))$ is true. So program e halts exactly when $\theta(e,m(e))$ holds, which a program decides by property (iii) of the halting matrix. No program decides halting. □

Kleene's reading realizes MP_θ by search, as in the proof of Theorem 6.11; the separation needs the modified reading, whose realizers must answer on every input of their type.

Theorem 7.54 (Σ_1 Markov letters reach no bit principle)**.** *Let Γ be a finite list of MP letters at Σ_1 formulas. No derivation from Γ whose EM and LPO entries are false concludes LPO_θ, WLPO_θ or LLPO_λ; quantifier-free MP rules and induction on every formula are allowed. In contrast, for every quantifier-free φ the instance LPO_φ has a derivation with no added rule.*

Conditions and scope.

Base and premises

The calculus of Chapter 6; hypotheses that are MP letters at Σ_1 formulas. Proved in classical mathematics about the calculus.

Conclusion

With Theorem 7.53, the price of MP_θ lies strictly between free and EM, and no finite list of Σ_1 Markov letters buys any of LPO_θ, WLPO_θ or LLPO_λ. At a quantifier-free matrix even LPO is free.

Proof. Every Σ_1 Markov letter has a Kleene realizer. For a true Σ_1 formula a program finds a realizer from the values of its free variables: it searches, in parallel, over witnesses for the existential quantifiers and over the steps of the subcomputations; equations are checked, a

disjunction returns the first side found true, and a bounded universal statement returns the program that, for y below the bound, runs the search for its matrix at y, which halts because the matrix is true there. The search halts exactly when the formula is true. So the letter is realized by the program that ignores the realizer of $\neg\neg\exists x\varphi$ and searches for an x at which φ is true together with its realizer: a realizer of $\neg\neg\exists x\varphi$ exists only if $\exists x\varphi$ is realized, hence true (a Σ_1 formula has no implication, so its realizers make it true), and then the search halts.

The three instances have no Kleene realizer. For LPO_θ this is the proof of Theorem 6.11: a realizer, applied to the computable realizers of $\forall x(\theta \vee \neg\theta)$, gives a tag that decides halting. For WLPO_θ the tag decides halting in the same way, as in the proof of Theorem 12.22: a tag for $\neg\forall x\neg\theta(e,x)$ comes with a realizer of that negation, so $\forall x\neg\theta(e,x)$ is false and program e halts. For LLPO_λ, the premise that $\lambda(e,\cdot)$ has at most one witness is true, and it has a realizer that does not depend on e, since a realizer of $\lambda(e,x)$ makes it true (its only negation is of θ, which a program decides); applied to e, to the computable realizer of $\forall x(\lambda \vee \neg\lambda)$ and to that realizer, a realizer of LLPO_λ gives a tag that is a total computable function $d(e)$, and if program e returns 0 the first side is false, so $d(e) \neq 0$, while if it returns 1 the second side is false, so $d(e) = 0$. That separates A_0 from A_1, which no program does.

By Lemma 7.52(3), Theorem E.9 with the letters as hypotheses, a derivation as in the theorem would give a Kleene realizer of its conclusion. For the last assertion: the proof of Theorem 6.9(3) derives $\exists x\varphi \vee \forall x\neg\varphi$ for quantifier-free φ with no added rule (the step called the alternative), and implication and universal introduction give LPO_φ. □

WLPO gives neither LPO nor Markov's principle

HAS derives LPO from WLPO and MP (Proposition 7.35), and the same derivation works at one matrix: WLPO_θ gives $\forall x\neg\theta$ or $\neg\forall x\neg\theta$, the second is $\neg\neg\exists x\theta$, and MP_θ turns it into $\exists x\theta$. So a model that separates WLPO_θ from LPO_θ must also refute MP_θ, and it must supply the halting bit, which WLPO_θ asks for, without supplying the search, which MP_θ asks for. Kleene's reading supplies the search; the modified reading of Theorem 12.22 refutes the bit. The model that works keeps the bit and bounds what can be done with it.

Theorem 7.55 (WLPO gives neither LPO nor MP at the halting matrix)**.** *Neither* $\mathrm{WLPO}_\theta \to \mathrm{LPO}_\theta$ *nor* $\mathrm{WLPO}_\theta \to \mathrm{MP}_\theta$ *has a derivation whose EM and LPO entries are false, whatever its induction; quantifier-free MP rules are allowed. Both* $\mathrm{LPO}_\theta \to \mathrm{WLPO}_\theta$ *and* $\mathrm{WLPO}_\theta \wedge \mathrm{MP}_\theta \to \mathrm{LPO}_\theta$ *have derivations with no added rule.*

Conditions and scope.

Base and premises
The calculus of Chapter 6, at every tier of induction. The non-derivations are proved in classical mathematics, with modified realizability by terms of Gödel's system T and Howard's majorizability.

Conclusion
At the halting matrix, WLPO lies strictly below LPO, and it does not reach Markov's principle.

Proof. The two derivations: a witness of $\exists x\,\theta$ refutes $\forall x\,\neg\theta$, which gives the first; the second is the argument above the theorem.

By Lemma 7.52(1), a derivation whose EM and LPO entries are false can be rebuilt with no added rule, so it suffices to treat derivations with no added rule.

The model. Kreisel's modified realizability can take its realizers among all functionals of finite type over the natural numbers, with the closed terms of Gödel's system T [70] as the programs. Every derivation of Heyting arithmetic from hypotheses gives a closed term of T that turns realizers of the hypotheses into a realizer of the conclusion, whatever functionals the realizers of the hypotheses are [6]. By Remark 6.12 a derivation with no added rule is a derivation of Heyting arithmetic, at any tier of induction. The second ingredient is Howard's *majorizability*, in Bezem's strong form [207, 208, 56]: a number a^* majorizes a when $a^* \geq a$, and a functional f^* majorizes f when, for all arguments, a^* majorizing a gives $f^*(a^*)$ majorizing $f(a)$ and $f^*(a)$. Every closed term of T is majorized by a closed term of T, and a functional majorized by a computable one applied to majorized arguments gives a value majorized by the computable value.

The check for LPO. Suppose a derivation gives a closed term R realizing $\mathrm{WLPO}_\theta \to \mathrm{LPO}_\theta$. Let $h(e)$ be 1 if program e halts on input 0 and 0 otherwise; h is not computable. The functional W that, at e and any decision realizer, returns the tag $h(e)$ with the zero realizer, realizes WLPO_θ: if $h(e) = 0$, every $\theta(e, x)$ is false, hence unrealized, so the zero realizes $\forall x\,\neg\theta(e, x)$; if $h(e) = 1$, that formula is false and unrealized, so the zero realizes its negation. And W is majorized by the computable functional that returns the tag 1. Property (iii) of the halting matrix gives a computable functional D with $D(e)$ realizing $\forall x(\theta(e, x) \vee \neg\theta(e, x))$, with a computable majorant. Now $R(W)(e)(D(e))$ realizes $\exists x\,\theta(e, x) \vee \forall x\,\neg\theta(e, x)$. If program e halts, the second side is false and has no realizer, so the realizer takes the first side, and its witness $x(e)$ satisfies $\theta(e, x(e))$. By majorizability $x(e) \leq g(e)$ for a computable function g, obtained by applying a majorant of R to the majorants of W and D. So program e halts exactly when $\theta(e, x)$ holds for some $x \leq g(e)$, which a program decides. That is impossible.

The check for MP. With a closed term R realizing $\mathrm{WLPO}_\theta \to \mathrm{MP}_\theta$, apply $R(W)(e)$ to the zero. If program e halts, the zero realizes $\neg\neg\exists x\,\theta(e, x)$, as in the proof of Theorem 7.53, and the output's witness is a halting time, again bounded by a computable function of e. □

The same model treats every principle whose computational content is a bit.

Theorem 7.56 (Bit letters give neither MP nor LPO)**.** *Let Γ be a finite list of LLPO letters and WLPO letters, at any formulas. No derivation from Γ whose EM and LPO entries are false concludes MP_θ or LPO_θ; quantifier-free MP rules and induction on every formula are allowed. In particular LLPO letters at Σ_1 formulas give neither.*

Conditions and scope.

Base and premises

The calculus of Chapter 6; hypotheses that are LLPO or WLPO letters at arbitrary formulas. Proved in classical mathematics, in the model of Theorem 7.55.

Conclusion

However many yes-or-no answers of the LLPO and WLPO kind are supplied, at whatever formulas, they buy neither Markov's principle nor LPO at the halting matrix.

Proof. By Lemma 7.52(1) we may assume no added rule. Each letter is realized by a functional majorized by a computable one. For a WLPO letter at φ, at given values of its parameters and of e, return the tag 0 when no instance $\varphi(e, x)$ is realized, and 1 otherwise, with the zero realizer: in the first case the zero realizes $\forall x \neg\varphi$, and in the second $\forall x \neg\varphi$ has no realizer, so the zero realizes its negation. For an LLPO letter, return 0 when no $\varphi(e, x + x)$ is realized and 1 otherwise. In the second case some $\varphi(e, x + x)$ is realized; a realizer of the premise that φ has at most one witness turns realizers of $\varphi(e, x + x)$ and $\varphi(e, S(y + y))$ into a realizer of the false equation $x + x = S(y + y)$, so no $\varphi(e, S(y + y))$ is realized and the zero realizes the second side. Each functional returns a bit and zeros, so it is majorized by the functional returning 1 and zeros. The checks of the proof of Theorem 7.55 then bound the witness of MP_θ or of LPO_θ by a computable function of e when program e halts. □

LLPO gives neither WLPO nor LPO

Kleene's reading and the reading by terms of T treat all bits alike, so neither can separate LLPO from WLPO. Lifschitz realizability can (Definition 12.68): a realizer of a disjunction may leave two candidates open, which is exactly what LLPO needs and WLPO forbids.

Theorem 7.57 (LLPO letters give neither WLPO nor LPO)**.** *Let Γ be a finite list of LLPO letters at any formulas and MP letters at Σ_1 formulas. No derivation from Γ whose EM and LPO entries are false concludes WLPO_θ or LPO_θ; quantifier-free MP rules and induction on every formula are allowed. In particular $\mathrm{LLPO}_\lambda \to \mathrm{WLPO}_\theta$ has no derivation whose EM, LPO and MP entries are false.*

Conditions and scope.

Base and premises

The calculus of Chapter 6; hypotheses that are LLPO letters at arbitrary formulas and Markov letters at Σ_1 formulas. Proved in classical mathematics with Lifschitz realizability.

Conclusion

At the halting matrix, LLPO_λ does not reach WLPO_θ or LPO_θ, and adding Markov letters at Σ_1 formulas does not close the gap.

Proof. By Lemma 7.52 the derivation becomes one in the theory of Theorem 12.22, from the same letters, and Lemma 12.69 carries Lifschitz realizers of the letters to one of the conclusion.

The letters are realized. A Σ_1 Markov letter is realized by the search of Theorem 7.54, its answer returned as a singleton. For an LLPO letter at φ, take the given realizer of $\forall x(\varphi \vee \neg\varphi)$ and return the number whose two candidates are the answers "no even witness" and "no odd witness", each with the zero realizer, and whose program searches, dovetailing over x and over steps, for an x at which every number up to the bound of the decision realizer at x whose tag is not 0 has been struck, then strikes the even answer if x is even and the odd one if x is odd. Such an x is found exactly when $\varphi(e, x)$ is realized: the decision realizer always keeps a

candidate, every candidate is correct, and when $\varphi(e, x)$ is realized its negation is not, so every number with a nonzero tag is struck. By the premise there is at most one such x, so at most one candidate is struck, and every candidate left is correct.

WLPO and LPO at θ are not. Suppose $\{r\}(e)$, applied to the computable decision realizer $D(e)$, realizes $\forall x \neg\theta(e, x) \vee \neg\forall x \neg\theta(e, x)$ for every e; it is a pair (p, b) whose candidates $k \leq b$ all carry the correct tag. If program e halts, every candidate has the tag 1, so every $k \leq b$ with tag 0 is struck after finitely many steps; if it never halts, every $k \leq b$ with tag 1 is struck. Since there is a candidate, exactly one of these two finite waits ends. Running both decides halting, which no program does. The argument for LPO_θ is the same, with the tags of $\exists x\,\theta$ and $\forall x \neg\theta$. □

Two disjunctions that cost something

A disjunction of two instances is weaker than either. Is it free? Not here.

Theorem 7.58 (Two meets are not free)**.** *Neither* $\mathrm{WLPO}_\theta \vee \mathrm{MP}_\theta$ *nor* $\mathrm{LLPO}_\lambda \vee \mathrm{MP}_\theta$ *has a derivation whose EM and LPO entries are false, while each follows from each of its disjuncts with an empty ledger. Read in the two-sorted language,* LLPO_λ *is not a theorem of the theory of Theorem 12.22.*

Proof. Disjunction introduction gives each disjunction from each disjunct. By Lemma 7.52 a derivation with false EM and LPO entries gives a theorem of the theory of Theorem 12.22, which has a modified realizer, and a modified realizer of a disjunction carries a tag and a realizer of the side it names. MP_θ has no modified realizer (Theorem 7.53). WLPO_θ has none: its tag would decide halting, by the argument of Theorem 12.22. LLPO_λ has none: a realizer of $\lambda(e, x)$ makes it true (its only negation is of a formula decided by a program), so the premise that $\lambda(e, \cdot)$ has at most one witness is realized by the zero. A realizer of LLPO_λ, applied to e, to the computable realizer of $\forall x(\lambda(e, x) \vee \neg\lambda(e, x))$ and then to the zero, gives a tag, and that tag would be a total computable function of e separating A_0 from A_1. So neither disjunction has a modified realizer, and LLPO_λ is not a theorem of that theory. □

The disjunctive Markov principle at the halting matrix

$\mathrm{MP}_\theta^\vee$ says: if two programs cannot both run forever, then one of them cannot fail to halt. It asks for a choice between two programs, not for a halting time.

Theorem 7.59 (The price of the disjunctive Markov principle)**.**

1. $\mathrm{MP}_\theta^\vee$ *has no derivation whose EM and LPO entries are false, and read in the two-sorted language it is not a theorem of the theory of Theorem 12.22.*
2. *It has a derivation whose ledger is exactly* {EM}*, and one whose EM and MP entries are false; the second uses LPO rules and induction on formulas with quantifiers.*
3. *It has a derivation with an empty ledger from one MP letter, the letter at the* Σ_1 *formula* $\theta(e_1, x) \vee \theta(e_2, x)$*.*
4. *From* $\mathrm{MP}_\theta^\vee$ *and MP letters at* Σ_1 *formulas, no derivation whose EM and LPO entries are false concludes* WLPO_θ*,* LLPO_λ *or* LPO_θ*; with LLPO letters at any formulas added, none concludes* WLPO_θ *or* LPO_θ*.*

5. *From* $\mathrm{MP}^{\vee}_{\theta}$*, LLPO letters and WLPO letters at any formulas, no derivation whose EM and LPO entries are false concludes* MP_{θ} *or* LPO_{θ}*.*

Conditions and scope.

Base and premises

The calculus of Chapter 6; the halting matrix; the hypotheses named in each part. The non-derivations are proved in classical mathematics.

Conclusion

At the halting matrix, $\mathrm{MP}^{\vee}$ is not free, lies strictly below the Σ_1 Markov letter at $\theta(e_1, x) \vee \theta(e_2, x)$ (parts 3 and 5; that letter gives MP_{θ} when $e_1 = e_2$), is supplied by EM or by LPO, and with Markov letters buys none of the bit instances. Whether MP_{θ} gives it is open (Remark 7.63(4)).

Proof. (3) Assume $\neg(\neg\exists x\,\theta(e_1, x) \wedge \neg\exists x\,\theta(e_2, x))$. A witness of $\exists x(\theta(e_1, x) \vee \theta(e_2, x))$ would give one of the two existentials, so the negation of that existential gives both negations, against the assumption: we have $\neg\neg\exists x(\theta(e_1, x) \vee \theta(e_2, x))$. The MP letter at the Σ_1 formula $\theta(e_1, x) \vee \theta(e_2, x)$, with e_1, e_2 as its parameters, gives the existential; a case split on its witness gives $\exists x\,\theta(e_1, x)$ or $\exists x\,\theta(e_2, x)$, and each gives its double negation. No added rule and no induction is used.

(2) The EM rule at $\exists x\,\theta(e_1, x)$ gives the first side, or $\neg\exists x\,\theta(e_1, x)$; in that case the assumption gives $\neg\neg\exists x\,\theta(e_2, x)$. For the second derivation, replace the EM rule by its derivation from LPO rules (Theorem 6.10), which uses induction on formulas with quantifiers.

(1) As in Theorem 7.58, it suffices that $\mathrm{MP}^{\vee}_{\theta}$ has no modified realizer. A realizer, applied to e_1, e_2 and to the zero, gives a total computable tag $t(e_1, e_2)$. If at least one of the two programs halts, the premise is true and has no realizable negation, so the zero realizes it, and the tag names a side whose double negation is realized, that is, a program that halts. So t would be a total computable selector that picks a halting program from every pair of which one halts. None exists. By Kleene's recursion theorem for two programs [19, Chapter XII] there are programs a and b such that a computes $t(a, b)$ and halts if it is not 0, and loops otherwise, while b computes $t(a, b)$ and halts if it is 0, and loops otherwise. Exactly one of a, b halts, and $t(a, b)$ names the other.

(4) $\mathrm{MP}^{\vee}_{\theta}$ has a Kleene realizer: on e_1, e_2 and a realizer of the premise, run the two programs in parallel and return the side of the first that halts. A realizer of the premise exists only if one of them halts, so the search ends there. With Theorem 7.54 this gives the first claim. For the second, the same parallel search, returned as a singleton, is a Lifschitz realizer, and Theorem 7.57 applies. Both claims also follow from part 3, by cutting in its derivation for each hypothesis $\mathrm{MP}^{\vee}_{\theta}$.

(5) $\mathrm{MP}^{\vee}_{\theta}$ is realized in the model of Theorem 7.55 by a bit: at e_1, e_2 return the tag 0 when some $\theta(e_1, x)$ is realized and 1 otherwise, with the zero realizer; when the premise is realized and no $\theta(e_1, x)$ is, some $\theta(e_2, x)$ is, and the zero realizes the second side. This functional is majorized by the one returning 1, and Theorem 7.56 realizes the letters; the checks of Theorem 7.55 finish. □

Table 7.5 collects the non-derivations at the halting matrix. Each matches a separation of the schemas over HAS (Table 7.4), here proved one sentence at a time and against every induction tier of the calculus. Of the positive steps of Table 7.4, only those listed under the table are proved at the instances. The others are not settled here: Remark 7.63 lists $\mathrm{LPO}_\theta \to \mathrm{MP}_\theta$, $\mathrm{WLPO}_\theta \to \mathrm{MP}^\vee_\theta$ and $\mathrm{MP}_\theta \to \mathrm{MP}^\vee_\theta$, and neither $\mathrm{WLPO}_\theta \to \mathrm{LLPO}_\lambda$ nor $\mathrm{LLPO}_\lambda \to \mathrm{MP}^\vee_\theta$ is derived in this book.

From (with false EM and LPO entries)	Not derived	Model
nothing	MP_θ, $\mathrm{MP}^\vee_\theta$	modified realizability
Σ_1 MP letters, $\mathrm{MP}^\vee_\theta$	LPO_θ, WLPO_θ, LLPO_λ	Kleene realizability
WLPO_θ	LPO_θ, MP_θ	T and majorants
LLPO and WLPO letters, $\mathrm{MP}^\vee_\theta$	MP_θ, LPO_θ	T and majorants
LLPO letters, Σ_1 MP letters, $\mathrm{MP}^\vee_\theta$	WLPO_θ, LPO_θ	Lifschitz realizability
nothing	$\mathrm{WLPO}_\theta \vee \mathrm{MP}_\theta$, $\mathrm{LLPO}_\lambda \vee \mathrm{MP}_\theta$	modified realizability

Table 7.5. What does not follow at the halting matrix, in the calculus of Chapter 6 with quantifier-free MP rules and induction on every formula (Theorems 7.53–7.59). The positive steps proved at the instances: one EM rule gives MP_θ and $\mathrm{MP}^\vee_\theta$; one Σ_1 Markov letter gives $\mathrm{MP}^\vee_\theta$; LPO_θ gives WLPO_θ; WLPO_θ and MP_θ together give LPO_θ.

The successor step costs what equality costs

The empty ledger allows induction on quantifier-free formulas only. Proposition 6.14 showed that it does not decide equality. The induction that would decide it runs on y for the formula $x = y \vee \neg(x = y)$; its base $x = 0 \vee \neg(x = 0)$ is free, by a quantifier-free induction on x. What does its step cost?

Proposition 7.60 (The price of the successor step)**.** *Let* $\sigma(x)$ *be* $\forall y\big((x = y \vee \neg(x = y)) \to (x = S(y) \vee \neg(x = S(y)))\big)$.

1. *$\sigma(x)$ has no derivation whose EM, MP and induction entries are false, even with LPO rules permitted.*
2. *It has a derivation whose ledger is exactly* {EM} *and one whose ledger is exactly* {MP}*, neither containing an induction rule; and one with no added rule, which uses induction on a formula with quantifiers.*

In particular the posit-free derivation with quantifier-free induction that one might expect for this one-step formula does not exist.

Proof. (2) Each conclusion $x = S(y) \vee \neg(x = S(y))$ is an EM instance, and the remark after Theorem 6.10 derives it from one MP rule at a quantifier-free body, with no induction. With induction on every formula, (6.9) gives it with no added rule.

(1) Suppose such a derivation of $\sigma(x)$. Induction on y for the quantifier-free formula $x = y \vee \neg(x = y)$ takes the base $x = 0 \vee \neg(x = 0)$, which quantifier-free induction on x derives by the split into zero and successor, and the step $\sigma(x)$ with its universal quantifier eliminated; it

gives $\forall y(x = y \vee \neg(x = y))$, and universal introduction gives $\forall x\,\forall y(x = y \vee \neg(x = y))$. The added inductions are quantifier-free, so the ledger keeps false EM, MP and induction entries. Proposition 6.14 shows that no such derivation exists. □

Weak excluded middle for Σ^0_2 and Π^0_2 statements, and the shift

Back to schemas over HAS. Chapter 28 shows that WLPO gives neither Π^0_2 weak excluded middle nor its shift (Theorem 28.32). Where do these principles sit, and what of the corresponding statement one quantifier lower?

Definition 7.61 (Three more principles over HAS)**.** With $\langle N, m\rangle = (N + m)\cdot(N + m) + m$, $\mathrm{Row}(X, N)$ and $\mathrm{All}(X)$ as in Definition 28.31, put $\mathrm{Gap}(X) :\equiv \exists N\forall m\,\neg\langle N, m\rangle \in X$ (some row is empty) and

$$\Sigma^0_2\text{-WEM} :\equiv \forall X\big(\mathrm{Dec}(X) \to \neg\mathrm{Gap}(X) \vee \neg\neg\mathrm{Gap}(X)\big),$$
$$\mathrm{DNS}_{\mathrm{ar}} :\equiv \forall X\big(\mathrm{Dec}(X) \to \forall N\neg\neg\mathrm{Row}(X, N) \to \neg\neg\mathrm{All}(X)\big).$$

$\mathrm{DNS}_{\mathrm{ar}}$ is the double-negation shift for the rows of a decidable matrix: if no row can fail to have an entry, then it cannot fail that every row has one.

Theorem 7.62 (The order of the weak arithmetic principles)**.** *Over intuitionistic second-order arithmetic:*

1. *HAS derives* $\mathrm{WLPO} \leftrightarrow \Sigma^0_2\text{-WEM}$, $\Pi^0_2\text{-WEM} \to \mathrm{WLPO}$ *and* $\mathrm{MP} \to \mathrm{DNS}_{\mathrm{ar}}$.
2. *HAS derives none of* $\mathrm{WLPO} \to \mathrm{DNS}_{\mathrm{ar}}$, $\Pi^0_2\text{-WEM} \to \mathrm{DNS}_{\mathrm{ar}}$ *and* $\mathrm{WLPO} \wedge \mathrm{DNS}_{\mathrm{ar}} \to \mathrm{LPO}$.
3. *Consequently*

$$\mathrm{WLPO} \;<\; \Pi^0_2\text{-WEM} \;<\; \mathrm{WLPO} \wedge \mathrm{DNS}_{\mathrm{ar}} \;<\; \mathrm{LPO},$$

where each principle derives the one before it and none derives the one after it; $\mathrm{DNS}_{\mathrm{ar}}$ *is comparable with neither WLPO nor* Π^0_2*-WEM; MP derives* $\mathrm{DNS}_{\mathrm{ar}}$ *but not conversely, and is comparable with none of WLPO,* Π^0_2*-WEM and* $\mathrm{WLPO} \wedge \mathrm{DNS}_{\mathrm{ar}}$*; and* $\Pi^0_2\text{-WEM} \wedge \mathrm{DNS}_{\mathrm{ar}}$ *does not derive LPO.*

Conditions and scope.

Base and premises
HAS (Definition 7.14) and its systems of truth values (Definition 7.19). The non-derivations are proved in classical mathematics with the axiom of choice.

Conclusion
Σ^0_2 weak excluded middle is WLPO; Π^0_2 weak excluded middle lies strictly between WLPO and LPO; the shift for rows lies below MP and is independent of WLPO.

Proof. (1) *WLPO gives* Σ^0_2*-WEM.* Let X be decidable, let Y_N be the set of m with $\langle N, m\rangle \in X$, and let comprehension give the set B of the N with $\mathrm{Z}(Y_N)$. WLPO at each Y_N makes B decidable, and $\mathrm{Gap}(X)$ is $\mathrm{E}(B)$. WLPO at B gives $\mathrm{Z}(B)$, hence $\neg\mathrm{Gap}(X)$, or $\neg\mathrm{Z}(B)$, which is $\neg\neg\mathrm{Gap}(X)$.

Σ^0_2-WEM gives WLPO. Let X be decidable and let M be the set of n such that some $k < n$ lies in X; it is decidable by a bounded search. Then $\mathrm{Z}(X) \leftrightarrow \mathrm{Gap}(M)$. If X is empty, so is M, and row 0 is empty. If row N of M is empty and $k \in X$, then $\langle N, S(k)\rangle \in M$, because $k < S(k) \le \langle N, S(k)\rangle$. So $\neg\mathrm{Gap}(M) \vee \neg\neg\mathrm{Gap}(M)$ gives $\neg\mathrm{Z}(X) \vee \neg\neg\mathrm{Z}(X)$, and $\neg\neg\mathrm{Z}(X)$ gives $\mathrm{Z}(X)$.

Π^0_2-WEM gives WLPO. Use the complement M' of M, the set of n with no $k < n$ in X. Then $\mathrm{Z}(X) \leftrightarrow \mathrm{All}(M')$. If X is empty, $\langle N, 0\rangle \in M'$ for every N. If every row of M' has an entry and $k \in X$, row $S(k)$ has an entry $\langle S(k), m\rangle$, and $k < \langle S(k), m\rangle$: with $s = S(k) + m$ we have $S(k) \le s \le s \cdot s \le s \cdot s + m$. So the entry is not in M', a contradiction. Weak excluded middle for $\mathrm{All}(M')$ then decides $\mathrm{Z}(X)$ weakly, as before.

MP gives $\mathrm{DNS}_{\mathrm{ar}}$. Each Y_N is decidable and, by hypothesis, not empty up to double negation, so MP gives a member; hence $\mathrm{All}(X)$, and its double negation. This is the first step of the proof of Proposition 28.33.

(2) By Lemma 7.21 each claim needs one system of truth values.

WLPO without the shift. HAS derives $\mathrm{DNS}_{\mathrm{ar}} \to$ Shift, since the shift's conclusion $\neg\mathrm{All}(X) \vee \neg\neg\mathrm{All}(X)$ is a weakening of $\neg\neg\mathrm{All}(X)$. The bounding frame of Theorem 28.32 gives WLPO the value $\top$ and Shift another value, so $\mathrm{DNS}_{\mathrm{ar}}$ has a value other than $\top$ there.

Π^0_2-WEM without the shift: a new frame. Order the finite bit strings by extension, and call a set of strings *open* when it contains every extension of each of its members; the cone $[s]$ of a string s is the set of its extensions. An open set is *regular* when it equals the set of strings all of whose extensions have an extension in it. The regular open sets form a Boolean algebra R, with meet the intersection and complement a^{c} the set of strings with no extension in a; the join of a and b is the complement of $a^{\mathrm{c}} \cap b^{\mathrm{c}}$. The *ideals* of R, the sets of elements closed under finite joins and under passing to smaller elements, form a system of truth values I, ordered by inclusion: meet is intersection, the join of a family is the ideal it generates, and the distributive law (7.12) holds, because an element of $a \wedge \bigvee_j b_j$ lies below a finite join of elements of the b_j and its meet with each of them lies in a. We use three facts.

(i) *Weak excluded middle holds in I for every formula.* Let J be an ideal, and let u be the set of strings all of whose extensions have an extension in some member of J. Then u is regular, and an element of R disjoint from every member of J is disjoint from u. So the principal ideal of u^{c} lies in $\neg J$ and that of u in $\neg\neg J$; their join contains $u \vee u^{\mathrm{c}}$, the top element. Hence $\neg J \vee \neg\neg J$ is the top ideal for every J, and in particular Π^0_2-WEM has the value $\top$.

(ii) *A matrix with dense rows.* Number the bit strings as $s_0, s_1, \ldots$. Row N has the entries $c_{N,0}$, the regular set of strings incompatible with s_N, and $c_{N,k+1} = [s_N 0^k 1]$ for $k \ge 0$. Value $\langle N, m\rangle \in X$ by the principal ideal of $c_{N,m}$ and every other number by the zero ideal. A principal ideal and the principal ideal of the complement are disjoint and join to the top, so $\mathrm{Dec}(X)$ has the value $\top$. An element disjoint from every entry of row N lies in $[s_N]$ and misses every $[s_N 0^k 1]$, so it contains no cone and is empty; hence $\neg\mathrm{Row}(X, N)$ is the zero ideal and $\neg\neg\mathrm{Row}(X, N)$ is the top, for every N.

(iii) *The rows meet in zero.* The value of $\mathrm{All}(X)$ is the largest ideal below every row join. A nonzero element a in it contains a cone $[s_N]$ and lies below some finite join $c_{N,0} \vee \cdots \vee c_{N,M}$ of row N. But the cone of $s_N 0^M$ lies in a and misses each of these entries, hence their join. So $\mathrm{All}(X)$ has the zero value, $\neg\neg\mathrm{All}(X)$ is the zero ideal, and the instance of $\mathrm{DNS}_{\mathrm{ar}}$ at X has the

value $\top \Rightarrow \bot = \bot$.

WLPO with the shift, without LPO. Take the open sets of $\beta\mathbb{N}$ (Section 7.12). WLPO has the value $\top$ and LPO does not (Table 7.2). Every nonempty open set contains an isolated point $\{n\}$, an atom of the system of truth values. In such a system, $\bigwedge_N \neg\neg r_N \leq \neg\neg \bigwedge_N r_N$ for every countable family: otherwise an atom $\{n\}$ lies below every $\neg\neg r_N$ and below $\neg \bigwedge_N r_N$; an atom below $\neg\neg r_N$ meets r_N, hence lies in it, so it lies in every r_N, hence in their meet, which contradicts the last inequality. With r_N the value of $\mathrm{Row}(X, N)$, the value of $\mathrm{All}(X)$ is $\bigwedge_N r_N$, so the hypotheses of every instance of $\mathrm{DNS}_{\mathrm{ar}}$ lie below its conclusion, and $\mathrm{DNS}_{\mathrm{ar}}$ has the value $\top$.

(3) The derivations: (1); LPO $\to$ WLPO and LPO $\to$ MP (Proposition 7.35) with MP $\to \mathrm{DNS}_{\mathrm{ar}}$; and WLPO $\wedge\, \mathrm{DNS}_{\mathrm{ar}} \to \Pi^0_2$-WEM, from WLPO $\to$ (Shift $\to \Pi^0_2$-WEM) (Proposition 28.33) and $\mathrm{DNS}_{\mathrm{ar}} \to$ Shift. The steps are strict: the bounding frame validates WLPO and not Π^0_2-WEM (Theorem 28.32); the frame I validates Π^0_2-WEM and not $\mathrm{DNS}_{\mathrm{ar}}$; and $\beta\mathbb{N}$ validates WLPO $\wedge$ $\mathrm{DNS}_{\mathrm{ar}}$, and with it Π^0_2-WEM, and not LPO. The one-point compactification of an uncountable set validates MP, hence $\mathrm{DNS}_{\mathrm{ar}}$, and not WLPO, hence not Π^0_2-WEM; $\beta\mathbb{N}$ validates WLPO, Π^0_2-WEM and $\mathrm{DNS}_{\mathrm{ar}}$ and not MP. These, with (2), give every incomparability claimed. □

Remark 7.63 (Open questions at the halting matrix)**.** Four questions about the instances are not settled here. Each asks for a derivation with no added rule, that is, with false EM, LPO and MP entries, at any tier of induction.

1. *Decidability of the halting matrix.* Does $\forall e\, \forall x\, (\theta(e, x) \vee \neg\theta(e, x))$ have a derivation with no added rule? Its truth is decided by a program (Lemma E.11(iii)); the question is whether the calculus derives that decision.

2. *LPO and Markov's principle at θ.* Does $\mathrm{LPO}_\theta \to \mathrm{MP}_\theta$ have a derivation with no added rule? A positive answer to question 1 gives one, by a derivation with no added rule and no induction: under the decision of θ, the LPO instance either produces a witness or refutes $\neg\neg\exists x\, \theta$. With it, LPO_θ would be exactly $\mathrm{WLPO}_\theta \wedge \mathrm{MP}_\theta$.

3. *WLPO and the disjunctive Markov principle at θ.* Does $\mathrm{WLPO}_\theta \to \mathrm{MP}^\vee_\theta$ have a derivation with no added rule? A positive answer to question 1 gives one, with no added rule and no induction.

4. *Markov's principle and its disjunctive half at θ.* Does $\mathrm{MP}_\theta \to \mathrm{MP}^\vee_\theta$ have a derivation with no added rule? If both this and question 3 have positive answers, $\mathrm{MP}^\vee_\theta$ follows from each of WLPO_θ and MP_θ while it is not free (Theorem 7.59), so it lies in the meet of the two.

The calculus does derive $\mathrm{MP}^\vee_\theta$ from the single Σ_1 Markov letter at $\theta(e_1, x) \vee \theta(e_2, x)$ (Theorem 7.59(3)); question 4 asks for it from the letter at θ itself, which is a different sentence.

Questions to work through

1. In Lemma 7.4, identify each use of addition compatibility and each use of transitivity. Why would cancelling a common addition have been unjustified?

2. In the constructive classification, which supplied value bounds the search for the period? Which bounds the search for the index? At what point is the pairwise decision procedure used?

3. In (7.4), explain why an individual pair can be decided by finite search even though $\exists n\, \theta(n)$ may not yet have a witness.

4. Trace both branches of the EM reversal. Which branch supplies P, and which supplies $\neg P$? Why was no initial decision of P needed to define the congruence?

5. In the WLPO part of Theorem 7.9, show that $\sim_\theta$ is equality exactly when θ has no witness. In the forward direction, where are the decidability of equality and of order between two counts used, and why do those uses need no added principle?

6. Show that a decidable congruence has at most one first collision, and that the event of γ for $\sim_{i,p}$ sits at $2(i + p) + (i \bmod 2)$. Why does the sequence need to record only the parity of the smaller element?

7. Show directly that $\sim_{2,3}$ is not cancellative. Describe the congruence on $\mathbb{Z}_\delta$ whose restriction is $\sim_{0,3}$, using the integer reading of its records.

8. In the reversal for the period parity in Corollary 7.13, let α have its only event at $n = 3$. Which records does $\approx_\alpha$ relate to $[0, 0]$, and what is its period? Which alternative of LLPO does the corollary's assertion return? Why would the index parity of Theorem 7.9 be useless here?

9. In the open sets of $\beta\mathbb{N}$, take $A_n = \{n\}$. Compute the values of $\exists n\, \alpha(n) = 1$, of $\forall n\, \alpha(n) = 0$ and of its negation. Read off from (7.13) why Markov's principle and LPO fail at this sequence while WLPO holds.

10. Show that in a chain every sequence decided at the value $\top$ has only the values $\bot$ and $\top$. Why does this make LPO hold, and which value refutes excluded middle in the chain $0 < 1 < 2 < \cdots < \infty$?

11. In the convergent sequence $\widehat{\mathbb{N}}$, take $A_n = \{n\}$. Compute the values of $\mathrm{Z}(X)$, $\mathrm{E}(X)$, $\mathrm{Ev}(X)$ and $\mathrm{Od}(X)$, and say why MP, LLPO and $\mathrm{MP}^\vee$ fail at this sequence. Then take $B_n = \{n\}$ for even n and $B_n = \emptyset$ for odd n, and show that the instance of $\mathrm{W}(X)$ at B excludes ∞. Why does WMP hold at this sequence?

12. In the model X_2 of Proposition 7.46, take $A_n = \{n\}$. Show that ∞ lies in the value of $\mathrm{C}_i^3(X)$ for some $i < 3$. Can the construction tell you which i? Why is that no obstacle to the value of LLPO_3 being $\top$?

13. In the cone, take $A_0 = \{a\}$ and $A_n = \emptyset$ for $n \geq 1$. Compute the values of $\mathrm{Dec}(X)$, $\mathrm{E}(X)$ and $\mathrm{Z}(X)$, and check that the instance of LPO at this sequence is $\top$ while the instance of WEM is not. What does the focal point show about the difference between the two principles?

Chapter 8

Changing the representation

A number can be written as a numeral or as a list of identical marks. Changing between these descriptions should not change the answer to an arithmetic question. But that expectation needs a proof. The translations must preserve the operations, and quantified statements must range over corresponding objects in both descriptions.

We will construct the translations and prove what they preserve. There are three distinct objects to keep in view: the arithmetic carrier, the interpretation of a formula, and the finite derivation of that formula. A theorem about one does not automatically settle a question about the others. We therefore take them in turn. We change the carrier and follow every formula through the change, measure what survives when a translation runs in only one direction, and compare the derivations themselves with those of an independently stated proof system, Peano arithmetic, and with its intuitionistic counterpart, Heyting arithmetic.

8.1 An interpretation is fixed by its operations

Chapter 2 established a unique reading of the start-and-step orbit into any pointed step system. The terms of Chapter 5 have a larger signature: variables, zero, successor, addition and multiplication. The same structural method applies to this explicitly stated signature.

Definition 8.1 (A realization of the term signature)**.** A term realization consists of a carrier A, an assigned element v_n for every variable position, an element 0_A, and operations

$$S_A : A \longrightarrow A, \qquad +_A, \cdot_A : A \times A \longrightarrow A.$$

An interpretation preserving the signature sends each variable x_n to v_n, sends 0 to 0_A, and commutes with the three operations. No arithmetic law is assumed merely by giving these operations.

Theorem 8.2 (Unique interpretation of terms)**.** *For every term realization, exactly one interpretation preserves the specified signature. It is the structural evaluation*

$$\begin{aligned} F_A(x_n) &= v_n, & F_A(0) &= 0_A, \\ F_A(S(t)) &= S_A(F_A(t)), \\ F_A(t+u) &= F_A(t) +_A F_A(u), \\ F_A(t \cdot u) &= F_A(t) \cdot_A F_A(u). \end{aligned}$$

Proof. The displayed recursion gives an interpretation because every term is finite and each recursive call concerns an immediate constituent term. It preserves the signature by its defining clauses.

For uniqueness, let G be any signature-preserving interpretation and induct on the term. At a variable and at zero, preservation specifies the answer. At a successor, preservation gives $G(S(t)) = S_A(G(t))$, and the induction hypothesis replaces $G(t)$ by $F_A(t)$. At a sum or product, preservation expresses the result using the two interpreted constituents; the two induction hypotheses replace them by their F_A values. Thus $G(t) = F_A(t)$ in every constructor case. □

This theorem concerns expressions. It does not make every realization a model of arithmetic. To interpret the arithmetic rules soundly, the operations must satisfy those rules. The next construction supplies a concrete realization for which the necessary agreement is proved.

8.2 Arithmetic on lists of one mark

Let a list contain repetitions of a single mark $\bullet$. The empty list is written $[\,]$; placing a mark at the front of u is written $\bullet :: u$. There is no additional information in a list entry: every entry is the same mark.

Definition 8.3 (The list arithmetic)**.** Take finite lists of the single mark as the carrier. Define zero to be the empty list, successor to prepend one mark, and addition to be concatenation, written $u +_L v = u +\!\!+ v$. Define multiplication by recursion on the second list:

$$u \cdot_L [\,] = [\,],$$
$$u \cdot_L (\bullet :: v) = (u \cdot_L v) +_L u.$$

These operations act directly on lists. Concatenation joins the two lists; multiplication appends one copy of the first list for every mark in the second. We can therefore compare this construction with ordinary arithmetic after both descriptions have been specified.

Write $L(u)$ for the length of a list. Write $R(n)$ for the list of n repetitions of the mark.

Theorem 8.4 (The two translations are inverse)**.** *For every natural number n and every list u of the single mark,*

$$L(R(n)) = n, \qquad R(L(u)) = u.$$

Length preserves zero, successor, addition and multiplication:

$$L([\,]) = 0, \qquad L(\bullet :: u) = L(u) + 1, \tag{8.1}$$
$$L(u +_L v) = L(u) + L(v), \qquad L(u \cdot_L v) = L(u)L(v). \tag{8.2}$$

In particular, lists of this one mark are equal exactly when their lengths are equal.

Proof. Induction on n proves $L(R(n)) = n$: the empty repetition has length zero, and one further repetition increases length by one. Induction on u proves the other round trip. The empty list is immediate. A nonempty list has the form $\bullet :: v$, since there is only one mark. Replicating its length produces $\bullet :: R(L(v))$, which is $\bullet :: v$ by the induction hypothesis.

The start and successor equations are the definition of length. For concatenation, induct on the first list. The empty first list leaves v, while removing one mark from a nonempty first list reduces both sides by one and leaves the induction hypothesis.

For multiplication, induct on v. At the empty list, both sides are zero. At $\bullet :: v$, the definition and the addition identity give

$$\begin{aligned} L(u \cdot_L (\bullet :: v)) &= L(u \cdot_L v) + L(u) \\ &= L(u)L(v) + L(u) \\ &= L(u)(L(v) + 1). \end{aligned}$$

This is the required successor case.

Finally, equal lists have equal lengths. If their lengths are equal, their replications are equal, and the second round-trip identity gives equality of the original lists. □

Both carriers also satisfy the faithful-generation conditions of Chapter 2. A nonempty list is not empty, equality of two lists with a mark prepended gives equality of their tails, and list induction reaches every list. The corresponding facts for natural numbers were already used in Part I. Thus the translation preserves the starting point and step as well as the recursive arithmetic operations.

The one-mark condition is essential to this example. Its role is visible in the round-trip proof: knowing the length reconstructs every entry because every entry has already been specified to be the same mark.

8.3 Terms agree under corresponding assignments

A formula may contain variables, so carrier translations alone are insufficient. We must translate the assignments to those variables. Let ρ_N assign natural numbers and let ρ_L assign lists. Call the assignments *related* when

$$L(\rho_L(k)) = \rho_N(k) \qquad \text{for every position } k. \tag{8.3}$$

Evaluate a term on lists by the same recursive clauses as before, using the list operations just defined. Write this value as $E^L_{\rho_L}(t)$, and the natural-number value as $E^N_{\rho_N}(t)$. Figure 8.1 shows the two routes.

Lemma 8.5 (Evaluation commutes with the translation)**.** *For related assignments and every arithmetic term t,*

$$L(E^L_{\rho_L}(t)) = E^N_{\rho_N}(t).$$

Proof. Induct on t. The variable case is (8.3). The zero case is $L([\,]) = 0$. The successor case follows from the length identity for successor and the induction hypothesis. For a sum, length of concatenation is the sum of lengths; apply the two induction hypotheses. For a product, use the multiplication identity in (8.2) and the same two induction hypotheses. These are all the term constructors. □

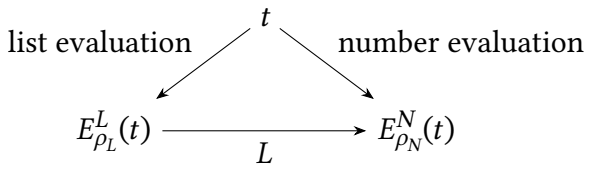

Figure 8.1. Related assignments make the two routes agree. The equation is proved for every term by following its construction.

8.4 Truth is preserved in both directions

Interpret formulas on lists directly. An equality says that its list values are equal. The propositional connectives keep their constructive readings. A universal quantifier ranges over every finite list of the mark, and an existential quantifier supplies one such list as a witness. Write this satisfaction relation as $\rho_L \vDash_L \varphi$.

Theorem 8.6 (Invariance of every arithmetic formula)**.** *If ρ_N and ρ_L are related, then for every formula of the language in Chapter 5,*

$$\rho_L \vDash_L \varphi \quad \Longleftrightarrow \quad \rho_N \vDash \varphi. \tag{8.4}$$

Proof. Induct on the formula, with the two assignments arbitrary. For an equality of terms, equal list values give equal lengths, and Lemma 8.5 gives equal number values. Conversely, equal number values give equal lengths, which give equal lists by Theorem 8.4. Falsehood is false on both sides.

For conjunction and disjunction, transport each component by its induction hypothesis. This preserves both the pair of proofs and the chosen side of a disjunction. For an implication, both directions of each component equivalence are needed. Given the implication in one interpretation, transport an antecedent from the other, apply the implication, and transport the consequent back. The reverse direction uses the same procedure with the roles interchanged.

For a universal formula, suppose first that its list interpretation holds. Choose any natural number n and use $R(n)$ for the new list variable. The extended assignments are related because $L(R(n)) = n$. The induction hypothesis transports the body to the number interpretation at n. Since n was arbitrary, the universal number interpretation holds.

Conversely, suppose the universal number interpretation holds and choose any list u. Use $L(u)$ for the new number variable. The extended assignments are related, and the induction hypothesis transports the body at $L(u)$ to the list body at u. This proves the list universal statement.

For an existential formula, a list witness u becomes the number witness $L(u)$; a number witness n becomes the list witness $R(n)$. In each direction the extended assignments are related, and the induction hypothesis transports the witness's property. This covers every formula constructor. □

The quantifier cases are why a one-way preservation result would have been insufficient. We needed every number to have a corresponding list and every list to have a corresponding

number, with the assigned values related. The round trips supply exactly that information. Section 8.5 measures what survives when only the first of them is available.

Corollary 8.7 (Validity is independent of these two presentations)**.** *A formula holds under every number assignment if and only if it holds under every list assignment. Every closed derivation with an empty ledger has a conclusion true in both presentations.*

Proof. For a given list assignment, take the lengths at every position to obtain a related number assignment. For a given number assignment, replicate each assigned number to obtain a related list assignment. Apply Theorem 8.6 in each direction. For the last assertion, soundness gives validity in the number interpretation, and the first assertion gives validity in the list interpretation. □

8.5 What survives a one-way translation

The list carrier came with translations in both directions. Many structures come with only one. Take a structure M for the arithmetic language, as in Definition 5.7: a carrier with an element 0_M and operations S_M, $+_M$ and $\cdot_M$, in which formulas are read by the clauses of Chapter 5 with quantifiers ranging over the whole carrier. Write $M, \sigma \vDash \varphi$ when an assignment σ of elements of M satisfies φ. Suppose that the six arithmetic rules of Chapter 5 hold in M as facts about its elements:

$$S_M(x) \neq 0_M, \qquad S_M(x) = S_M(y) \Rightarrow x = y,$$
$$x +_M 0_M = x, \quad x +_M S_M(y) = S_M(x +_M y), \quad x \cdot_M 0_M = 0_M, \quad x \cdot_M S_M(y) = x \cdot_M y +_M x.$$

Nothing is assumed about induction in M. Write $S^n(0)$ for the term with n successors, the *numeral* of n. Its value in M is $\nu(n) = S_M^n(0_M)$, and $\nu\rho$ denotes the assignment $k \mapsto \nu(\rho(k))$.

Theorem 8.8 (The numerals form a copy of the numbers)**.** *Under these six conditions, ν is injective and satisfies*

$$\nu(m + n) = \nu(m) +_M \nu(n), \qquad \nu(mn) = \nu(m) \cdot_M \nu(n).$$

Consequently, for every assignment ρ of natural numbers and every quantifier-free formula ψ:

1. *$M, \nu\rho \vDash \psi$ holds exactly when $\rho \vDash \psi$;*
2. *if $\rho \vDash \exists x_1 \cdots \exists x_k \psi$, then $M, \nu\rho \vDash \exists x_1 \cdots \exists x_k \psi$;*
3. *if $M, \nu\rho \vDash \forall x_1 \cdots \forall x_k \psi$, then $\rho \vDash \forall x_1 \cdots \forall x_k \psi$.*

Proof. The map ν is the reading of the orbit into the pointed step system $(M, 0_M, S_M)$ constructed in Chapter 2, written in natural-number coordinates. Its injectivity is the argument of Lemma 2.5. That argument used only separation and injectivity of the step, and its induction runs over the numbers, not over M. For addition, induct on n: $\nu(m + 0) = \nu(m) = \nu(m) +_M 0_M$, and

$$\nu(m + n + 1) = S_M(\nu(m + n)) = S_M(\nu(m) +_M \nu(n)) = \nu(m) +_M \nu(n + 1).$$

Multiplication follows the same pattern, using the addition identity at the successor step. By induction on terms, every term evaluates under $v\rho$ to the numeral of its value under ρ.

For (1), induct on the formula. An equation holds in M when two numerals are equal, which by injectivity happens exactly when the two values are equal. Falsehood and the connectives transport componentwise. For (2), induct on k: a witness n in $\mathbb{N}$ becomes the witness $v(n)$ in M, the extended assignments are again related by v, and (1) transports the quantifier-free body. For (3), instantiate each universal quantifier of M at numerals and apply (1). □

The two remaining directions fail, and one structure shows both. The structure W of Section 5.7 adds two points a and b to the natural numbers. It keeps the operations of $\mathbb{N}$ on numbers and sets, for every number n and every element x,

$$S(a) = a, \qquad S(b) = b, \qquad a + n = a, \qquad b + n = b, \qquad x + a = x + b = b;$$

a product is 0 when either factor is 0, and b when neither factor is 0 and one of them is a or b. Section 5.7 checks that the six conditions hold in W. For example, $x + S(a) = x + a = b = S(b) = S(x + a)$, and $a \cdot S(0) = b = 0 + a = a \cdot 0 + a$. The sentence $\exists x(S(x) = x)$ is true in W, witnessed by a, and false in $\mathbb{N}$. The sentence $\forall x \neg(S(x) = x)$ is true in $\mathbb{N}$ and false in W. So existential statements need not come down, and universal statements need not go up.

The same two sentences settle the question for every pattern of quantifiers. A *prefix* is a finite string $Q_1x_1 \cdots Q_kx_k$ in which each Q_j is $\forall$ or $\exists$ and each quantifier binds a new variable; placing it before a quantifier-free formula ψ gives a formula with that prefix. Say that a prefix *goes up* when, for every structure M obeying the six conditions, every quantifier-free ψ and every assignment ρ of natural numbers, the formula with that prefix that holds at ρ in $\mathbb{N}$ also holds at $v\rho$ in M. Say that it *comes down* when the converse holds.

Proposition 8.9 (No other prefix transfers)**.** *A prefix goes up exactly when all its quantifiers are existential, and comes down exactly when all its quantifiers are universal; only the empty prefix does both. If a prefix contains a universal quantifier, some quantifier-free ψ gives a formula with that prefix that is true in $\mathbb{N}$ and false in W under every assignment. If it contains an existential quantifier, some ψ gives one that is true in W and false in $\mathbb{N}$ under every assignment.*

Proof. Theorem 8.8 gives the positive directions, the empty prefix by its first assertion. Suppose the prefix contains a universal quantifier, and let x be its variable. Take ψ to be $\neg(S(x) = x)$. Every other quantifier of the prefix binds a variable that ψ does not mention, so it changes nothing, in $\mathbb{N}$ or in W, because both carriers have elements. The formula therefore holds exactly when $\forall x \neg(S(x) = x)$ does: in $\mathbb{N}$, and not in W, where $S(a) = a$. If the prefix contains an existential quantifier with variable x, take ψ to be $S(x) = x$. The formula then holds exactly when $\exists x(S(x) = x)$ does: in W, witnessed by a, and not in $\mathbb{N}$. □

The proposition is about all formulas with a given prefix, not about each formula separately. A single universal sentence can go up. The sentence $\forall x(x + 0 = x)$ holds in every structure obeying the six conditions, because it is one of them.

The failure has one source: the numerals miss a and b. In the list carrier the second round trip supplied every list as the expansion of its length; here nothing supplies a numeral for a. Supplying one is the work of the generation condition of Definition 2.4, which makes the

reading reach every element by Lemma 2.6. The theorem shows how far the first round trip reaches without it.

8.6 What happens to the proof and its ledger

Throughout this comparison, the formula and its derivation remain the same finite expressions. We changed their interpretation. A rule labelled EM in a derivation is still that rule, and a quantified induction formula still contains a quantifier. The resource scan of Theorem 6.5 reads those expressions; it does not read their interpreted number or list values. It therefore retains the same record for this change of interpretation.

For example, the reflexivity-and-disjunction proof of $(0 = 0) \vee \neg(0 = 0)$ remains the same empty-ledger derivation. Its formula holds whether zero is interpreted as a number or as the empty list. The alternative proof invoking EM still records that invocation. A change of carrier does not remove an occurrence from a proof tree.

This is the exact scope of the accounting claim. Here the syntax and rules are fixed, the carrier translation is explicit, and satisfaction is preserved and reflected for every formula. Translating the tree into a different proof language is a separate task, and each such translation needs its own correspondence theorem. Section 8.7 proves such a correspondence for the standard presentations of Peano arithmetic and of Heyting arithmetic. It does not cover other proof languages, or procedures for accepting trees in general.

8.7 A second proof language: Peano arithmetic

The standard first-order presentation of arithmetic is Peano arithmetic. It was formulated with no ledger in view, so it is a fair test of what the rules of Chapters 5 and 6 describe. We state it over the same terms and formulas, with the same lifting and substitution operations.

Definition 8.10 (Peano arithmetic)**.** The *axioms* of Peano arithmetic are all instances, for terms t and u, of

$$\neg(S(t) = 0), \qquad S(t) = S(u) \to t = u,$$
$$t + 0 = t, \qquad t + S(u) = S(t + u), \qquad t \cdot 0 = 0, \qquad t \cdot S(u) = t \cdot u + t.$$

A derivation of $\Gamma \vdash_{\mathrm{PA}} \varphi$ is a finite tree built from hypotheses in Γ, axioms, reflexivity, equality substitution, the introduction and elimination rules for $\wedge$, $\vee$, $\to$, $\forall$ and $\exists$ with the freshness conditions of Chapter 5, the rule for an impossible case, induction for every formula, and excluded middle, $\Gamma \vdash_{\mathrm{PA}} \varphi \vee \neg\varphi$ for every formula φ. No ledger appears in the definition.

The two systems differ in three visible places. Injectivity of the successor is an axiom here and a rule there. Excluded middle is an ordinary rule here and a recorded additional principle there. Induction is unrestricted in both, but only the rules of Chapter 6 record whether its formula contains a quantifier. Deleting excluded middle from the definition gives the usual presentation of Heyting arithmetic, the intuitionistic counterpart of Peano arithmetic.

Theorem 8.11 (The rules with excluded middle are Peano arithmetic)**.** *For every finite context* Γ *and every formula* φ*, the following are equivalent:*

1. $\Gamma \vdash_{\mathrm{PA}} \varphi$*;*
2. φ *has a derivation from* Γ *by the rules of Chapters 5 and 6 whose ledger has false LPO and MP entries.*

Moreover, the translation from (1) to (2) produces a derivation whose EM entry is true exactly when the Peano derivation uses excluded middle, and whose induction entry is true exactly when it uses induction on a formula containing a quantifier.

Proof. From (1) to (2), translate the Peano derivation node by node. Hypotheses, reflexivity, equality substitution, the connective and quantifier rules, the rule for an impossible case and induction have identical counterparts. Five of the axioms are rules of Chapter 5 with no premises. The injectivity axiom becomes a short derivation: assume $S(t) = S(u)$, apply the injectivity rule, and discharge the assumption. Excluded middle becomes an EM leaf. No LPO or MP leaf is ever produced. By Theorem 6.5, the ledger of the result is read from its EM leaves and its induction nodes, and these correspond exactly to the uses of excluded middle and the inductions of the original tree, with the same induction formulas.

From (2) to (1), translate the derivation node by node in the same way. The injectivity rule becomes the injectivity axiom followed by implication elimination, and an EM leaf becomes excluded middle. By Theorem 6.5, the ledger hypothesis excludes LPO and MP leaves, so no other case arises. Both translations preserve contexts, including the lifted contexts of the quantifier rules, because the two systems share their formulas and their lifting and substitution operations. □

Two consequences are worth recording. A Peano derivation that never uses excluded middle becomes a posit-free derivation. By Corollary 6.7, every environment satisfying its hypotheses then satisfies its conclusion, with none of EM, LPO or MP assumed in the metatheory. If, in addition, its inductions are on quantifier-free formulas only, the translation has the empty ledger.

Conversely, a posit-free derivation translates into a Peano derivation that never uses excluded middle. The posit-free derivations are therefore exactly the translations of derivations in Heyting arithmetic, the system obtained by deleting excluded middle from Definition 8.10, up to one point of form that the next corollary states exactly.

Corollary 8.12 (The posit-free derivations are Heyting arithmetic)**.** *For every finite context* Γ *and every formula* φ*, the following are equivalent:*

1. φ *has a derivation from* Γ *in Heyting arithmetic, that is, a Peano derivation that never uses excluded middle;*
2. φ *has a posit-free derivation from* Γ*.*

Moreover, the translation from (1) to (2) in Theorem 8.11 turns every derivation in Heyting arithmetic into a posit-free derivation, and every posit-free derivation has the judgment and the ledger of such a translation. The two trees differ only where the posit-free derivation applies the injectivity rule to a premise: the translation there derives $S(t) = S(u) \to t = u$, by the injectivity rule under a discharged assumption, and applies implication elimination.

Proof. Restrict both translations in the proof of Theorem 8.11 to trees without excluded middle. From (1) to (2), no EM leaf is produced, and no LPO or MP leaf ever is, so the result is posit-free. From (2) to (1), a posit-free derivation has no EM, LPO or MP leaf, by Theorem 6.5, so its translation never uses excluded middle. For the last assertion, translate a posit-free derivation d into Heyting arithmetic and back. Every node returns unchanged except an application of the injectivity rule, which returns as the injectivity axiom, rederived under a discharged assumption, followed by implication elimination. That short derivation has the same conclusion and the same context, and its only new leaf is a hypothesis, which adds nothing to the ledger. The induction nodes and their formulas are those of d. So the result has the judgment and the ledger of d. □

The theorem and its corollary compare proof systems over one language. They do not show that any of these systems is consistent, and they say nothing about languages with further types or symbols; Section 20.3 takes up that comparison for the typed language of Chapter 9, and Section 20.3.11 proves that Peano arithmetic and the typed language are consistent. What they settle are the names of the two fragments: allowing excluded middle and nothing else, the rules of Chapter 5 prove exactly the theorems of Peano arithmetic, and allowing no added principle, exactly the theorems of Heyting arithmetic. In both, the ledger shows where the quantified inductions occur, and in the first, where the classical step occurs.

8.8 A quotient represents what a reading retains

Chapter 7 studied readings that can identify different counts. Their quotients provide a second useful comparison of representations.

Let r preserve zero and addition from the orbit into an additive commutative monoid V. Its *range* consists of the values actually reached by r. Its kernel identifies x and y exactly when $r(x) = r(y)$. Write $[x]$ for the class of x under that kernel.

Theorem 8.13 (The kernel quotient and the range)**.** *The map*

$$[x] \longmapsto r(x)$$

is an addition-preserving bijection from the kernel quotient onto the range of r. If the kernel is the index–period congruence with parameters i, p, the corresponding index–period quotient represents that same range.

Proof. If x and y represent the same class, the definition of the kernel gives $r(x) = r(y)$. Hence the displayed map is well defined. It preserves zero and addition because r does. If two classes have the same image, their representatives have equal readings and therefore belong to the same kernel class; this proves injectivity. Every value in the range is $r(x)$ for a representative

x, so it is the image of $[x]$; this proves surjectivity. If the kernel is the specified index–period relation, replacing the relation by that equal description gives the corresponding quotient. □

The target of this bijection is the range, not automatically all of V. That distinction prevents unused target values from being counted as information carried by the reading. It also explains the role of the classification: the parameters describe precisely the retained identifications, while this theorem connects their quotient to the values the reader actually reaches.

8.9 The limits are part of the invariance theorem

The constructions in this chapter give positive reasons for independence from a notation. The arithmetic operations were defined in two ways, the translations were specified, and each connective and quantifier was checked under those translations. The resource record stayed attached to the same finite derivation.

The hypotheses exclude concrete failures. Consider a carrier with one element, using that element both as zero and as the successor of every element. It has operations for the term signature, so the theorem giving a unique interpretation of terms applies. But its zero is a successor. It therefore fails the faithful-generation conditions and does not supply the arithmetic interpretation just proved invariant. A mere assignment of operations is not enough.

The surrounding mathematics also remains present. Finite expressions, functions, equality, recursion and the interpretation of quantifiers are the tools used to state and prove the equivalence. We have proved a particular representation-independence result with those tools. The next part examines the different kinds of recursive construction themselves, including what becomes available when their rules grow stronger.

Questions to work through

1. In the list round-trip proof, identify the use of the assumption that the list has only one possible mark. Which later proof depends on the resulting injectivity of length?
2. Explain both directions of the universal-quantifier case in Theorem 8.6. Which translation supplies the new variable in each direction?
3. Why does the implication case require preservation and reflection of its components, rather than preservation alone?
4. In Theorem 8.13, locate the exact use of the kernel definition. Why is surjectivity onto the range immediate, while surjectivity onto the whole target was not claimed?
5. Verify in W that $x \cdot S(y) = x \cdot y + x$ when x is a number $n > 0$ and $y = a$, and when $x = y = a$. Why does $\forall x \neg(S(x) = x)$ fail in W while every numeral instance $\neg(S(S^n(0)) = S^n(0))$ holds there?
6. The one-element carrier at the end of this chapter has operations for the term signature. Which of the six conditions of Theorem 8.8 fails there, and which conclusion of the theorem fails with it?

7. Translate the Peano axiom $S(t) = S(u) \to t = u$ into a derivation by the rules of Chapter 5 and record its ledger. Then translate a use of the injectivity rule back into Peano arithmetic.

8. A Peano derivation of $\forall x(0 + x = x)$ uses induction on $0 + x = x$. What is the ledger of its translation? Compare it with the example in Chapter 6.

9. For the prefix $\exists y \forall x$, write the formula that Proposition 8.9 uses to show that it does not go up, and the one that shows it does not come down. Check each in $\mathbb{N}$ and in W. Why does $\forall x(x + 0 = x)$ not contradict the proposition?

Part III

Construction, iteration and the continuum

Chapter 9

Iteration, recursion and induction

Repeating an operation, using the position of a step, and proving a statement at every position are different abilities. On the finite tallies constructed in Chapter 1, we have all three. That can make their differences difficult to see. To separate them, we must ask what each rule would permit on a carrier whose structure has not already been settled.

This chapter does that with two pictures. In the first, two distinct roots lead to the same successor. An iterator works perfectly well there. In the second, two chains run alongside one another. Indexed recursion works on both, although only one begins at the designated start. These examples locate the work done by the stronger rules.

The conclusions concern a precisely specified language. We will give its rules, construct the examples, and prove that the examples respect every rule they are meant to interpret. That last step matters: an appealing picture alone cannot establish that a statement is underivable.

9.1 Three ways to proceed from a start

Write O for an orbit carrier, $0 : O$ for its designated start, and $S : O \to O$ for its successor operation. At this point, these are a type and two operations. We have not assumed that S is injective or that every element of O is reached from 0.

An *iterator* has a fixed target type B, a starting value $b : B$, and a step $g : B \to B$. Its equations are

$$\mathsf{I}(B, b, g, 0) \equiv b, \tag{9.1}$$

$$\mathsf{I}(B, b, g, Sx) \equiv g(\mathsf{I}(B, b, g, x)). \tag{9.2}$$

The symbol $\equiv$ means equality by the computation rules of the language. The step sees the previous result. It need not be told the position at which it is acting.

An *indexed recursor* still has a fixed target B, but its step receives both the position and the previous result:

$$g : \prod_{x : O} (B \to B).$$

Its equations are

$$\mathsf{R}(B, b, g, 0) \equiv b, \tag{9.3}$$

$$\mathsf{R}(B, b, g, Sx) \equiv g(x, \mathsf{R}(B, b, g, x)). \tag{9.4}$$

The notation $\prod_{x : O}$ denotes a dependent function type: a function takes an $x : O$ and returns a value of the type written after the product sign. Here that return type happens to be the same $B \to B$ for every x.

A *dependent eliminator* allows the target itself to depend on the position. Given a type expression $P(x)$, a value $b : P(0)$, and

$$g : \prod_{x:O}\big(P(x) \to P(Sx)\big),$$

it provides $\mathsf{E}(P, b, g, x) : P(x)$, with equations

$$\mathsf{E}(P, b, g, 0) \equiv b, \tag{9.5}$$

$$\mathsf{E}(P, b, g, Sx) \equiv g(x, \mathsf{E}(P, b, g, x)). \tag{9.6}$$

When $P(x)$ states a property, this is induction: supply a proof at the start and a method for carrying a proof through one step, then obtain a proof at each position. When $P(x)$ describes a kind of data, the same rule constructs that data.

A family asks a different question at each position

Here is the family that will later separate indexed recursion from dependent elimination. Use recursion to rebuild a position from the designated start:

$$c(x) = \mathsf{R}(O, 0, \lambda z : O.\, \lambda y : O.\, Sy, x).$$

Its equations say $c(0) \equiv 0$ and $c(Sx) \equiv S(c(x))$. Now ask for an identity proof between the rebuilt position and the supplied one:

$$P(x) = \mathrm{Id}_O(c(x), x).$$

The input x occurs in the question itself. At the start, the question is the identity of 0 with itself. At a successor, an answer to the previous question can be carried through S. A dependent eliminator would put those answers together into a proof of $P(x)$ at every x. The construction of the step proof is given explicitly in Lemma 9.5.

The two-chain picture will explain why the last step matters. Recursion can rebuild both chains into the first one, so rebuilding an element of the second chain need not recover that element. Having a recursive function c is therefore different from having the requested identity proof at every input. A dependent function of type $\prod_{x:O} P(x)$ must return a proof of the question belonging to the input it receives.

These displays already suggest two inclusions. Indexed recursion can ignore the position and act as an iterator. Dependent elimination can use a constant family $P(x) = B$ and act as indexed recursion. The interesting question is whether either inclusion can be reversed.

9.2 The language in which the question is exact

We use a small typed language. Its type expressions are generated by

$$O, \qquad \mathbf{0}, \qquad \prod_{x:A} B(x), \qquad \mathrm{Id}_A(t, u), \qquad D(t).$$

Here $\mathbf{0}$ is the empty type. An element of $\mathrm{Id}_A(t, u)$ is an identity proof between two terms of type A. The last form, $D(t)$, is optional; we will specify exactly when it is available.

A context is a finite list of typed variables. Each type in the list may use variables declared earlier. A type family $P(x)$ is a type expression in a context containing x; it is not an arbitrary family borrowed from the mathematics in which we discuss the language. There are no variables standing for types or type families, and no type whose elements are all types. In particular, there is no universe inside this language. There is also no dependent-pair constructor.

Terms consist of variables, 0, successors, functions, applications, identity proofs and their eliminator, empty-type elimination, and the three orbit operations just displayed. We consider three fragments: the iterator fragment permits I; the indexed fragment additionally permits R; the dependent fragment additionally permits E.

The typing rules are as follows. The empty context is valid, and a valid context may be extended by a type formed in it. The types O and $\mathbf{0}$ may be formed in every valid context. A product type requires its domain A in the context and its codomain $B(x)$ in the context extended by $x : A$. An identity type requires A and two terms of that type. The type $D(t)$, when enabled, requires $t : O$.

A declared variable has its declared type. The term 0 has type O, and S sends terms of type O to terms of type O. Function introduction and application have the familiar rules

$$\frac{\Gamma, x : A \vdash t : B(x)}{\Gamma \vdash \lambda x : A.\, t : \prod_{x:A} B(x)}, \qquad \frac{\Gamma \vdash f : \prod_{x:A} B(x) \quad \Gamma \vdash u : A}{\Gamma \vdash f(u) : B(u)},$$

with the displayed types required to be formed. The notation $\Gamma \vdash t : A$ says that the term t has type A under the assumptions in Γ.

Reflexivity supplies $\mathrm{refl}_x : \mathrm{Id}_A(x, x)$. The identity eliminator, called J, works as follows. Fix $x : A$ and a type family $Q(y, p)$ in the context $y : A,\ p : \mathrm{Id}_A(x, y)$. From $d : Q(x, \mathrm{refl}_x)$ it supplies

$$J(A, x, Q, d, y, p) : Q(y, p), \qquad J(A, x, Q, d, x, \mathrm{refl}_x) \equiv d.$$

Thus a construction on an identity proof is specified at reflexivity and transported along that proof. Empty-type elimination supplies a term of any formed type from a term of $\mathbf{0}$.

The typing rules for I, R and E require exactly the types of their arguments stated in the preceding section, and $x : O$. All earlier variables in the context remain available as parameters. Computation uses the six orbit equations, the J equation, and function evaluation

$$(\lambda x : A.\, t)(u) \equiv t[u/x].$$

An equation is available only in a fragment that permits its orbit operation.

We optionally add the *start discriminator*, with equations

$$D(0) \equiv \mathrm{Id}_O(0, 0), \qquad D(Sx) \equiv \mathbf{0}. \tag{9.7}$$

It gives a type-level distinction between the start and a successor. The superscripts $-$ and $+$ will mean that this discriminator is disabled or enabled, respectively.

For precision, raw conversion is the least equivalence relation containing the enabled computation equations and closed under every expression constructor and capture-avoiding

substitution. It is defined on raw expressions: an intermediate expression in a conversion chain need not be well typed. A *typed* equality requires both endpoints to have the stated type; a type equality requires both endpoint types to be formed. A term may be converted from A to B only through such a type equality. We do not turn an identity proof into a raw conversion, and we add neither function extensionality nor an η equation.

The word "raw" deserves an example. As an expression, the function application $(\lambda x : \mathbf{0}.\, x)(0)$ rewrites to 0. But its function expects an input from the empty type, while the supplied 0 has type O. The application cannot be typed. A soundness proof cannot therefore justify every intermediate raw rewrite merely by appealing to the typing of the original endpoints. Section 9.8 handles this issue in two steps: typed expressions satisfy a safety condition, and convertible safe endpoints reduce forward to a common expression without losing their interpreted value. That is why the later proof needs both safety and confluence.

Finally, a substitution from a context Γ to a context Δ assigns to each declared variable of Γ a term of its substituted type in Δ. Substitution acts on types, terms and typed equalities. Only the finitely many variables in the source context are required. These formation, introduction, elimination, conversion and substitution rules constitute the whole calculus used below.

Definition 9.1 (Admissibility)**.** A rule is admissible in a fragment if, whenever its premises have derivations in that fragment, its conclusion has a derivation there too. For indexed recursion and dependent elimination, we require a term with both displayed computation equations as typed equalities, uniformly over every finite parameter context and every permitted type expression.

This definition makes a negative result strong enough to be useful. It rules out every construction from the available rules, including one we have not thought to try. A single instance with derivable premises and an underivable conclusion refutes admissibility.

9.3 What indexed recursion immediately gives

The additional position argument in R has a direct use. Choose target O, base 0, and step $(x, y) \mapsto x$. Define

$$\operatorname{pred}(x) = \mathsf{R}(O, 0, \lambda z : O.\, \lambda y : O.\, z, x). \tag{9.8}$$

Then the computation rules give

$$\operatorname{pred}(0) \equiv 0, \qquad \operatorname{pred}(Sx) \equiv x.$$

The second equation is a left-inverse law for successor.

Theorem 9.2 (Indexed recursion supplies injectivity)**.** *In either indexed fragment, with or without D, there is a term of*

$$\prod_{x:O} \prod_{y:O} \big(\mathrm{Id}_O(Sx, Sy) \to \mathrm{Id}_O(x, y)\big).$$

Proof. The term in (9.8) is well typed because its step accepts two orbit elements and returns the first. Given $p : \mathrm{Id}_O(a, b)$, identity elimination applies pred to that path: use the family $Q(z, q) =$

$\mathrm{Id}_O(\mathrm{pred}(a), \mathrm{pred}(z))$ and the base $\mathrm{refl}_{\mathrm{pred}(a)}$. This constructs a proof of $\mathrm{Id}_O(\mathrm{pred}(a), \mathrm{pred}(b))$. Set $a = Sx$ and $b = Sy$. The two predecessor computations convert the resulting type to $\mathrm{Id}_O(x, y)$. Abstracting over x, y, p gives the required term. No discriminator is used. □

The start discriminator gives a different fact.

Theorem 9.3 (The discriminator separates the start)**.** *In every fragment with D enabled, there is a term of*

$$\prod_{x:O} \big(\mathrm{Id}_O(0, Sx) \to \mathbf{0}\big).$$

Proof. By (9.7), refl_0 is a term of $D(0)$. If $p : \mathrm{Id}_O(0, Sx)$, apply identity elimination with family $Q(y, q) = D(y)$ and that base term. The result has type $D(Sx)$, which converts to $\mathbf{0}$. Abstract over x and p. The construction uses neither recursion nor induction. □

The two arguments identify two different resources. The predecessor retrieves the input of a successor. The discriminator distinguishes the start from a successor. Neither argument silently assumes the other fact.

9.4 An iterator can merge two roots

Consider distinct elements $a, u, v_1, v_2, \ldots$, with designated start a and step

$$S(a) = v_1 = S(u), \qquad S(v_n) = v_{n+1} \quad (n \geq 1).$$

The subscripts here are the finite natural numbers of the ambient mathematics. They are being used to construct a model of the language; they do not add an induction rule to that language. Figure 9.1 draws the structure.

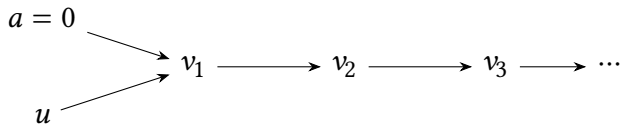

Figure 9.1. Two roots with one common tail. Iteration can give both roots the same starting value, so its equations do not detect the merger.

For any set B, any $b \in B$, and any function $g : B \to B$, define

$$I(a) = b, \qquad I(u) = b, \qquad I(v_n) = g^n(b). \tag{9.9}$$

Both roots satisfy $I(Sx) = g(I(x))$: each side is $g(b)$. At a tail element, the equation is $g^{n+1}(b) = g(g^n(b))$. Thus the iterator exists for every target and step, although successor is not injective.

The discriminator can be interpreted too. Give $D(a)$ and $D(u)$ the one-element set, and give each $D(v_n)$ the empty set. Then $D(a)$ interprets $\mathrm{Id}(a, a)$, and every $D(Sx)$ is empty. The extra root u is allowed to share the start's discriminator value; the discriminator equations never require the converse implication $D(x) \Rightarrow x = 0$.

Theorem 9.4 (The iterator boundary)**.** *In the fixed calculus of Section 9.2, the iterator fragment, with either choice of discriminator, has no closed term proving successor injectivity. Indexed recursion is not admissible in it.*

Proof. Interpret the orbit type by the merging structure. Interpret product types by sets of dependent functions, the empty type by the empty set, and an identity type by a singleton when its endpoints are equal and the empty set otherwise. The soundness proof in Section 9.8 verifies all the rules of the iterator fragment for this interpretation, in every finite parameter context and with either choice of D.

If an injectivity term existed, apply its interpreted function to a, u and the identity proof between $S(a)$ and $S(u)$. It would produce an element of the empty identity set between the distinct elements a and u. This is impossible.

For indexed recursion, use the closed premises $B = O$, $b = 0$ and $g(x, y) = x$, all expressible in the iterator fragment. An admissible recursor would give a function r with $r(Sx) = x$. In the model this would require both $r(v_1) = a$ and $r(v_1) = u$. Since $a \neq u$, no such function exists. Soundness therefore excludes a term with the required equations. □

The first example answers a common temptation: the ability to repeat an operation does not, by itself, make the underlying step reversible. The position argument in indexed recursion is doing real work.

9.5 Recursion can leave a whole chain unreached

Now let

$$O = \{0, 1\} \times \mathbb{N}_\delta, \qquad 0_O = (0, 0), \qquad S(i, n) = (i, Sn).$$

There are two disjoint successor chains. Only the first starts at the designated 0_O (Figure 9.2).

$$(0,0) \longrightarrow (0,1) \longrightarrow (0,2) \longrightarrow \cdots$$

$$(1,0) \longrightarrow (1,1) \longrightarrow (1,2) \longrightarrow \cdots$$

Figure 9.2. Indexed recursion can start with the same value on both chains. Its step can read the chain's index without making the second root reachable from the designated start.

For a fixed B, b, g, define the recursor on each chain by

$$R(i, 0) = b, \qquad R(i, Sn) = g((i, n), R(i, n)). \tag{9.10}$$

The initial equation holds at $(0, 0)$, and the successor equation holds everywhere by construction. There is no conflict in also starting the second chain at b. The equations specify no separate base value there. Ordinary iteration is obtained by choosing a step that ignores (i, n).

Set $D(0, 0)$ to the singleton and $D(i, n)$ to the empty set at every other point. The discriminator equations hold too. Thus even the indexed fragment with the discriminator leaves room for the second chain.

To expose what fails, we need a family expressible in the language. The informal property "belongs to the first chain" would not suffice unless the language could express it. Instead define the term

$$c(x) = \mathsf{R}(O, 0, \lambda z : O.\, \lambda y : O.\, Sy, x), \qquad P(x) = \mathrm{Id}_O(c(x), x). \tag{9.11}$$

The term c rebuilds the successor history from the designated start. It satisfies

$$c(0) \equiv 0, \qquad c(Sx) \equiv S(c(x)).$$

In the two-chain model, induction on the finite index gives

$$c(i, n) = (0, n). \tag{9.12}$$

At index zero the equation is the base clause of the recursor. If it holds at n, the successor clause applies S to $(0, n)$ and gives $(0, Sn)$. This proves the formula at every finite index.

Lemma 9.5 (A family with a base and a step)**.** *In either indexed fragment, $P(x)$ from* (9.11) *is a formed type family, with a closed term of $P(0)$ and a closed term of $\prod_{x:O}(P(x) \to P(Sx))$.*

Proof. The term $c(x)$ is an indexed recursor with a well-typed step, so its identity type with x is formed. At 0, its computation makes refl_0 a term of $P(0)$. For the step, take $p : \mathrm{Id}_O(c(x), x)$. Apply S to this path using J, with motive $\mathrm{Id}_O(S(c(x)), Sy)$ and reflexivity base. The result is a proof of $\mathrm{Id}_O(S(c(x)), Sx)$. Convert the first endpoint using $c(Sx) \equiv S(c(x))$. This is a proof of $P(Sx)$, and abstraction over x, p gives the required step. □

Theorem 9.6 (The indexed-recursion boundary)**.** *In either indexed fragment of the fixed calculus, there is no closed term of $\prod_{x:O} P(x)$ for this expressed family. Dependent elimination is not admissible. Nor is the rule asserting pointwise uniqueness of two maps with the same start and successor equations.*

Proof. The two-chain interpretation satisfies every rule of the indexed fragment by Section 9.8. At the second root, formula (9.12) gives

$$P(1, 0) = \mathrm{Id}_O((0, 0), (1, 0)).$$

Its interpretation is empty. A function inhabiting $\prod_{x:O} P(x)$ would have to return an element of this empty set at $(1, 0)$, so no such function, and hence no such term, exists.

Lemma 9.5 supplies the premises of dependent elimination inside the indexed fragment itself. If that rule were admissible, it would supply exactly the impossible term.

For uniqueness, compare c with $q(x) = x$. Both are terms $O \to O$; both satisfy $f(0) = 0$ and $f(Sx) = S(f(x))$, with identity proofs obtained from their computation equations. But at $(1, 0)$, c returns $(0, 0)$ and q returns $(1, 0)$. A term asserting their pointwise equality would again produce an element of an empty identity set there. All the proposed rule's premises have terms, while its conclusion does not. □

The failure occurs at a specific, expressible family. It does not rely on allowing an arbitrary external predicate as an induction motive. The two maps also show why merely solving recurrence equations does not establish uniqueness on a carrier whose generated part may be smaller than the whole.

9.6 Induction does not invent a discriminator

The preceding models separate the two weaker fragments. A different argument shows that, in this language, the start discriminator is still an additional resource even after dependent elimination is available.

Assign a truth value $v(A)$ to every raw type expression:

$$v(O) = \mathsf{true}, \qquad v(\mathbf{0}) = \mathsf{false},$$
$$v(\mathrm{Id}_A(t,u)) = \mathsf{true}, \qquad v(D(t)) = \mathsf{true},$$
$$v\left(\prod_{x:A} B\right) = v(A) \Rightarrow v(B).$$

Here $\Rightarrow$ is ordinary Boolean implication. The valuation deliberately ignores the terms inside a type. It is a tool for checking derivations, not a set interpretation in which identity means equality of denoted elements.

Lemma 9.7 (Substitution cannot change this truth value)**.** *Renaming variables or substituting terms in A preserves $v(A)$. When the discriminator is disabled, raw type conversion also preserves it.*

Proof. For substitution and renaming, induct on the type expression. The orbit and empty types do not change. Identity and discriminator types always have value true, whatever their contained terms. At a product, the two induction hypotheses preserve the antecedent and consequent of the Boolean implication.

For conversion, induct on its construction. Reflexivity, symmetry and transitivity preserve equality of truth values. Product congruence uses its two induction hypotheses. Identity and discriminator congruence preserve the constant value true. The substitution case uses the first part. The two special discriminator equations are unavailable when D is disabled. These are all the type-conversion cases; term conversions inside an identity or a discriminator cannot affect its value. □

Theorem 9.8 (Truth preservation without the discriminator)**.** *In any of the three fragments with D disabled, if $\Gamma \vdash t : A$ and every type declared in Γ has value true, then $v(A) = \mathsf{true}$. In particular every inhabited closed type has value true.*

Proof. Induct simultaneously on the finite derivations of terms, equalities and substitutions. A variable inherits the true value of its declared type; weakening does not change it by Lemma 9.7. Zero and successor have type O. Reflexivity has an identity type, whose value is true.

For a function, if the domain has value false, its product type has value true immediately. If the domain has value true, extend the true context by that domain and apply the induction hypothesis to the body. The codomain is true, so the product is true. For application, a true implication together with a true argument type gives a true codomain. Substitution for the argument preserves that value.

Identity elimination has a base term of $Q(x, \mathrm{refl}_x)$. The induction hypothesis makes this type true. Since substitution does not change the value of Q, the target $Q(y, p)$ is true as well. Empty-type elimination cannot have its premise in a true context: that premise would make $v(\mathbf{0})$ true.

For iteration and indexed recursion, the base term already makes the fixed target B true. For dependent elimination, the base term makes $P(0)$ true; substitution invariance then makes $P(x)$ true at every argument. These observations handle the orbit rules even when the strongest one is enabled.

Type equality preserves the valuation by Lemma 9.7; term equality inherits truth from either typed endpoint. Type conversion therefore preserves the term assertion. A derivable substitution sends a true target context to a true source context, since each source variable has a term of its substituted type in the target. Apply the induction hypothesis to the original judgment in that source context, then use substitution invariance. This handles substituted terms and equalities. Context and type formation add no assertion that a type is inhabited. All derivation rules have now been covered. □

Corollary 9.9 (A strict discriminator boundary)**.** *Without D, even the dependent fragment has no closed term of*

$$\prod_{x:O} \big(\mathrm{Id}_O(0, Sx) \to \mathbf{0}\big).$$

Proof. The inner implication has value $\mathsf{true} \Rightarrow \mathsf{false} = \mathsf{false}$. The outer product has the same false value because $v(O)$ is true. Theorem 9.8 excludes an inhabitant. □

The hypothesis disabling D is essential. When its equations are enabled, $D(S0) \equiv \mathbf{0}$ equates a type assigned true by this valuation with one assigned false. The valuation then ceases to preserve conversion, exactly where the positive construction in Theorem 9.3 becomes available.

9.7 The strict sequence of resources

Let $\mathscr{I}^-$, $\mathscr{R}^-$, and $\mathscr{E}^-$ denote the iterator, indexed and dependent fragments without D. Let $\mathscr{E}^+$ be the dependent fragment with D.

Theorem 9.10 (Three strict extensions)**.** *Every derivation in one of the following fragments is also a derivation, of the same judgment, in the next:*

$$\mathscr{I}^- \subsetneq \mathscr{R}^- \subsetneq \mathscr{E}^- \subsetneq \mathscr{E}^+.$$

The three strictness witnesses are, respectively, successor injectivity, the section $\prod_{x:O} P(x)$ *from* (9.11)*, and start separation.*

Proof. Each extension retains the earlier grammar and rules. Induct on a conversion derivation to retain its equations, and on a typing derivation to retain its judgment. At a rule that requires an enabled operation, the larger fragment still enables it. Every other rule and every context

is unchanged. Thus these are inclusions on actual finite derivations, not only comparisons of their interpretations.

Theorem 9.2 supplies the first witness in $\mathscr{R}^-$, and Theorem 9.4 excludes it from $\mathscr{I}^-$. Lemma 9.5 supplies the inputs for a dependent eliminator; applying that eliminator and abstracting over x gives the second witness in $\mathscr{E}^-$. Theorem 9.6 excludes it from $\mathscr{R}^-$. Finally, Theorem 9.3 supplies start separation in $\mathscr{E}^+$, and Corollary 9.9 excludes it from $\mathscr{E}^-$. □

The first two separations also hold with the discriminator enabled throughout: both countermodels interpret it. The third separation concerns adding the discriminator itself. How much arithmetic the top fragment $\mathscr{E}^+$ proves is a separate question. Chapter 20 answers it: $\mathscr{E}^+$ proves the negative translations of exactly the theorems of Peano arithmetic (Theorem 20.39).

There is no conflict with the arithmetic developed in Part I. There we constructed the finite tallies and used their structural elimination rule; generation from the start was built into the construction. Here we ask which conclusions follow from selected rules on a type O before its full structure has been established. The two countermodels identify precisely what is lost when the stronger rule is withheld. They are not alternative faithful representations of the already constructed tallies.

9.8 Why the countermodels cover every rule

The negative results used a soundness claim for the complete fixed calculus. This section proves that claim. A reader following the main structural argument can return to it after the chapter; its purpose is to close the gap between the two pictures and the statements about all derivations.

9.8.1 A total interpretation and its limits

Work in ordinary classical set theory for this external proof. Encode each orbit carrier injectively as a set, choosing the designated start different from the empty set. The two concrete encodings may be made from tagged ordered pairs of finite tally codes. Extend decoding to all sets by returning the designated start when a set is not an orbit code. Consequently S, I and R have total external interpretations, although their typing rules will permit only arguments in the appropriate domains. The unused indexed recursor in the merging model, and the unused dependent eliminator in both models, receive the default value $\varnothing$.

An environment ρ assigns a set to each variable. Define the interpretation of types recursively by

$$
\begin{aligned}
[\![O]\!]_\rho &= \text{the encoded orbit carrier},\\
[\![\mathbf{0}]\!]_\rho &= \varnothing,\\
\left[\!\!\left[\prod_{x:A} B\right]\!\!\right]_\rho &= \prod_{a \in [\![A]\!]_\rho} [\![B]\!]_{\rho[x:=a]},\\
[\![\mathrm{Id}_A(t,u)]\!]_\rho &= \begin{cases} \{\varnothing\}, & [\![t]\!]_\rho = [\![u]\!]_\rho,\\ \varnothing, & \text{otherwise.} \end{cases}
\end{aligned}
$$

The product consists of all graphs of functions with the stated domain and values in the corresponding fibers. Interpret $D(t)$ by the discriminator set at $[\![t]\!]_\rho$.

A variable is interpreted by its environment entry. Zero and successor use the model's start and step. A function is interpreted by the graph

$$[\![\lambda x \,:\, A.\, t]\!]_\rho = \{(a, [\![t]\!]_{\rho[x:=a]}) \,:\, a \in [\![A]\!]_\rho\}.$$

For application, look for an output paired with the given input in the interpreted graph: choose one if it exists, and use $\emptyset$ otherwise. On a function graph at an input in its domain the output is unique, so this choice has no effect. Reflexivity, empty-type elimination and the unavailable dependent eliminator are interpreted as $\emptyset$. The interpretation of $J(A, x, Q, d, y, p)$ is that of its base d. Finally I and R use the concrete operations (9.9) and (9.10), with interpreted base and step.

All raw expressions now have values. This does *not* make every raw computation equation preserve values. For example,

$$(\lambda x \,:\, \mathbf{0}.\, x)(0) \equiv 0$$

is a raw function-evaluation equation. The function's graph is empty, so the left side has default value $\emptyset$, whereas the right side is the designated nonempty start code. This application has no valid typing derivation. The soundness claim must use its typing hypotheses.

Two elementary facts about the interpretation will be used repeatedly. If $a \in A$, applying the graph of f on A to a returns $f(a)$. If a graph with domain A belongs to a dependent function set with domain B, then $A = B$: the first coordinates of the pairs in either description are exactly its domain. These facts follow directly from the definition of a function graph.

9.8.2 Substitution and safe expressions

For a substitution σ, let $\rho\sigma$ assign to each variable the value of its substituting term in ρ. Structural recursion on expressions gives

$$[\![A[\sigma]]\!]_\rho = [\![A]\!]_{\rho\sigma}, \qquad [\![t[\sigma]]\!]_\rho = [\![t]\!]_{\rho\sigma}. \tag{9.13}$$

For a variable the assertion is the definition of $\rho\sigma$. For a constant it is immediate. At a binder, extend both environments by the same new value and leave the bound variable fixed; the induction hypothesis then identifies the body values. At every remaining constructor, apply its defining operation to the equal constituent values. The J family has two binders and uses two such extensions. This proves both identities, together with their renaming versions.

We next define a property called *safety*, relative to a model and an environment. It records the domain conditions needed by evaluation, without claiming that the whole expression is typed. The definition follows the raw syntax.

For types, O and $\mathbf{0}$ are safe. A product is safe when its domain is safe and its codomain is safe at every value in that domain. An identity type is safe when its two endpoint terms are safe. A discriminator type is safe when its argument is safe.

For terms, variables, zero, reflexivity, empty-type elimination and the unavailable dependent eliminator are safe. A successor is safe when its argument is safe and has value in the orbit

carrier. A function is safe when its domain is safe and its body is safe at every value in that domain. An application is safe when both constituents are safe and there is a dependent function set containing the value of its function, whose domain contains the value of its argument. A J term is safe exactly when its base term is safe; the interpretation reads only that base.

An iterator is safe when its base, step and orbit argument are safe, the argument lies in the orbit carrier, and there is a set B containing the base value on which the step value is a function $B \to B$. For an indexed recursor, replace that last condition by a step function from the orbit carrier to $B \to B$. The type annotations ignored by these interpretations impose no additional safety condition.

Lemma 9.11 (Safety under substitution)**.** *Suppose e is safe in $\rho\sigma$, and every substituting term for a free variable of e is safe in ρ. Then $e[\sigma]$ is safe in ρ.*

Proof. Induct on e. A variable uses the corresponding substitution hypothesis. Constructors that are safe without conditions remain so. At a successor, application, iterator or recursor, the induction hypotheses give safety of the constituents, while (9.13) preserves all the required set memberships and function domains. At an identity or discriminator type, use the hypotheses for its term arguments. At a product or function, fix a value in the domain, extend the environment and lift the substitution beneath the binder. The new variable is safe by definition; all previous variables retain their hypotheses by renaming. Apply the body induction hypothesis in that extended environment. The J case uses its base hypothesis. This also shows why no condition is needed on substitution components outside the finite set of free variables. □

9.8.3 Joining conversions without changing the language

A conversion can pass through untyped intermediate expressions. We therefore cannot justify it by asserting that every step in its original zigzag preserves values. Instead we join the two endpoints by forward reductions that preserve values whenever they start safely.

Define an external parallel reduction relation $e \Rrightarrow e'$. It permits constituents to reduce in parallel under every constructor, including binders. It also permits a visible function application or enabled iterator/recursor equation to contract, with its constituents reduced in parallel. For example,

$$b \Rrightarrow b', \quad t \Rrightarrow t' \quad \Longrightarrow \quad (\lambda x : A.\, b)(t) \Rrightarrow b'[t'/x].$$

It includes the two enabled discriminator contractions. Finally, it has the external erasures

$$J(A, x, Q, d, y, p) \Rrightarrow d' \quad (d \Rrightarrow d'),$$

and sends reflexivity, empty-type elimination and raw dependent elimination to refl_0. These erasures reflect the chosen set interpretation. They are not new computation rules or new equalities in the object language.

Lemma 9.12 (Parallel substitution and joining)**.** *Parallel reduction is preserved by substitution. More generally, if $e \Rrightarrow e'$ and each component of σ reduces to the corresponding component of τ, then $e[\sigma] \Rrightarrow e'[\tau]$. The parallel relation has the diamond property, and its finite-step closure is confluent. In either weaker fragment, raw-convertible expressions have a common reduct in this external relation.*

Proof. Prove the substitution assertion by induction on the parallel derivation. Constructor cases use their constituent induction hypotheses; beneath a binder, lift both substitutions and retain the bound variable. In the function-contraction case, the substitution composition identity identifies the two results of substituting first or contracting first. The iterator and recursor contractions retain their form under substitution, as do the discriminator contractions. A J erasure reduces to the substituted base, and the other erasures still reduce to refl_0. This covers every parallel rule.

The diamond property follows by Takahashi's method of complete developments [85]. For each expression e, define its complete development e^* by developing the constituents and contracting the outer redex if its original outer form is a visible redex. Erase J to its developed base and the other erasable forms to refl_0. An operation disabled by the fragment retains its constructor. A redex newly exposed only after developing a constituent need not be contracted at this stage.

We claim that $e \Rrightarrow u$ implies $u \Rrightarrow e^*$. Induct on the displayed parallel step. For a constructor whose outer form is not a redex, reduce its constituents by the induction hypotheses. If an application originally has a lambda at its head, a congruence step leaves a lambda there, so contract it using the developed body and argument. If the first step already contracted it, parallel substitution gives the same developed result. For an iterator or recursor at zero, both possibilities lead to the developed base. At a successor, both lead to the developed step applied to the corresponding recursive expression; the recursor also receives the developed predecessor. With primes marking the results of the first step on the constituents, the congruence result $\mathsf{R}(B', b', g', Sx')$ and the contraction result $g'(x', \mathsf{R}(B', b', g', x'))$ both reduce in parallel to

$$\mathsf{R}(B, b, g, Sx)^* = g^*\big(x^*, \mathsf{R}(B^*, b^*, g^*, x^*)\big).$$

The discriminator cases lead to the same unit or empty type. A congruence step on J can be followed by erasure; an erasure step can be followed by development of its base. For the remaining erasable forms both paths end at refl_0. These exhaust the possible overlaps.

Thus any two parallel steps from e are joined at e^*. This is the diamond property. For finite reduction chains, use the diamond repeatedly to move a single step past a finite chain; induction on the other chain then fills a finite grid of diamonds and produces a common endpoint. This proves confluence of the finite-step closure.

Having a common reduct is consequently an equivalence relation: reflexivity and symmetry are immediate, and confluence joins the two reducts needed for transitivity. It is closed under constructors and substitution by the corresponding parallel rules. Each enabled computation equation has a common reduct: function, iterator, recursor and discriminator equations use their contractions, while the J equation uses erasure. The dependent computation equations are absent in the two weaker fragments. Induction on raw conversion now proves its inclusion in this common-reduct relation. □

Lemma 9.13 (Safe parallel reduction preserves values)**.** *In the merging model for the iterator fragment, and in the two-chain model for the indexed fragment, if e is safe and $e \Rrightarrow e'$, then e' is safe and $[\![e]\!] = [\![e']\!]$. Both choices of discriminator are allowed.*

Proof. The concrete iteration and recursion operations stay within their target set whenever their base and step do. For the merging model this follows by induction on the tail level in (9.9). For the two-chain model it follows by induction on the second coordinate in (9.10). The base and successor equations hold by those definitions. The discriminator equations hold by the definitions at the roots and tails.

Now induct on the parallel step, simultaneously for types and terms. At a product, the domain values agree by induction; at each point of that common domain, the fiber values agree too. Their sets of dependent functions are therefore equal. At a lambda, the same pointwise argument gives equality of graphs. Identity and discriminator types depend only on the relevant term values. Successor and application congruence preserve their domain witnesses and values using the constituent equalities. Iterator and recursor congruence similarly preserve their common target set and interpreted operations.

For a function contraction, safety of the application supplies a function-set domain containing the argument. The graph-domain fact identifies that domain with the lambda's declared domain. Graph application therefore equals evaluation of the body with that argument substituted. Use the induction hypotheses for the body and argument, then Lemma 9.11, to obtain both the value and safety of the contracted term. No off-domain default is used.

At an iterator or recursor zero contraction, use its base equation and the base induction hypothesis. At a successor contraction, safety supplies the predecessor in the orbit carrier. The target-closure fact proved above puts the recursive result in B. The step can therefore be applied, once for the iterator and twice for the indexed recursor; its concrete successor equation gives the claimed value. The induction hypotheses preserve all the needed memberships.

The discriminator contractions use its two equations. The interpretation and safety of J are precisely those of its base, so its congruence and erasure cases follow from the base induction hypothesis. Reflexivity, empty-type elimination and raw dependent elimination all have value $\varnothing$, as does refl_0; their erasures preserve safety and values directly. These are all the parallel rules. □

Corollary 9.14 (Coherence at safe endpoints)**.** *In either concrete interpretation, two raw-convertible expressions that are both safe in an environment have equal values there.*

Proof. By Lemma 9.12, the endpoints have a common external reduct. Apply Lemma 9.13 successively along each finite reduction chain. Each chain preserves safety and value. Both original values equal the value of the common reduct, hence equal one another. □

9.8.4 Soundness of the complete typing derivations

Theorem 9.15 (The two concrete models are sound)**.** *Every derivation in the iterator fragment has a valid interpretation in the merging model. Every derivation in the indexed fragment has a valid interpretation in the two-chain model. Both statements hold with or without the*

discriminator and in every finite parameter context. In particular, a typed term denotes a member of its type, and typed equalities denote equal values.

Proof. Prove a stronger assertion by simultaneous induction on the derivation. In an environment satisfying its context, every formed type is safe; every typed term is safe and belongs to its interpreted type; both endpoints of each typed equality are safe and have equal values. A derivable substitution takes a satisfying target environment to a satisfying source environment and has safe components at all declared source variables.

Context extension adds exactly the required membership. Variables use their context entries. Orbit and empty-type formation are safe directly. Product formation uses safety of the domain and the codomain in each extended environment; identity and discriminator formation use the safety of their term arguments. Zero belongs to the carrier, and the concrete successor preserves that carrier.

For function introduction, the body induction hypothesis gives a safe value in the correct fiber at every domain point. Its graph therefore belongs to the product type and is safe. For application, the two premises give a dependent function and an argument in its domain. Applying that graph yields a member of the required fiber, and (9.13) identifies the fiber with the substituted result type. The same premises give safety.

Reflexivity denotes $\emptyset$, which is an element of the singleton identity set at equal endpoints. For J, the identity premise says that the two endpoint values agree and the path value is $\emptyset$. Substituting these equal values into the motive makes the target fiber the same as the base fiber, which already contains the base value. Safety comes from that base. Empty-type elimination has no possible premise in a satisfying environment, since nothing belongs to $\emptyset$.

Iteration and indexed recursion use the proved closure of their concrete operations in the target set; their premises supply exactly the safety conditions stated above. Dependent elimination cannot be a rule of either fragment under consideration.

For type or term equality, the induction hypotheses supply safety of both endpoints. Corollary 9.14 then proves equality of their values, despite any untyped intermediates in the raw conversion. Converting a term's type preserves membership because the two interpreted types are equal.

For substitution, the premises type every component associated with a declared source variable. Their membership conclusions give a satisfying source environment, and their safety conclusions cover every variable that can occur in a source judgment. Formula (9.13) transports membership and equalities; the finite-variable form of Lemma 9.11 transports safety. This handles substitution of types, terms and both kinds of equality. It finishes the induction over all the original rules. □

The external set theory and its choices belong to this nonderivability proof. No universe, external family, semantic soundness assumption or additional equation has been inserted into the object calculus. The negative conclusions therefore apply to the exact rules stated at the beginning of the chapter.

Questions to work through

1. Check the iterator equation separately at a, at u, and at v_n in the merging model. Explain why setting $D(u)$ to the singleton does not violate either discriminator equation.

2. Carry out the two function-evaluation steps in $\mathrm{pred}(Sx)$ after the recursor equation has been applied. Identify the point at which the indexed step uses information unavailable to an ordinary iterator step.

3. Verify the base and successor equations for both c and $q(x) = x$ in the two-chain model. Locate the element at which their pointwise equality fails.

4. Why does dependent elimination preserve truth when the valuation ignores the motive's argument? Which discriminator equation invalidates this valuation?

Chapter 10

Finite construction and effective description

A finite tally can be written down. A rule for producing tallies can also be written down. These are different objects. The first records a result; the second may produce different results when given different inputs, and may fail to finish on some inputs.

There is a third distinction. Suppose that, for every requested accuracy, a description specifies a finite rational interval. Each interval is finite data. It does not follow that one finite rule produces all those intervals. The placement of the word "one" matters. This chapter makes that difference precise, while showing how finite arithmetic and finite programs fit into the same generated records.

10.1 An explicit budget for a tally

Write $L(x)$ for the number of steps in $x \in \mathbb{N}_\delta$, as in Chapter 1. The inverse reading takes an ordinary natural number k to the tally with k steps. The two readings are inverse by their construction. We use ordinary natural numbers to index budgets in the surrounding mathematics.

Definition 10.1 (A finite stage)**.** For a budget n, let

$$F_n = \{x \in \mathbb{N}_\delta \,:\, L(x) \le n\}.$$

If $n \le m$, the inclusion $j_{n,m} : F_n \longrightarrow F_m$ retains the same tally and regards it as satisfying the larger budget.

There are exactly $n+1$ elements in F_n: the tallies with lengths $0, 1, \dots, n$. This is an explicit correspondence. Send a tally to its length and send an index back to the tally with that many steps. The two composites are identities. In particular, a stage is finite because its elements have been enumerated, not because a finiteness assumption has been attached to it.

The inclusions satisfy

$$j_{n,n} = \mathrm{id}, \qquad j_{m,k} \circ j_{n,m} = j_{n,k} \quad (n \le m \le k).$$

Both equations say that enlarging a budget does not change a record. Every $x \in \mathbb{N}_\delta$ lies in its own finite stage $F_{L(x)}$. No search for a suitable stage is needed: the record supplies its budget.

This gives more than an increasing list of finite sets. It tells us exactly when calculations or readings defined separately on those sets determine a single reading of the generated orbit.

Definition 10.2 (Agreement across budgets)**.** Let A be a fixed target. A compatible family consists of maps $f_n : F_n \to A$ such that

$$f_m(j_{n,m}(x)) = f_n(x) \qquad (n \le m,\ x \in F_n). \tag{10.1}$$

Compatibility is a substantial condition. It says that the answer assigned to an already available record does not change merely because the reader is given a larger permitted budget.

Theorem 10.3 (Finite readings glue uniquely)**.** *For every compatible family (f_n), exactly one map $f : \mathbb{N}_\delta \to A$ restricts to f_n on every F_n. It is given explicitly by*

$$f(x) = f_{L(x)}(x).$$

Proof. The expression on the right is defined because $x \in F_{L(x)}$. If $x \in F_n$, then $L(x) \le n$, and compatibility gives

$$f_n(x) = f_n(j_{L(x),n}(x)) = f_{L(x)}(x) = f(x).$$

Thus f has every required restriction. Conversely, any map g with those restrictions satisfies $g(x) = f_{L(x)}(x)$ by applying its restriction at the particular budget $L(x)$. Hence $g(x) = f(x)$ for every x. □

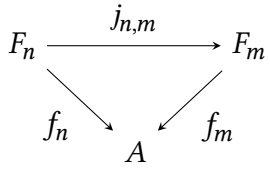

Figure 10.1. A larger budget retains the record. Agreement along the two routes is the hypothesis that makes the single global reading possible.

The proof uses one stage for each input. It does not require an apparatus that stores the whole orbit. Nor does it turn an arbitrary compatible family into an executable rule: the maps f_n were supplied as mathematical data. The theorem establishes precisely the unique assembly of those maps.

10.2 Arithmetic carries its own finite bounds

The length identities from Chapter 3 immediately give finite output budgets:

$$\begin{aligned} S &: F_n \longrightarrow F_{n+1}, \\ + &: F_n \times F_m \longrightarrow F_{n+m}, \\ \cdot &: F_n \times F_m \longrightarrow F_{nm}. \end{aligned} \tag{10.2}$$

For example, $L(x + y) = L(x) + L(y) \le n + m$. Similarly, $L(xy) = L(x)L(y) \le nm$. These are bounds for the size of the resulting tally. They do not count the intermediate work of a chosen calculating device.

If the input budgets are enlarged, the output tally is unchanged. For $n \le n'$ and $m \le m'$, adding after inclusion gives the same tally as adding first and then including into $F_{n'+m'}$. The multiplication statement is identical with the product budget. The proof is especially short: an inclusion retains its underlying tally, and the operations are the same operations on those tallies on both routes.

There is a useful discipline here. A claim of finite construction should identify what its budget measures. Equations (10.2) measure record length. An execution-time claim or a physical storage claim would require its own construction and bound; Chapter 15 gives one, for the solutions of polynomial differential equations whose computed trajectory passes a finite region certificate.

10.3 A record with a decoder

We can make the representation entirely explicit. Prepare a finite bit record $U(x)$ consisting of $L(x)$ repetitions of the bit 0. Define a budgeted decoder D_n as follows: count the length of the supplied bit record r. If that length is at most n, return the tally with that many steps, regarded as an element of F_n. Otherwise return failure.

The decoder uses the record's length. It does not inspect whether its bits are all zero. Preparing only zeros makes one canonical record for each tally; the decoder is allowed to accept other records of the same length too.

Proposition 10.4 (Exact finite recovery)**.** *For every $x \in F_n$,*

$$D_n(U(x)) = x, \qquad \text{length}(U(x)) \le n.$$

Every record longer than n is rejected.

Proof. The length of $U(x)$ is $L(x)$. The budget condition on x therefore selects the successful branch of D_n. Its answer is the tally reconstructed from $L(x)$, which is x by the length round trip. The same length identity proves the preparation bound. A longer input selects the failure branch by definition. □

This construction gives both directions of a representation, together with an exact recovery law. It is stronger than merely counting possible records. It is still a mathematical preparation and reading procedure. Identifying the physical actions that prepare, retain and read it is a further task, addressed in Part V.

10.4 A finite rule can describe an unbounded calculation

We now specify the programs used in this chapter. They are the usual finite expressions for partial recursive functions. A *partial* function may return a natural number on an input, or may remain undefined. Write $c(n)\downarrow v$ when program c returns v on input n. Returning a value is single-valued.

First fix an effective pairing of two natural numbers into one. One explicit choice is

$$\langle a, b\rangle = \begin{cases} b^2 + a, & a < b, \\ a^2 + a + b, & b \le a. \end{cases} \tag{10.3}$$

It lists pairs by successive square boundaries. Given k, set $s = \lfloor \sqrt{k} \rfloor$ and $t = k - s^2$. If $t < s$, recover (t, s); otherwise recover $(s, t - s)$.

To check the round trip, note that $0 \le t \le 2s$. In the first case, $t < s$ selects the first branch of (10.3), giving $s^2 + t = k$. In the second, $0 \le t - s \le s$ selects the second branch, again giving $s^2 + t = k$. Conversely, if $a < b$, the paired number lies between b^2 and $(b + 1)^2$, and its remainder is $a < b$. If $b \le a$, it lies between a^2 and $(a + 1)^2$, with remainder $a + b \ge a$. The decoder therefore returns the original pair in both cases.

Definition 10.5 (The program expressions)**.** There are four basic programs: the constant zero function, successor, and the two projections that recover the first and second members of a paired input. From programs f, g form the following further programs.

1. Pairing runs both on the same input and pairs their answers.
2. Composition runs g and then runs f on its answer.
3. Primitive recursion, on input $\langle a, n\rangle$, starts with $f(a)$ and performs n steps. At step y, with previous answer v, it runs $g(\langle a, \langle y, v\rangle\rangle)$.
4. Search, on input $\langle a, m\rangle$, runs f successively on $\langle a, m\rangle, \langle a, m + 1\rangle, \ldots$, returning the first tested position whose answer is zero.

Each program expression is a finite tree built from these eight constructors.

The partial behavior is part of the definition. Composition cannot proceed until its inner program returns. A recursive calculation cannot proceed past an undefined base or step. Search continues past a position only after that call returns a nonzero answer. If it waits forever at an earlier position, it does not skip ahead to a later zero.

Primitive recursion uses a supplied finite step count. Search need not have such a bound. Both have finite descriptions. Consequently, a finite program description is neither a certificate that execution terminates nor a bound on how long execution takes.

Proposition 10.6 (Expressions capture partial recursion)**.** *A partial function obtained from the four basic functions by pairing, composition, primitive recursion and unbounded search has a program expression. Conversely, every program expression defines such a partial recursive function.*

Proof. Induct on a construction of the partial recursive function. A basic function has the corresponding basic expression. At a pairing, composition or primitive-recursion step, apply that expression constructor to the programs given by the induction hypotheses. Their evaluation clauses give exactly the required function.

For a search beginning at zero, pair the input with zero and pass it to the search expression. This supplies its initial position. In the converse direction, induct on the finite program tree. The basic and three binary constructors are their corresponding closure rules. Search from a supplied position is ordinary search on the offset j, applying the test at $m + j$, then adding m to the successful offset. These are compositions and a search of partial recursive functions. Thus both directions include the stated search behavior. □

Here a total function is called *computable* when its value on every input is given by such a partial recursive function. This is the conventional mathematical definition used for the remainder of the chapter. No premise about the capabilities of every physical process enters that definition.

10.5 Storing the program preserves its execution

The expression tree can itself be assigned a natural number. To remove any ambiguity, here is a complete coding. Give the four basic programs the codes $0, 1, 2, 3$, in the order listed above. If the codes of f, g are u, v, set

$$\begin{aligned} e(\mathrm{pair}(f, g)) &= 4\langle u, v\rangle + 4, \\ e(\mathrm{comp}(f, g)) &= 4\langle u, v\rangle + 6, \\ e(\mathrm{rec}(f, g)) &= 4\langle u, v\rangle + 5, \\ e(\mathrm{search}(f)) &= 4u + 7. \end{aligned} \tag{10.4}$$

For a number at least four, subtract four and inspect its remainder modulo four. Remainders $0, 2, 1, 3$ select pairing, composition, recursion and search, respectively. Divide by four to recover the paired subcodes, or the single subcode for search. Decode the subcodes by the same procedure. Every subcode is smaller than the number being decoded, so the procedure terminates.

Lemma 10.7 (The program coding is reversible)**.** *Decoding $e(c)$ returns the identical finite expression c.*

Proof. Induct on the expression tree. The four basic cases follow from their distinct codes. Each composite code has the remainder selecting its own constructor. Integer division removes that remainder and the initial offset. For a binary constructor, the pairing round trip recovers the two subcodes; for search, it recovers the one subcode directly. Apply the induction hypotheses to those subcodes. The reconstructed constructor and children are exactly the original tree. □

Store c as the tally $P(c)$ with $e(c)$ steps. Recovery first reads its length and then applies the program decoder. This connects the program coding to the orbit constructed in Part I.

Theorem 10.8 (Faithful program storage)**.** *Recovery after storage returns c. In particular, storage is injective, and executing the recovered program has exactly the same partial function as executing c. Both returned answers and undefined behavior are preserved.*

Proof. The length of $P(c)$ is $e(c)$, so the recovery assertion is Lemma 10.7. If two stored tallies are equal, recovering both gives equality of their program expressions. Finally, execution after recovery is execution of the identical expression. Equality of these partial functions preserves undefined inputs as well as defined outputs; no termination assumption is needed. □

For a bit representation, prepare $U(P(c))$. Its length is exactly $e(c)$. The decoder with budget $e(c)$ first recovers $P(c)$ and then recovers c, by Proposition 10.4 and Theorem 10.8. Longer records are refused at the budget check. This unary representation is deliberately simple. Its size bound concerns this specified representation, with no claim that it is the shortest encoding of the program.

10.6 One program for every requested precision

We next apply program storage to rational intervals. The full construction of the continuum from these intervals is the subject of the next chapter. For now we need only the finite data and their consistency conditions.

Definition 10.9 (An interval protocol)**.** An interval protocol p assigns to each natural number n a closed rational interval

$$I_n(p) = [\ell_n(p), u_n(p)]$$

with $\ell_n(p) \le u_n(p)$, such that

$$I_{n+1}(p) \subseteq I_n(p), \qquad u_n(p) - \ell_n(p) \le \frac{1}{n+1}. \tag{10.5}$$

The index is a precision request. The interval at that index gives the specified rational enclosure, and later requests refine it. The definition requires a family with these properties. It does not yet require a method for producing its endpoints.

Fix the usual effective encoding of rational pairs by natural numbers, with an inverse decoder on valid codes. Rational numbers are finite data: they have reduced signed numerators and positive denominators, as developed in Chapter 4. Write $E_p(n)$ for the code of $(\ell_n(p), u_n(p))$. We use the injectivity of this coding when comparing answers.

Definition 10.10 (A uniform program name)**.** A program c names p if

$$\forall n \quad c(n)\!\downarrow E_p(n). \tag{10.6}$$

One finite expression must work at every precision. The nesting and width bounds remain properties of the specified protocol. A terminating program that prints arbitrary rational pairs does not acquire those properties merely by terminating.

Lemma 10.11 (A name specifies at most one protocol)**.** *If a program names both p and q, their interval families are equal.*

Proof. For each n, single-valued execution gives $E_p(n) = E_q(n)$. Injectivity of the pair encoding gives equality of both rational endpoints. Thus the intervals agree at every index, which is equality of the protocol families. □

Different programs may name the same family. The lemma asserts the other direction: a fixed program does not leave the answers undetermined.

The constant protocol $[q, q]$ has a concrete name for every rational q. If k is the code of (q, q), start with the zero program and compose with successor k times. Induction on k shows that this finite expression returns k on every input. The interval conditions hold because its width is zero and every interval is the same.

Theorem 10.12 (The criterion for an executable name)**.** *An interval protocol has a uniform program name if and only if its endpoint code function $n \mapsto E_p(n)$ is computable. The same criterion holds when the name must be stored as a distinction tally and recovered before execution.*

Proof. If c names p, its partial evaluation is the total function returning $E_p(n)$ at every n. Proposition 10.6 therefore gives computability. Conversely, that proposition supplies a finite expression for a computable endpoint function, and equality with that total function is precisely (10.6).

For the storage assertion, store a supplied name as $P(c)$ and use Theorem 10.8. In the reverse direction, recover the program from a purported stored name. Its execution is the required uniform name. Storage has changed the representation without changing the criterion. □

10.7 A finite prefix is a different quantifier

Suppose we ask only for the first N endpoint pairs. These form a finite table

$$T_{p,N} = (E_p(0), E_p(1), \dots, E_p(N-1)).$$

Given this table, a program can return its nth entry when $n < N$, and return zero otherwise. Finite list lookup is primitive recursive: it follows the list until the requested position or its end, with a default answer at the end. Its fixed entries are finite constants. Thus the expression construction of Proposition 10.6 gives a program for the lookup.

Theorem 10.13 (Every supplied finite prefix has a program)**.** *For every interval protocol p and every N, there is a program c such that*

$$\forall n < N \quad c(n)\!\downarrow E_p(n).$$

The program may depend on the entire supplied finite table.

Proof. Use the lookup program just constructed from $T_{p,N}$. Below N, its entry at n is $E_p(n)$ by the definition of the table. The default branch is irrelevant to the stated range of inputs. □

The premise is access to the table as data. The proof supplies no method for extracting it from an unknown physical quantity. Nor does the theorem supply a procedure that takes N and generates the required table.

For a fixed p, compare the two assertions:

$$\forall N\, \exists c\, \forall n < N \quad c(n)\!\downarrow E_p(n),$$
$$\exists c\, \forall n \quad c(n)\!\downarrow E_p(n).$$

The first permits a different finite table and program at each budget. The second requires one program for all budgets. Chapter 11 will prove that the first does not imply the second for general interval protocols in the classical real display. The proof will use a precise countability obstruction, not a failure to find a clever program.

This is the point at which finite construction needs uniformity. Every individual tally has a finite stage. Every finite program has a tally representation that preserves its execution. A whole family of rational intervals has such a program name exactly when its endpoint function is computable. Those are three established statements, each with its own object and its own quantifiers.

These program expressions have a second use. The terms of the typed language of Chapter 9 can be compiled into them and stored as numbers by (10.4). Identity proofs compile to the program that returns 0, identity elimination to the program of its base term, elimination from the empty type to a default program fixed by its target type, and E in the same way as R. A function is then a program code, applied through one fixed universal program that searches for a finite record of the computation and checks each candidate with one fixed test program. Chapter 20 uses this to compare the strongest typed fragment, $\mathscr{E}^+$, with Peano arithmetic: it proves the negative translations of exactly the theorems of Peano arithmetic. One direction of that comparison translates Peano derivations into typed terms. The other runs the typed terms as compiled programs. It needs derivations, by the arithmetic rules, that the test accepts a record of every computation and accepts only genuine records; that chapter shows how the record and its test are built so that the rules can supply them.

Questions to work through

1. In the proof of Theorem 10.3, identify the particular inclusion used for an input $x \in F_n$. Where is compatibility needed, and where is the own-budget construction sufficient?

2. Explain why increasing both input budgets in an addition changes neither its underlying inputs nor its result. What quantity is bounded by $n + m$, and what quantity has not been bounded?

3. Follow storage, bit preparation, budgeted decoding and program recovery for an arbitrary program c. Cite the round-trip identity used at each step. Why does this argument need no assertion that c terminates?

4. A program prints correct endpoint pairs for the first N requests and then prints zeros. Which conclusion of this chapter can it satisfy? Which additional obligation is required for it to be a uniform name?

Chapter 11

The continuum through rational enclosures

A rational interval tells us both an answer and how much remains unresolved. If a length lies between two rational bounds, narrowing those bounds improves the description without pretending that a finite record contains every digit. The question is how a coherent sequence of such records relates to a real number, and what is lost when only that number is retained.

We use the interval protocols of Definition 10.9. Their intervals are nested and have width at most $1/(n+1)$ at request n. The arithmetic of the endpoints is rational arithmetic. A protocol is a mathematical family of these intervals; a uniform executable name is the additional structure studied in Chapter 10.

This chapter compares protocols with the ordinary classical real line. That comparison uses its completeness and Archimedean property, together with classical reasoning. These are resources of the surrounding mathematics in which the comparison is proved. They are not new rules silently inserted into the object languages of Part II.

11.1 Why every later interval constrains every earlier one

Fix a protocol p, and abbreviate its interval by $I_n = [\ell_n, u_n]$. Regard its rational endpoints as real numbers when making the comparison. Nesting says

$$\ell_n \le \ell_{n+1}, \qquad u_{n+1} \le u_n.$$

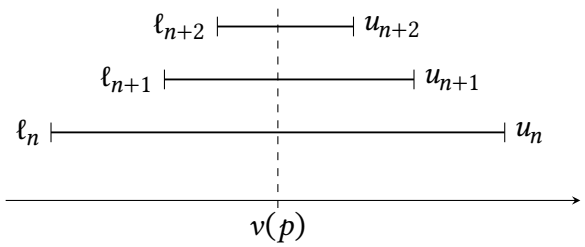

Figure 11.1. Nesting retains earlier constraints. The displayed value lies in every interval; the width condition makes that value unique. The drawing shows the containment pattern, not a prescribed sequence of widths.

Induction on the distance between indices therefore gives

$$a \le b \quad \Longrightarrow \quad \ell_a \le \ell_b \quad \text{and} \quad u_b \le u_a.$$

The indices in a lower and upper bound need not be the same. For any a, b, let $k = \max(a, b)$. Then

$$\ell_a \le \ell_k \le u_k \le u_b. \tag{11.1}$$

This simple observation is the reason a single value can satisfy every interval. Every upper endpoint bounds all the lower endpoints, even those arising at much later requests.

11.2 A unique value lies in every enclosure

The set of lower endpoints is nonempty and bounded above by u_0, using (11.1). Completeness of the classical real line therefore supplies its least upper bound. Define the *displayed value* by

$$v(p) = \sup\{\ell_n : n \in \mathbb{N}\}. \tag{11.2}$$

The word "displayed" identifies the comparison being made: one real number is retained from the more detailed interval family.

Proposition 11.1 (The value satisfies every finite enclosure)**.** *For every n,*

$$\ell_n \le v(p) \le u_n.$$

Proof. Every member of a set is at most its supremum, so $\ell_n \le v(p)$. Equation (11.1) says that u_n is an upper bound for the entire set of lower endpoints. The least-upper-bound property then gives $v(p) \le u_n$. □

Existence used nesting and completeness. Uniqueness uses the quantitative width bound. We first isolate the small estimate that will be used twice.

Lemma 11.2 (No positive quantity is below every reciprocal bound)**.** *If a real number a satisfies $0 \le a \le 1/(n+1)$ for every natural number n, then $a = 0$.*

Proof. If a were positive, the Archimedean property would give a natural number $n > 1/a$. Hence $n + 1 > 1/a$, and taking reciprocals of these positive numbers would give $1/(n+1) < a$, contradicting the supplied bound. Nonnegativity then leaves $a = 0$. □

Theorem 11.3 (Uniqueness of the displayed value)**.** *If y belongs to every interval of p, then $y = v(p)$.*

Proof. Both y and $v(p)$ lie between ℓ_n and u_n. Therefore

$$0 \le |y - v(p)| \le u_n - \ell_n \le \frac{1}{n+1}$$

for every n. Lemma 11.2 gives $|y - v(p)| = 0$, hence equality. □

This result provides a useful way to prove an identity of displayed values. Instead of calculating a supremum directly, show that the proposed answer lies in every interval. The uniqueness theorem then identifies it with the displayed value.

11.3 When two protocols describe the same point

Two different interval families may retain different finite information while describing the same limiting point. Exact equality of the families would be too strong for this comparison.

Definition 11.4 (Observational equality)**.** Protocols p and q are observationally equal, written $p \simeq q$, if their intervals overlap at every matching precision:

$$\forall n \quad \ell_n(p) \le u_n(q) \quad \text{and} \quad \ell_n(q) \le u_n(p). \tag{11.3}$$

Each pair of inequalities is a rational comparison. The definition requires all of them. It is a mathematical condition on two families, not a claim that a finite inspection decides the condition in every case.

Theorem 11.5 (Overlap at every precision is exactly equality of value)**.** *For all interval protocols p, q,*

$$p \simeq q \quad \Longleftrightarrow \quad v(p) = v(q).$$

Proof. Suppose first that the intervals overlap at request n. Since each value lies in its own interval, one direction of the difference satisfies

$$\begin{aligned} v(p) - v(q) &\le u_n(p) - \ell_n(q) \\ &\le \big(u_n(p) - \ell_n(p)\big) + \big(u_n(q) - \ell_n(q)\big). \end{aligned}$$

The second inequality uses $\ell_n(p) \le u_n(q)$. Interchanging p and q gives the same bound for the negative difference. Consequently,

$$|v(p) - v(q)| \le \frac{2}{n+1}.$$

Apply this bound at request $2m+1$. Its right side is $1/(m+1)$, so Lemma 11.2 implies equality of the values.

Conversely, if the values are equal, their common value belongs to both intervals at every request. Thus $\ell_n(p) \le v(p) = v(q) \le u_n(q)$, and the reverse cross inequality follows in the same way. These are precisely the overlap conditions. □

In particular, $\simeq$ is reflexive, symmetric and transitive: each property follows by translating to equality of values and back. Overlap of arbitrary single intervals is not what proves transitivity here. The theorem uses overlap at every precision, nesting and shrinking widths together.

There are therefore two distinct equalities in use. Equality of protocols retains every rational answer. Observational equality retains the displayed point. Chapter 10's uniqueness of a program name concerns the first equality, because the program returns the exact endpoint pair.

11.4 Rationals and arithmetic act on the intervals

A rational q determines the constant protocol $[q, q]$. It contains q at every request and has width zero, so its displayed value is q by Theorem 11.3. Two such constant protocols are observationally equal exactly when their rational values are equal. The rational arithmetic constructed earlier is thus preserved faithfully in this comparison.

For addition, the main issue is the precision budget. Adding intervals adds their widths. Reading both operands at request n would give only the bound $2/(n+1)$. Instead, read both at request $k = 2n+1$ and define

$$I_n(p+q) = [\ell_{2n+1}(p) + \ell_{2n+1}(q),\ u_{2n+1}(p) + u_{2n+1}(q)]. \tag{11.4}$$

Proposition 11.6 (Addition respects the protocol conditions)**.** *The intervals in* (11.4) *form an interval protocol, and*

$$v(p+q) = v(p) + v(q).$$

Proof. The lower endpoint does not exceed the upper endpoint because that is true for both operands. As n increases, the index $2n+1$ increases; monotonicity of both lower endpoint sequences and antitonicity of both upper sequences give nesting of the sum intervals.

The width of the sum interval is the sum of the two operand widths. Hence it is at most

$$\frac{1}{2n+2} + \frac{1}{2n+2} = \frac{1}{n+1}.$$

Finally, add the two lower bounds and the two upper bounds for the operand values. They show that $v(p) + v(q)$ lies in every sum interval. Apply Theorem 11.3 to identify its value. □

Negation reverses and negates the endpoints:

$$I_n(-p) = [-u_n(p), -\ell_n(p)]. \tag{11.5}$$

The new interval has the same width. The two nesting inequalities exchange roles under sign reversal, so it is again a protocol. Negating the value bounds shows that $-v(p)$ lies in every new interval, giving

$$v(-p) = -v(p).$$

Define $p - q = p + (-q)$. The two established value identities then give

$$v(p-q) = v(p) - v(q).$$

These constructions work on the rational enclosures themselves. Their agreement with real addition, negation and subtraction is proved afterward. The sum's reindexing is also visible: its finite answers need not be the same interval family as another construction with the same displayed sum. Observational equality is the comparison that retains the common value.

11.5 Every classical real has such a display

We have sent each protocol to a real number. The reverse coverage statement has an explicit interval formula. Fix a classical real r, and let

$$k_n = \lfloor r 2^n \rfloor, \qquad I_n^r = \left[\frac{k_n}{2^n}, \frac{k_n + 1}{2^n}\right]. \tag{11.6}$$

The endpoints are rational because k_n is an integer. The floor inequalities show that r lies in each interval.

Lemma 11.7 (The next dyadic floor stays in the previous interval)**.** *For every n,*

$$2k_n \le k_{n+1} \le 2k_n + 1.$$

Proof. The definition of floor gives $k_n \le r2^n < k_n + 1$. Multiply by two:

$$2k_n \le r2^{n+1} < 2k_n + 2.$$

Since both k_{n+1} and the bounds are integers, taking the floor gives the lower bound $2k_n$ and the upper bound $2k_n + 1$. □

Theorem 11.8 (Coverage of the classical real line)**.** *The family in* (11.6) *is an interval protocol with displayed value r. Consequently every classical real is the displayed value of an interval protocol.*

Proof. The lower dyadic bound in Lemma 11.7, divided by 2^{n+1}, says that the new lower endpoint is at least the old one. The upper bound, after adding one and dividing by 2^{n+1}, says that the new upper endpoint is at most the old one. This is nesting.

The interval width is 2^{-n}. We have $n + 1 \le 2^n$ by induction: it is equality at zero, and from $n + 1 \le 2^n$ and $1 \le 2^n$ we obtain $n + 2 \le 2^n + 2^n = 2^{n+1}$. Taking reciprocals proves $2^{-n} \le 1/(n + 1)$, the required width bound.

The floor inequalities put r in every interval, and uniqueness of the value gives $\nu(I^r) = r$. □

The formula takes r as a supplied classical real. Evaluating an exact floor at every request is not, by itself, a procedure for extracting these integers from an unknown quantity. The theorem establishes coverage by general interval families. A finite program name still requires the computability condition of Theorem 10.12.

Remark 11.9 (What the floor digits cost)**.** For $0 \le r < 1$, the integers k_n of (11.6) record the binary digits of r. Here $k_0 = 0$, and by Lemma 11.7 each digit $k_{n+1} - 2k_n$ is 0 or 1: it says which half of the previous interval contains r. The decision between the halves is classical. On the line $\mathbb{R}_\delta$ of Chapter 12, which assumes no classical completeness, the statement that every point of $[0, 1]$ has a binary expansion is equivalent to LLPO given countable choice, and binary expansions for all points of $[0, 1]$ already yield LLPO with no choice at all (Section 12.9). The obstacle is a point that may lie on a dyadic boundary: choosing its half requires a decision that no finite stage supplies. If a digit may also be -1, consecutive intervals overlap and the obstacle disappears. Every point of $[-1, 1]$ has a signed-digit expansion, each digit read off one stage of one sequence naming the point, with no omniscience principle and no choice principle.

Taken together, the results identify exactly what the display retains. It covers the classical real line; it identifies two protocols exactly when they overlap at every precision; and it preserves the rational embedding, addition, negation and subtraction constructed above. None of those assertions requires identifying all interval protocols with finite programs.

11.6 Why finite prefixes do not provide a uniform name

We can now prove the promised distinction between finite data at each precision and one program for every precision. The argument has two steps. There are only countably many program-named values. The classical real line has more than countably many points.

Lemma 11.10 (There are only countably many named values)**.** *The set of displayed values of uniformly program-named interval protocols is countable.*

Proof. A named protocol retains a finite program and the protocol it names. For a fixed program, Lemma 10.11 permits at most one such protocol. Retaining the program is therefore an injection of named protocols into the finite program expressions. Those expressions inject into the natural numbers by Lemma 10.7. Named protocols are consequently countable. Their displayed values form an image of a countable set, so that image is countable too. □

For completeness, the uncountability needed here can be seen directly from Cantor's argument. Binary sequences cannot be listed as $b_0, b_1, b_2, \ldots$: the sequence whose nth bit is the opposite of $b_n(n)$ differs from every sequence at its corresponding position.

These sequences inject into the classical real line. For a binary sequence b, with its bits regarded as 0 or 1, use the convergent sum

$$C(b) = \sum_{n=0}^{\infty} b(n)\, 3^{-n}. \tag{11.7}$$

Convergence follows by comparison with the geometric series. If two sequences first differ at position k, their contributions before k agree. The contribution at k differs by 3^{-k}, while all later contributions together can change the difference in the opposite direction by at most

$$\sum_{n>k} 3^{-n} = \frac{1}{2}\, 3^{-k}.$$

The first difference therefore cannot be canceled. The map is injective, and a countable real line would make the binary sequences countable as well, contradicting the diagonal argument. This is a classical cardinality argument; the infinite sums and the deduction from distinct sequences to a first differing position are used in that setting.

Theorem 11.11 (The finite-prefix and uniform-name boundary)**.** *In the classical comparison of this chapter, every interval protocol has a program for each supplied finite prefix, but some interval protocol has no single program naming all its intervals. The same failure holds if names are required to be stored in distinction tallies.*

Proof. The first assertion is Theorem 10.13. By Lemma 11.10 and the uncountability just proved, choose a real r outside the set of named values. By Theorem 11.8, it is the value of its dyadic protocol p. If p had a uniform name, its value r would belong to the excluded countable set, a contradiction.

If p had a stored program name, recovering it would give an ordinary uniform name by Theorem 10.8. The same contradiction therefore applies after storage. □

The result rules out a specific quantifier reversal. It does not say that a particular unnamed protocol has been obtained by a finite measurement, or that a physical process has performed a noncomputable operation. It concerns the difference between all families allowed by a mathematical definition and the families produced by finite programs.

There is a further question even for executable families. Producing successively narrower intervals is one task; deciding exact equality or choosing the sign of an arbitrary limiting quantity is another. The next chapter asks what additional logical principles those decisions require. It also takes apart the completeness used in this chapter. On a line built from the ratios of Chapter 4, with no classical real line assumed, limits, least upper bounds and suprema each receive their own exact price.

Questions to work through

1. Prove the cross-endpoint inequality (11.1) when $a \leq b$, then when $b \leq a$. Explain how the maximum-index proof combines the two cases.

2. In Theorem 11.5, identify where overlap is used and where the width bound is used. Why is the request $2m + 1$ convenient?

3. Check both nesting inequalities for the negated protocol. Then explain why proving enclosure of $-\nu(p)$ avoids a direct calculation with suprema.

4. Trace the contradiction in Theorem 11.11. Which result supplies a protocol for the selected real, and which result shows that a name for this protocol is impossible?

Chapter 12

Exact comparison has a cost

Suppose successive measurements enclose a quantity ever more closely, yet zero remains inside every enclosure received so far. More precision can eventually reveal that the quantity is positive or negative. What would justify a procedure that always decides whether it is exactly zero?

The difficulty is the word "always." A finite calculation can settle a strict inequality once the separation is larger than its error. An exact zero decision must also settle the case in which no separating witness ever appears. This chapter identifies the additional logical principle required by each of four precise forms of comparison: deciding exact zero, producing a witnessed sign, choosing one of two sides, and turning a proof that a quantity is not zero into a sign. Each result has two directions: the principle supplies the comparison, and the comparison supplies the principle. The chapter then asks the same question of completeness, the property of the line that the classical comparison of Chapter 11 took for granted.

We use a regular dyadic presentation to keep every finite comparison in integer arithmetic. This is a specified presentation with its own error condition. The classical completeness argument of Chapter 11 is not used in the proofs below. Nor do we silently transfer an operation between this presentation and the interval protocols of that chapter. Section 12.8 shows that nothing depends on the dyadic denominators: rounding matches these presentations, point for point, with regular sequences of the ratios of Chapter 4, and every price proved here holds there unchanged.

12.1 Finite stages and exact predicates

A dyadic rational is an integer divided by a power of two. At stage n, write the approximation as

$$x_n = \frac{q_n}{2^n}, \qquad q_n \in \mathbb{Z}.$$

The numerator is finite data. A sequence of arbitrary numerators need not describe one coherent quantity, so the presentation includes a regularity condition.

Definition 12.1 (Regular dyadic presentation)**.** A regular dyadic presentation consists of a sequence $(q_n)_{n\ge 0}$ of integers such that, for every m, n,

$$|q_m 2^n - q_n 2^m|(m+1)(n+1) \le 2^{m+n}(m+n+2). \tag{12.1}$$

In rational notation, the same condition reads

$$|x_m - x_n| \le \frac{1}{m+1} + \frac{1}{n+1}. \tag{12.2}$$

The rational notation abbreviates the integer condition: multiply by the positive denominator $2^{m+n}(m+1)(n+1)$ to recover (12.1).

We will write x for the whole presentation. This notation does not discard the numerators or their regularity. In particular, each decision made at a specified stage uses the numerator at that stage.

Definition 12.2 (Five comparisons with zero)**.** For a regular dyadic presentation x, define

$$\begin{aligned} Z(x) &: \quad \forall n,\ |q_n|(n+1) \le 2 \cdot 2^n, \\ P(x) &: \quad \exists n,\ 2 \cdot 2^n < q_n(n+1), \\ N(x) &: \quad \exists n,\ q_n(n+1) < -2 \cdot 2^n, \\ U(x) &: \quad \forall n,\ -2 \cdot 2^n \le q_n(n+1), \\ D(x) &: \quad \forall n,\ q_n(n+1) \le 2 \cdot 2^n. \end{aligned}$$

These are, respectively, the zero predicate, positive and negative witness predicates, and nonnegative and nonpositive predicates for this presentation.

In rational notation, $Z(x)$ says that every stage lies within $2/(n+1)$ of zero. The predicate $P(x)$ supplies a stage above this tolerance; $N(x)$ supplies one below its negative. The predicates $U(x)$ and $D(x)$ say that all stages respect the corresponding one-sided bounds. Their letters will keep the full quantified statements visible while we compare their logical strength.

This is the link with the enclosure picture of the preceding chapter. Finite data are tested against a stated error allowance. A positive or negative witness clears that allowance at a particular stage; the zero predicate keeps every stage within a shrinking band around zero. The nonnegative and nonpositive predicates prohibit witnesses on the other side. The regularity condition keeps the stages consistent enough that opposite witnesses cannot both occur, as the next lemma proves. These names refer to the displayed predicates of this presentation; using them does not invoke a map from an interval protocol or a completed classical real.

The factor two is part of these definitions. The theorems concern this regularity condition and these thresholds. They do not claim that an arbitrary choice of tolerances would give the same statements without a separate argument.

Every inequality at a fixed index is decidable by finite integer arithmetic. The quantifiers are where the questions change. To establish $P(x)$ it suffices to produce one index. To establish $Z(x)$ requires a reason that works at every index. Failing to find a witness in the stages already examined supplies neither such a reason nor an exact zero decision.

Lemma 12.3 (Opposite witnesses are incompatible)**.** *A regular dyadic presentation cannot satisfy both $P(x)$ and $N(x)$.*

Proof. Suppose m witnesses $P(x)$ and n witnesses $N(x)$. In rational notation,

$$x_m > \frac{2}{m+1}, \qquad x_n < -\frac{2}{n+1}.$$

Subtracting gives

$$x_m - x_n > \frac{2}{m+1} + \frac{2}{n+1}.$$

The right side is strictly greater than $1/(m+1)+1/(n+1)$, whereas regularity bounds $|x_m - x_n|$ by that smaller quantity. This is a contradiction. All denominators here are positive integers. Clearing them gives the same contradiction entirely in integer arithmetic. □

This lemma will do essential work in the proof of Theorem 12.8. Without regularity, a list could alternate between large positive and negative values, and that argument would fail.

12.2 Questions about a binary sequence

Let $\alpha : \mathbb{N} \to \{0, 1\}$ be a binary sequence. The value at each specified index is decidable. The principles WLPO, LPO and LLPO of Definition 7.8 in Chapter 7, together with the binary form $\mathrm{MP}_{\mathrm{bin}}$ of Markov's principle stated there, concern what can be concluded about all its values together.

WLPO decides whether the all-zero assertion holds. Its negative answer does not itself provide an index. LPO supplies an index in its second branch. LLPO has a different premise and conclusion: with at most one event, one parity class is entirely free of events. It need not tell us whether an event occurs in the other class. $\mathrm{MP}_{\mathrm{bin}}$ decides nothing: it turns a proof that not every value is zero into an index whose value is one.

The binary form of LPO makes the witness distinction of Chapter 6 concrete. These are principles about arbitrary sequences in the stated domain; there is no unmentioned restriction to sequences generated by a selected class of programs.

12.3 Encoding an event as a small jump

The reverse implications need a construction that turns information about a binary sequence into information about a regular dyadic presentation. It must be possible to construct each finite stage without first deciding whether the sequence ever contains a 1.

At stage n, inspect only

$$\alpha(0), \alpha(1), \dots, \alpha(n).$$

If they are all zero, report that no event has yet been found. Otherwise, report the least index $N \le n$ with $\alpha(N) = 1$. This is a bounded search. Once such a first index has been found, every later search reports the same index: all smaller entries have already been checked.

Choose a sign $\sigma(N) \in \{-1, 1\}$ for each possible first index. Define the jump numerators by

$$q_n = \begin{cases} 0, & \text{if no event has been found through stage } n, \\ \sigma(N)2^{n-N}, & \text{if the first event is at } N \le n. \end{cases} \tag{12.3}$$

Thus the rational stages are zero before the first event and $\sigma(N)2^{-N}$ from then on. The exponent $n - N$ in the numerator is nonnegative whenever that branch is used. No unbounded search is required to produce q_n.

Lemma 12.4 (The jump presentation is regular)**.** *For every binary sequence and every choice of signs of absolute value one,* (12.3) *defines a regular dyadic presentation.*

Proof. Compare stages m and n. If neither bounded search has found an event, both stages are zero. If both have found one, they report the same first index, so both rational stages equal $\sigma(N)2^{-N}$. In either case their difference is zero.

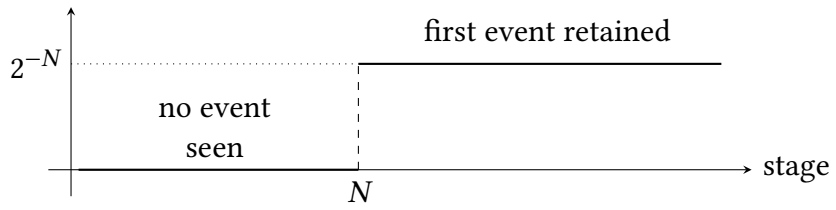

Figure 12.1. A positive jump presentation. The first event fixes the later rational stage. A later first event produces a smaller jump; the drawing shows the construction, with no claim that the vertical scale is uniform across different choices of N.

In the remaining case, interchange m, n if necessary so that the search at m has found no event and the search at n has found its first event at N. Then $m < N \le n$, and the absolute difference between the rational stages is 2^{-N}.

For every positive integer N, $N < 2^N$. This follows by induction: $1 < 2$, and $N+1 \le 2N < 2^{N+1}$ when $N \ge 1$ and $N < 2^N$. Since $m + 1 \le N$, it follows that

$$2^{-N} < \frac{1}{m+1} \le \frac{1}{m+1} + \frac{1}{n+1}.$$

This is the required regularity bound. The case $N = 0$ cannot occur in this branch, since it requires $m < N$. □

Let $j_{\sigma,\alpha}$ denote this presentation. Its decisive property is an exact relationship between its zero predicate and the original sequence.

Lemma 12.5 (A jump is zero exactly when no event occurs)**.** *For every allowed sign sequence,*

$$Z(j_{\sigma,\alpha}) \quad \Longleftrightarrow \quad \forall k,\ \alpha(k) = 0.$$

Proof. If every entry is zero, every jump numerator is zero, so every inequality in $Z(j_{\sigma,\alpha})$ holds.

Conversely, suppose $Z(j_{\sigma,\alpha})$. Fix an index k. Its binary value is decidable. If $\alpha(k) = 1$, bounded search through k supplies a first event $N \le k$. Choose the later stage

$$n_0 = 2^{N+1}.$$

This stage is at least N, and its rational absolute value is 2^{-N}. The zero predicate at n_0 would require

$$\frac{1}{2^N} \le \frac{2}{2^{N+1}+1}.$$

Multiplying by the positive denominators gives $2^{N+1} + 1 \le 2^{N+1}$, a contradiction. Therefore $\alpha(k) = 0$. Since k was arbitrary, every entry is zero. □

The displayed stage is a sufficient witness, not a claim about an optimal running time. Its purpose is to show exactly how a nonzero jump eventually exceeds the shrinking zero tolerance.

12.4 Exact zero decisions are equivalent to WLPO

Theorem 12.6 (The logical price of an exact zero decision)**.** *The following statements are equivalent:*

1. *Every regular dyadic presentation x satisfies $Z(x) \vee \neg Z(x)$.*
2. *WLPO holds for every binary sequence.*

Proof. Suppose first that the exact zero decision is available. Given α, construct its positive jump presentation, using $\sigma(N) = 1$ for every N. Apply the decision to it. By Lemma 12.5, the zero branch gives $\forall n, \alpha(n) = 0$. In the other branch, that all-zero assertion would imply the zero predicate, contradicting the decision. Thus it gives $\neg\forall n, \alpha(n) = 0$. This is WLPO.

Conversely, assume WLPO and let x be any regular dyadic presentation. Form a binary sequence of tolerance violations:

$$b(n) = \begin{cases} 1, & 2 \cdot 2^n < |q_n|(n+1), \\ 0, & |q_n|(n+1) \le 2 \cdot 2^n. \end{cases}$$

Each value is obtained by a decidable integer comparison. The assertion that every $b(n)$ is zero is exactly $Z(x)$. WLPO applied to b therefore gives $Z(x) \vee \neg Z(x)$. □

The second branch is still only a negative assertion. Asking instead for an exhibited positive or negative stage is a stronger request. The next theorem prices the full three-way answer; Theorem 12.11 prices the passage from the negative assertion to a sign on its own.

12.5 Sign trichotomy is equivalent to LPO

Theorem 12.7 (The logical price of a witnessed sign)**.** *The following statements are equivalent:*

1. *Every regular dyadic presentation x satisfies $P(x) \vee Z(x) \vee N(x)$.*
2. *LPO holds for every binary sequence.*

Proof. Assume the three-way comparison. Given α, construct its positive jump presentation. A zero answer gives that every entry of α is zero, by Lemma 12.5. A negative answer is impossible: every numerator of this presentation is nonnegative.

A positive answer supplies a stage n whose numerator exceeds the positive tolerance. The bounded search through n must therefore have found an event; otherwise the numerator would be zero. Its reported index N satisfies $\alpha(N) = 1$. These branches give LPO.

Conversely, assume LPO and use the violation sequence b from the preceding proof. If all entries vanish, $Z(x)$ holds. Otherwise LPO supplies an index n such that

$$2 \cdot 2^n < |q_n|(n+1).$$

The sign of the integer q_n is decidable. If $q_n \ge 0$, the inequality is a positive witness. If $q_n \le 0$, it becomes $q_n(n+1) < -2 \cdot 2^n$, a negative witness. Thus the required three-way comparison follows. □

Both reverse constructions use the same event encoding. What changes is the information returned by the comparison: a negative zero assertion in one case, an actual separating stage in the other.

12.6 One-sided order is equivalent to LLPO

The third comparison asks only for $U(x) \vee D(x)$: every presentation is nonnegative or nonpositive in the precise sense of Definition 12.2. It does not require a strict sign witness or a zero decision.

Theorem 12.8 (The logical price of order dichotomy)**.** *The following statements are equivalent:*

1. *Every regular dyadic presentation x satisfies $U(x) \vee D(x)$.*
2. *LLPO holds for every binary sequence with at most one event.*

Proof. Assume the order dichotomy. Let β have at most one entry equal to 1. Construct its jump presentation using the parity sign

$$\sigma(N) = \begin{cases} 1, & N \text{ even}, \\ -1, & N \text{ odd}. \end{cases}$$

If $U(j_{\sigma,\beta})$ holds, every odd entry of β must vanish. Indeed, an event at an odd index N would be its unique event, hence its first. At stage $n_0 = 2^{N+1}$ the rational value would be -2^{-N}. The nonnegative predicate would require

$$-\frac{2}{n_0 + 1} \leq -\frac{1}{2^N},$$

contradicting the same denominator calculation as in Lemma 12.5. The decidable binary value at each odd index is consequently zero. Similarly, $D(j_{\sigma,\beta})$ forces every even entry to vanish. These alternatives give LLPO.

For the converse, assume LLPO and fix a regular presentation x. First make a sequence of signed events by interleaving its finite comparisons:

$$\begin{aligned} e(2k) = 1 \quad &\Longleftrightarrow \quad 2 \cdot 2^k < q_k(k+1), \\ e(2k+1) = 1 \quad &\Longleftrightarrow \quad q_k(k+1) < -2 \cdot 2^k. \end{aligned}$$

Put zero in each remaining position. There may be many positive events, or many negative events. LLPO requires at most one event, so applying it directly to e would be invalid.

Instead retain only the first event. Define $f(j) = 1$ precisely when the bounded search through $e(0), \ldots, e(j)$ reports its first event at j. Put $f(j) = 0$ otherwise. Uniqueness of a first index proves that f has at most one event. LLPO can now be applied to f.

Suppose its even positions are all zero. We show $D(x)$. Fix k and decide the integer inequality defining $D(x)$ at k. If it holds, there is nothing more to prove. If it fails, k is a positive witness, so $e(2k) = 1$. Bounded search through $2k$ supplies a first event at an index j, with $f(j) = 1$.

If j is even, this contradicts the LLPO branch. If j is odd, it supplies a negative witness for x, contradicting the positive witness by Lemma 12.3. Hence the inequality must hold. Since k was arbitrary, $D(x)$ follows.

If instead all odd positions of f are zero, the symmetric argument gives $U(x)$. A hypothetical negative witness would force a first event that is either forbidden by that branch or is an incompatible positive witness. Thus $U(x) \vee D(x)$ follows in both cases. □

Two details make this proof work. Taking only the first event supplies the premise required by LLPO. Regularity then excludes a first event of the opposite sign. Neither step can be replaced by an appeal to the visual appearance of a converging sequence.

12.7 The difference between denying and finding

The form of Markov's principle used here is the binary form $\mathrm{MP}_{\mathrm{bin}}$ of Definition 7.8: for every binary sequence, $\neg(\forall n, \alpha(n) = 0)$ implies $\exists n, \alpha(n) = 1$. We keep to this form rather than silently changing between formulations of Markov's principle.

Proposition 12.9 (LPO separates into a decision and a witness principle)**.** *For the binary principles of Definition 7.8,*

$$\mathrm{LPO} \iff \mathrm{WLPO} \wedge \mathrm{MP}_{\mathrm{bin}}.$$

Moreover, LPO implies LLPO.

Proof. LPO gives either an all-zero assertion or an event. An event contradicts the all-zero assertion, so these alternatives give WLPO. If the all-zero assertion is already denied, LPO's all-zero branch is impossible, leaving an event. This gives $\mathrm{MP}_{\mathrm{bin}}$.

Conversely, WLPO decides the all-zero assertion. Keep its positive branch; apply $\mathrm{MP}_{\mathrm{bin}}$ in its negative branch to obtain an event. The resulting alternatives are exactly LPO.

Finally, suppose a sequence has at most one event. Apply LPO to its subsequence of even entries. If every even entry vanishes, one LLPO branch is already established. Otherwise there is an even event. An odd event would then be a different second event, contrary to the premise. Since each odd entry is binary, every odd entry is zero. This gives the other LLPO branch. □

WLPO's negative branch, applied to a presentation, gives only $\neg Z(x)$. Here is what that leaves undone. Let α be a binary sequence that is known not to be all zero, and let j be its positive jump presentation. Lemma 12.5 gives $\neg Z(j)$. Yet every stage of j before the first event is 0, so a stage above the positive tolerance can be exhibited only once an event of α has been found. For this presentation, turning $\neg Z(j)$ into $P(j)$ is the same task as turning $\neg(\forall n, \alpha(n) = 0)$ into an event. We now show that the passage from a proof that a presentation is not zero to an actual sign costs exactly $\mathrm{MP}_{\mathrm{bin}}$ in general. First we identify exactly what such a proof says.

Lemma 12.10 (Zero is the absence of both witnesses)**.** *For every regular dyadic presentation x,*

$$Z(x) \quad \Longleftrightarrow \quad \neg P(x) \wedge \neg N(x).$$

Consequently $\neg Z(x)$ holds exactly when $\neg\neg\big(P(x) \vee N(x)\big)$ holds.

Proof. Suppose $Z(x)$. A positive witness at stage n would give

$$2 \cdot 2^n < q_n(n+1) \leq |q_n|(n+1),$$

contrary to the zero bound $|q_n|(n+1) \leq 2 \cdot 2^n$ at the same stage. A negative witness fails in the same way, with $-q_n$ in place of q_n.

Conversely, suppose that neither witness exists, and fix n. The zero bound at n is a decidable integer comparison. If it failed, the sign of the integer q_n would turn the failure into a positive witness, when $q_n \geq 0$, or a negative witness, when $q_n \leq 0$, exactly as in the proof of Theorem 12.7. Both are excluded, so the bound holds at n. Since n was arbitrary, $Z(x)$ follows.

The equivalence says that $Z(x)$ is $\neg(P(x) \vee N(x))$. Negating both sides gives the second statement. □

A proof that x is not zero is therefore exactly a proof that a sign witness cannot be ruled out. Removing that double negation is the content of the next theorem.

Theorem 12.11 (The logical price of a sign for a nonzero quantity)**.** *The following statements are equivalent:*

1. *Every regular dyadic presentation x satisfies $\neg Z(x) \to P(x) \vee N(x)$.*
2. $\mathrm{MP}_{\mathrm{bin}}$ *holds for every binary sequence.*

Proof. Assume $\mathrm{MP}_{\mathrm{bin}}$, and let x satisfy $\neg Z(x)$. Form the violation sequence b from the proof of Theorem 12.6. The assertion that every $b(n)$ is zero is exactly $Z(x)$, so $\neg Z(x)$ says that b is not all zero. $\mathrm{MP}_{\mathrm{bin}}$ supplies an index n with $b(n) = 1$. The sign of q_n then gives a positive or a negative witness at n, as in the converse half of Theorem 12.7.

Conversely, assume the first statement, and let α be a binary sequence that is not all zero. Construct its positive jump presentation j, with $\sigma(N) = 1$ for every N. By Lemma 12.5, $Z(j)$ would make every entry of α zero, so $\neg Z(j)$. The first statement gives $P(j) \vee N(j)$. The negative branch is impossible because every numerator of j is nonnegative. A positive witness at stage n has a nonzero numerator, so the bounded search through n has found a first event $N \leq n$, and $\alpha(N) = 1$. This is the conclusion of $\mathrm{MP}_{\mathrm{bin}}$. □

The same price appears in a statement that mentions only one sign.

Corollary 12.12 (Stability of positivity)**.** *Every regular dyadic presentation satisfies* $\neg\neg P(x) \to P(x)$ *if and only if* $\mathrm{MP}_{\mathrm{bin}}$ *holds. The same is true of* $\neg\neg N(x) \to N(x)$*.*

Proof. The predicate $P(x)$ says that the binary sequence of positive tests, $p(n) = 1$ exactly when $2 \cdot 2^n < q_n(n+1)$, has an event. If $\neg\neg P(x)$, then p is not all zero, and $\mathrm{MP}_{\mathrm{bin}}$ supplies the event.

Conversely, let α be a binary sequence that is not all zero, and let j be its positive jump presentation. As in the preceding proof, $\neg Z(j)$, so Lemma 12.10 gives $\neg\neg(P(j) \vee N(j))$. Since $N(j)$ is impossible, this is $\neg\neg P(j)$. Stability gives $P(j)$, and the event of α is read off as before.

For N, replace every numerator q_n by $-q_n$. The regularity condition is unchanged, and the new presentation has a positive witness exactly where the old one had a negative witness. □

The four comparisons now fit together. For a single presentation, a witnessed sign is precisely an exact zero decision together with a sign for the nonzero case.

Proposition 12.13 (Trichotomy is a decision plus a sign)**.** *For every regular dyadic presentation* x*,*

$$P(x) \vee Z(x) \vee N(x) \quad \Longleftrightarrow \quad \big(Z(x) \vee \neg Z(x)\big) \wedge \big(\neg Z(x) \to P(x) \vee N(x)\big).$$

Proof. Suppose the three-way alternative. In the middle case $Z(x)$ holds, and the implication is satisfied because its premise is refuted. In either outer case, Lemma 12.10 gives $\neg Z(x)$, and the required sign is already present. Conversely, decide $Z(x)$. The positive answer is the middle alternative; the negative answer yields a sign through the implication. □

Quantify over all presentations and price the three parts with Theorems 12.7, 12.6 and 12.11. The result is again LPO $\Longleftrightarrow$ WLPO $\wedge$ $\mathrm{MP}_{\mathrm{bin}}$, this time obtained through the comparisons rather than from the binary sequences directly. Proposition 12.9 is the direct proof. Table 12.1 collects the four comparisons.

Comparison, for every regular dyadic presentation	Exact price	Proved in
$Z(x) \vee \neg Z(x)$	WLPO	Theorem 12.6
$P(x) \vee Z(x) \vee N(x)$	LPO	Theorem 12.7
$U(x) \vee D(x)$	LLPO	Theorem 12.8
$\neg Z(x) \to P(x) \vee N(x)$	$\mathrm{MP}_{\mathrm{bin}}$	Theorem 12.11

Table 12.1. Four comparisons with zero and their exact prices. Each row is an equivalence between the displayed statement, asserted for every presentation, and the named principle for every binary sequence in its domain.

The four equivalences therefore distinguish exact comparison tasks without assuming that they are interchangeable. They also show why approximation alone does not discharge the comparison obligation: the jump construction turns an arbitrary sequence question into that obligation.

An equivalence identifies the logical resource a task supplies and uses. Our claim is the explicit two-way reduction for the stated carrier, thresholds and binary principles. No classical completeness, choice principle, unbounded witness selection or physical measurement postulate is hidden in those reductions. That the four principles differ from one another is a separate, independence question, and Theorem 7.38 settles it: for each pair, a model of intuitionistic second-order arithmetic satisfies one of the two and refutes the other. In particular $\mathrm{MP}_{\mathrm{bin}}$ is comparable with neither WLPO nor LLPO.

12.8 One line built from ratios

The dyadic denominators kept every stage comparison in integer arithmetic. They are a convenience, not the source of the prices. To see this, build the continuum directly from the ratio records of Chapter 4.

Definition 12.14 (The line built from ratios)**.** A *regular sequence* is a sequence $s = (s_n)_{n\ge 0}$ of ratio records such that

$$|s_m - s_n| \le \frac{1}{m+1} + \frac{1}{n+1} \qquad \text{for all } m, n,$$

each inequality read in integer arithmetic after its positive denominators are cleared. Regular sequences s and t *name the same point*, written $s \approx t$, if for every k there is an N such that $|s_n - t_n| \le 1/(k+1)$ for every $n \ge N$. The *line* $\mathbb{R}_\delta$ is the set of regular sequences taken up to $\approx$. A ratio record q determines the point $\eta(q)$ of its constant sequence.

The relation $\approx$ is an equivalence relation; for transitivity, use the tolerance $1/(2k+2)$ for both given pairs and add the two bounds. Every regular dyadic presentation, read stage by stage as the ratio records $(q_n, 2^n)$, is a regular sequence: condition (12.2) is exactly the condition of the definition.

Naming the same point asks for eventual agreement within every tolerance, a condition with three quantifiers. For the point zero it collapses to a single bound at each stage: the zero predicate of this chapter.

Lemma 12.15 (Bishop's zero condition)**.** *A regular sequence s satisfies $s \approx \eta(0)$ if and only if $|s_n| \le 2/(n+1)$ for every n.*

Proof. If every stage satisfies the bound, take $N = 2k+1$ for the tolerance $1/(k+1)$: every $n \ge N$ has $|s_n| \le 2/(n+1) \le 1/(k+1)$.

Conversely, suppose $s \approx \eta(0)$, and fix m. The bound at m is a decidable comparison, so it suffices to refute its failure. If $|s_m| > 2/(m+1)$, regularity gives, for every n,

$$|s_n| \ge |s_m| - \frac{1}{m+1} - \frac{1}{n+1} > \frac{1}{m+1} - \frac{1}{n+1}.$$

For $n \ge 2m+2$ the right side is at least

$$\frac{1}{m+1} - \frac{1}{2m+3} = \frac{m+2}{(m+1)(2m+3)} \ge \frac{1}{2m+3}.$$

So every stage from $2m+2$ on lies outside the tolerance $1/(2m+3)$, contradicting $s \approx \eta(0)$ at that tolerance. □

A second estimate shows that a clearly positive stage is never lost.

Lemma 12.16 (A positive stage persists)**.** *If a regular sequence satisfies $s_N > 2/(N+1)$, then $s_m > 1/(2N+2)$ for every $m \geq 2N+1$.*

Proof. Since $m+1 \geq 2N+2$, regularity gives

$$s_m \geq s_N - \frac{1}{N+1} - \frac{1}{m+1} > \frac{1}{N+1} - \frac{1}{m+1} \geq \frac{1}{N+1} - \frac{1}{2N+2} = \frac{1}{2N+2}. \qquad \square$$

Call a point x *positive*, written $x > 0$, when a regular sequence naming it has a stage with $s_N > 2/(N+1)$. This belongs to the point, not to the sequence. To see it, let $t \approx s$, and take M such that $|s_m - t_m| \leq 1/(4N+4)$ for every $m \geq M$. For every $m \geq \max(M, 8N+7)$, Lemma 12.16 gives

$$t_m > \frac{1}{2N+2} - \frac{1}{4N+4} = \frac{1}{4N+4} \geq \frac{2}{m+1},$$

so t has a positive stage too. Define $x < 0$ in the same way, with a stage below $-2/(N+1)$. Write $x \geq 0$ for $\neg(x < 0)$ and $x \leq 0$ for $\neg(x > 0)$.

For a regular dyadic presentation, read as a regular sequence, these are the predicates of Definition 12.2. Its stages $q_n/2^n$ give $x > 0$ exactly when $P(x)$ and $x < 0$ exactly when $N(x)$: the inequalities are the same, with the denominator 2^n cleared. Each stage comparison is decidable, so $U(x)$, which says that no stage is a negative witness, is $\neg N(x)$, and $D(x)$ is $\neg P(x)$. In rational notation $Z(x)$ says that every stage lies within $2/(n+1)$ of zero, so by Lemma 12.15 it says that the point is $\eta(0)$.

The line contains nothing beyond the dyadic presentations.

Theorem 12.17 (One continuum, two presentations)**.** *For a regular sequence s, let r_n be the integer nearest to $2^n s_{2n+1}$, rounding halves upward. Then (r_n) is a regular dyadic presentation naming the same point as s. Two regular dyadic presentations name the same point exactly when $|q_n - q'_n|(n+1) \leq 2 \cdot 2^n$ for every n. Under this correspondence Z, P, N, U and D become $x = \eta(0)$, $x > 0$, $x < 0$, $x \geq 0$ and $x \leq 0$. No choice principle is used.*

Proof. The rounding error is at most one half, so $|r_n/2^n - s_{2n+1}| \leq 2^{-(n+1)}$, and $2n+2 \leq 2^{n+1}$ makes this at most $1/(2n+2)$. Using regularity of s at the stages $2m+1$ and $2n+1$ for the middle term,

$$\left|\frac{r_m}{2^m} - \frac{r_n}{2^n}\right| \leq \frac{1}{2m+2} + \left(\frac{1}{2m+2} + \frac{1}{2n+2}\right) + \frac{1}{2n+2} = \frac{1}{m+1} + \frac{1}{n+1}.$$

This is exactly (12.2), with nothing to spare. In the same way,

$$\left|\frac{r_n}{2^n} - s_n\right| \leq \frac{1}{2n+2} + \left(\frac{1}{2n+2} + \frac{1}{n+1}\right) = \frac{2}{n+1}.$$

A bound of $2/(n+1)$ at every stage gives agreement within $1/(k+1)$ from stage $2k+1$ on, as in the first half of Lemma 12.15. So the rounded presentation names the point of s.

The same remark proves one direction of the second assertion, whose bound reads $|x_n - x'_n| \leq 2/(n+1)$ in rational notation. Conversely, suppose that x and x' name the same point, and

fix n. For any k, choose a stage $p \geq k$ beyond the one from which the two presentations agree within $1/(k+1)$. Regularity of both presentations gives

$$|x_n - x'_n| \leq |x_n - x_p| + |x_p - x'_p| + |x'_p - x'_n| \leq \frac{2}{n+1} + \frac{2}{p+1} + \frac{1}{k+1} \leq \frac{2}{n+1} + \frac{3}{k+1}.$$

If $|x_n - x'_n|$ exceeded $2/(n+1)$, it would exceed it by a positive ratio (u, d) with $u \geq 1$; choosing $k + 1 > 3d$ makes $3/(k+1)$ smaller than that excess, a contradiction. The bound at n is a decidable comparison, so it holds. We call this argument the *Archimedean step*: a ratio that is at most $c + C/(k+1)$ for every k is at most c.

The predicates correspond as explained before the theorem. Every step is an explicit integer computation, a bounded estimate or the Archimedean step; no choice principle enters. □

Corollary 12.18 (The four prices on the line)**.** *For the points of $\mathbb{R}_\delta$, each of the following assertions, made for every point x, is equivalent to the principle named: $x = \eta(0) \vee x \neq \eta(0)$, to WLPO; $x > 0 \vee x = \eta(0) \vee x < 0$, to LPO; $x \geq 0 \vee x \leq 0$, to LLPO; $x \neq \eta(0) \to x > 0 \vee x < 0$, to $\mathrm{MP}_{\mathrm{bin}}$; and $\neg\neg(x > 0) \to x > 0$, to $\mathrm{MP}_{\mathrm{bin}}$.*

Proof. Through Theorem 12.17, each assertion for all points is equivalent to the corresponding assertion for all regular dyadic presentations. In one direction, every presentation names a point and the predicates correspond. In the other, an assertion about one given point is a proposition, so we may use one regular sequence naming that point and its rounded presentation; no selection among infinitely many points is needed. Theorems 12.6, 12.7, 12.8 and 12.11 and Corollary 12.12 then give the prices. □

The line also carries the arithmetic one expects, at no logical price. For regular sequences s and t, put

$$(s+t)_n = s_{2n+1} + t_{2n+1}, \qquad (-s)_n = -s_n, \qquad (st)_n = s_j t_j \quad \text{with } j = 2K(n+1) - 1,$$

where K is the larger of $\lfloor |s_0| \rfloor + 3$ and $\lfloor |t_0| \rfloor + 3$. Regularity keeps every stage within 2 of the first, since $|s_n - s_0| \leq 1/(n+1) + 1$, so $|s_n| \leq |s_0| + 2 < \lfloor |s_0| \rfloor + 3 \leq K$, and likewise $|t_n| < K$, for every n. Write $x < y$ for $y - x > 0$ and $x \leq y$ for $\neg(y < x)$.

Proposition 12.19 (The ordered field structure is free)**.** *These operations give regular sequences and respect $\approx$. They make $\mathbb{R}_\delta$ a commutative ring into which η embeds the ratios, preserving and reflecting their order; for records with positive denominators, $(u, d) < (v, e)$ means $ue < vd$. Moreover:*

1. *$<$ is irreflexive and transitive, and it is* cotransitive*: if $x < y$, then $x < z$ or $z < y$ for every z. Adding a point preserves $<$, and multiplying by a positive point preserves $<$;*
2. *$\leq$ is reflexive and transitive, and $x \leq y \leq x$ implies $x = y$;*
3. *x has a multiplicative inverse exactly when $x < 0$ or $x > 0$;*
4. *every point lies below $\eta(n)$ for some natural number n;*

5. *every two points have a least upper bound* $\max(x, y)$ *and a greatest lower bound* $\min(x, y)$*, and every* $x \geq 0$ *has exactly one square root* $y \geq 0$*.*

None of these statements uses an omniscience principle or a choice principle.

Proof. Throughout, s, t and u are regular sequences, and $K_s = \lfloor |s_0| \rfloor + 3$, so that the constant K of a product is the larger of K_s and K_t. Regularity gives $|s_n - s_0| \leq 1 + 1/(n+1) \leq 2$, so $|s_n| \leq K_s$ at every stage. Two tools, proved in Appendix F.4, carry the routine estimates. First, s and t name the same point exactly when $|s_n - t_n| \leq 2/(n+1)$ for every n, and a bound $|s_n - t_n| \leq C/(n+1)$ at every stage, for one fixed C, already gives $s \approx t$ (Lemma F.8). Second, say that s *follows* ratios $f(M)$ with constant C when

$$|s_n - f(M)| \leq C\Big(\frac{1}{n+1} + \frac{1}{M+1}\Big) \qquad \text{for all } n, M.$$

A regular sequence follows its own stages with constant 1; that is its regularity. If s follows f and t follows g, then $s + t$, $-s$ and st follow $f + g$, $-f$ and fg, with constants computed from those of s and t and a bound on f; and two sequences that follow ratios differing by at most $F/(M+1)$ name the same point (Lemma F.9). The second tool turns every identity of ratios into an identity of points.

The operations. The sum is regular: its stages at m and n read s and t at $2m+1$ and $2n+1$, so they differ by at most $2\big(1/(2m+2) + 1/(2n+2)\big) = 1/(m+1) + 1/(n+1)$. Negation changes no distance. For the product,

$$|s_i t_i - s_j t_j| \leq |s_i|\,|t_i - t_j| + |t_j|\,|s_i - s_j| \leq K\big(|s_i - s_j| + |t_i - t_j|\big),$$

and at $i+1 = 2K(m+1)$ and $j+1 = 2K(n+1)$ the right side is at most $K\big(2/(i+1) + 2/(j+1)\big) = 1/(m+1) + 1/(n+1)$. If $s \approx s'$ and $t \approx t'$, then $|s_M - s'_M|$ and $|t_M - t'_M|$ are at most $2/(M+1)$. The product st follows the ratios $s_M t_M$, the product $s't'$ follows $s'_M t'_M$, and these differ by at most $2(K_t + K_{s'})/(M+1)$; so $st \approx s't'$. Sums and negations respect $\approx$ by the same argument with simpler bounds. The operations are therefore operations on points.

A commutative ring. For each ring law the two sides follow the same ratios. For instance $(st)u$ follows $(s_M t_M)u_M$ and $s(tu)$ follows $s_M(t_M u_M)$, and these ratios are equal. In the same way, commutativity and associativity of sums and products, distributivity, the laws of $\eta(0)$ and $\eta(1)$, and $s + (-s) \approx \eta(0)$ reduce to the corresponding identities of ratios, applied to the stages.

The ratios. Sums, negatives and products of constant sequences are constant sequences, of the sum, negative and product, so η preserves the operations. Next, $\eta(q) = \eta(r)$ exactly when $|q - r| \leq 1/(k+1)$ for every k, that is when $q = r$. The point $\eta(r) - \eta(q)$ is named by the constant sequence $r - q$, which has a positive stage exactly when $r - q > 0$: if $r - q = \langle u; d\rangle$ with $u \geq 1$, any N with $N + 1 > 2d$ gives one, and if $r - q \leq 0$ no stage is positive. So $\eta(q) < \eta(r)$ exactly when $q < r$, which for records (u, d) and (v, e) with positive denominators says $ue < vd$.

Item 1. Positivity is closed under sums and products, and a positive stage of a sum gives a positive stage of a summand (Lemma F.10). The point $x - x$ is named by a sequence whose stages are all 0, so $x < x$ fails. If $x < y$ and $y < z$, then $z - x = (z - y) + (y - x)$ is positive. If $x < y$ and z is any point, then $y - x = (y - z) + (z - x)$, so $y - z$ or $z - x$ is positive: $z < y$ or $x < z$. Finally $(y + z) - (x + z) = y - x$, and $yz - xz = (y - x)z$ is a product of positive points when $x < y$ and $z > 0$.

Item 2. Reflexivity is irreflexivity of $<$. If $x \le y \le z$ and $z < x$, cotransitivity gives $z < y$ or $y < x$, and both are excluded; so $x \le z$. If $x \le y \le x$, then $x - y$ is neither positive nor negative, since $x < y$ says that $y - x = -(x - y)$ is positive. So no stage of a sequence naming $x - y$ lies above $2/(n+1)$ or below $-2/(n+1)$; each such comparison is decided, every stage lies within $2/(n+1)$ of 0, and Lemma 12.15 gives $x - y = \eta(0)$, that is $x = y$.

Item 3. If $x > 0$ or $x < 0$, the explicit inverse described below is a regular sequence whose product with x is $\eta(1)$ (Lemma F.11). Conversely, let s name x, let t name y, and suppose $xy = \eta(1)$. The product sequence names the positive point $\eta(1)$, so it has a positive stage N: with $j + 1 = 2K(N+1)$, $s_j t_j > 2/(N+1)$. Since $|t_j| \le K$,

$$|s_j| > \frac{2}{(N+1)K} = \frac{4}{j+1} > \frac{2}{j+1}.$$

The sign of the ratio s_j is decided, so $s_j > 2/(j+1)$ or $s_j < -2/(j+1)$, and $x > 0$ or $x < 0$.

Item 4. Every stage of s has $|s_m| \le K_s$, so the stages of $\eta(K_s + 1) - x$, which are $K_s + 1 - s_{2n+1}$, are at least 1, and the stage $n = 2$ exceeds $2/3$. Hence $x < \eta(K_s + 1)$.

Item 5. The maximum is computed stagewise, $\max(s,t)_n = \max(s_n, t_n)$, and $|\max(a,b) - \max(c,d)| \le \max(|a-c|, |b-d|)$ for ratios. So $\max(s,t)$ is regular, and by Lemma F.8 it respects $\approx$. It is an upper bound: if $\max(x,y) < x$, the difference $x - \max(x,y)$ has a positive stage N, which reads $s_{2N+1} - \max(s_{2N+1}, t_{2N+1}) > 2/(N+1)$, impossible. It is the least one: if $x \le z$ and $y \le z$ but $z < \max(x,y)$, a positive stage N of $\max(x,y) - z$ reads $\max(s_{2N+1}, t_{2N+1}) - u_{2N+1} > 2/(N+1)$; whichever of s_{2N+1}, t_{2N+1} is the larger, a decided comparison, gives a positive stage of $x - z$ or of $y - z$, which is excluded. The same argument gives the strict form: if $w < \max(x,y)$, then $w < x$ or $w < y$. The minimum is computed stagewise in the same way and is the greatest lower bound.

Two nonnegative square roots of x are equal. Let $y, z \ge 0$ with $yy = zz = x$, and suppose $y < z$. Then $0 < z$, because $0 \le y < z$, and cotransitivity applied to $0 < z$ gives $0 < z + y$ or $z + y < z$, the second meaning $y < 0$; so $z + y > 0$. The product $(z - y)(z + y)$ of positive points is positive, yet it equals $zz - yy = \eta(0)$. So $\neg(y < z)$, likewise $\neg(z < y)$, and item 2 gives $y = z$. A nonnegative square root exists by trisection (Lemma F.12). Fix a sequence s naming x and a natural number $K \ge 1$ with $x \le \eta(K^2)$. Starting from $[0, K]$, each step cuts the current interval $[a, b]$ of ratios into thirds at $c_1 < c_2$; since $a \ge 0$, the squares satisfy $c_2^2 - c_1^2 \ge (b-a)^2/3$. One stage of s, read with an error smaller than half this gap, decides by a comparison of ratios whether $\eta(c_1^2) < x$ or $x < \eta(c_2^2)$, and the step keeps $[c_1, b]$ or $[a, c_2]$ accordingly. The left ends form, after a fixed reindexing, a regular sequence; its point y is nonnegative, and yy and x lie in intervals of widths tending to 0, so they are equal. Each decision is computed from the one sequence s, so no choice is made, and by uniqueness the point y does not depend on which sequence naming x was used.

No principle. Every step above is a stage estimate, a comparison of two ratios, or the Archimedean step, and every sequence used is computed from given sequences. So none of these statements uses an omniscience principle or a choice principle. □

With two points the prices of Corollary 12.18 reappear, together with the field and lattice statements that name a side. Table 12.2 lists them.

Assertion, for all points x, y of $\mathbb{R}_\delta$	Exact price
$x < y \vee \neg(x < y)$	LPO
$x < y \vee x = y \vee y < x$	LPO
$x \le y \vee \neg(x \le y)$; also $x = y \vee x \neq y$	WLPO
$x \le y \vee y \le x$	LLPO
$\max(x, y) = x \vee \max(x, y) = y$	LLPO
$xy = \eta(0) \to x = \eta(0) \vee y = \eta(0)$	LLPO
$\neg(y \le x) \to x < y$; also $x \neq y \to x < y \vee y < x$	$\mathrm{MP}_{\mathrm{bin}}$
$x \neq \eta(0) \to x$ has a multiplicative inverse	$\mathrm{MP}_{\mathrm{bin}}$
$\neg\neg(x \le y) \to x \le y$	none

Table 12.2. Order and algebra on the line. Each priced row is equivalent to the named principle for binary sequences, in both directions, with no choice principle; the last row is proved outright.

Two rows deserve a word. Deciding $x < y$ is deciding $x \le y$ together with the stability $\neg(y \le x) \to x < y$, the same split as LPO = WLPO + $\mathrm{MP}_{\mathrm{bin}}$. And the classical field axiom, that a nonzero element is invertible, holds exactly under $\mathrm{MP}_{\mathrm{bin}}$. Without it the line is a field in the sense of item 3 of Proposition 12.19: what has an inverse is what is apart from zero.

Proof of the prices in Table 12.2. Every row compares two points through their difference, by the ring laws of Proposition 12.19. The statement $x < y$ says that $y - x > 0$; $y < x$ says that $x - y > 0$, that is $y - x < 0$, since negating a sequence negates its stages; $x \le y$ says $\neg(x - y > 0)$; $x = y$ says $x - y = \eta(0)$; and $z < \eta(0)$ says $z < 0$. An assertion about all pairs of points is therefore equivalent to one about all single points z: put $z = y - x$ in one direction, and $x = \eta(0)$ or $y = \eta(0)$ in the other. Two further facts are used. For a binary sequence α, let j_α also denote the point of its positive jump presentation. Then $j_\alpha > 0$ exactly when α has an event: a positive witness has a nonzero numerator, so the bounded search through its stage has found an event, as in the proof of Theorem 12.11; and an event at N gives, by bounded search through N, a first event $N' \le N$, which makes the stage $2^{N'+1}$ a positive witness, by the computation in the proof of Lemma 12.5. And for a point z, read through one regular dyadic presentation (Theorem 12.17), $z > 0$ exactly when the binary sequence p_z of positive tests, $p_z(n) = 1$ exactly when $2 \cdot 2^n < q_n(n+1)$, has an event.

Row 1. Assume LPO and let x, y be points. LPO applied to p_{y-x} gives an event, so $x < y$, or no event, so $\neg(x < y)$. Conversely, the assertion at $\eta(0)$ and j_α gives $j_\alpha > 0$, hence an event of α, or $\neg(j_\alpha > 0)$; in the second case no $\alpha(n)$ is 1, and each $\alpha(n)$, being binary, is 0. This is LPO.

Row 2. With $z = y - x$ the three alternatives are $z > 0$, $z = \eta(0)$ and $z < 0$, so the row is equivalent, in both directions, to the second assertion of Corollary 12.18, whose price is LPO.

Row 3. Assume WLPO and let $z = x - y$, so that $x \le y$ says $\neg(z > 0)$. WLPO applied to p_z gives that p_z is all zero, so $\neg(z > 0)$ and $x \le y$, or that it is not, so $\neg\neg(z > 0)$, which is $\neg(x \le y)$. Conversely, the assertion at j_α and $\eta(0)$ gives $\neg(j_\alpha > 0)$, so α is all zero, or $\neg\neg(j_\alpha > 0)$, so α is not all zero, since otherwise j_α would be $\eta(0)$. This is WLPO. For $x = y \vee x \neq y$, the reduction to $z = x - y$ gives the first assertion of Corollary 12.18, whose price is WLPO.

Row 4. With $z = x - y$, $x \le y$ says $\neg(z > 0)$, which is $z \le 0$, and $y \le x$ says $\neg(z < 0)$, which is $z \ge 0$. So the row is the third assertion of Corollary 12.18, whose price is LLPO.

Row 5. If $x \le y$, then y is an upper bound of x and y, so $\max(x,y) \le y \le \max(x,y)$ and $\max(x,y) = y$; if $y \le x$, then $\max(x,y) = x$. So row 4 gives row 5. Conversely, $\max(x,y) = x$ gives $y \le \max(x,y) = x$, and $\max(x,y) = y$ gives $x \le y$; so row 5 gives row 4, and both cost LLPO.

Row 6. Assume LLPO, and let $xy = \eta(0)$. Write $|x|$ for $\max(x,-x)$. By row 4, $|x| \le |y|$ or $|y| \le |x|$; suppose the first. If x were positive or negative, then $|x| > 0$, because $x \le |x|$ and $-x \le |x|$; so $|y| > 0$, because $u < v \le w$ gives $u < w$; so $y > 0$ or $-y > 0$ by the strict form of item 5 of Proposition 12.19. Then x and y would be invertible by item 3, and so would be $xy = \eta(0)$, which is neither positive nor negative. Hence x is neither positive nor negative, and $x = \eta(0)$ by item 2. The second case gives $y = \eta(0)$. Conversely, assume the domain law, and let β have at most one event. Let x and y be the points of the positive jump presentations of $k \mapsto \beta(2k)$ and $k \mapsto \beta(2k+1)$. No stage of either is negative. If xy were positive or negative, it would be invertible, so x and y would be invertible, hence positive, and each of the two sequences would have an event; these would be two different events of β. So xy is neither positive nor negative, $xy = \eta(0)$, and the domain law gives $x = \eta(0)$ or $y = \eta(0)$. By Lemma 12.5 and Theorem 12.17, every even entry of β is 0, or every odd entry is. This is LLPO.

Row 7. With $z = y - x$, $\neg(y \le x)$ is $\neg\neg(z > 0)$ and $x < y$ is $z > 0$, so the first form is the stability of positivity, the fifth assertion of Corollary 12.18. The second form, $x \ne y \to x < y \vee y < x$, reads $z \ne \eta(0) \to z > 0 \vee z < 0$, the fourth assertion. Both cost $\mathrm{MP}_{\mathrm{bin}}$.

Row 8. By item 3 of Proposition 12.19, x is invertible exactly when $x > 0$ or $x < 0$, so the row is the fourth assertion of Corollary 12.18, whose price is $\mathrm{MP}_{\mathrm{bin}}$.

Row 9. The statement $x \le y$ is the negation $\neg(y < x)$, and $\neg\neg\neg P$ implies $\neg P$ for every proposition P. So $\neg\neg(x \le y) \to x \le y$ holds outright.

In every row each point is read through one sequence naming it, as in the proof of Corollary 12.18, the jump presentations are explicit, and the principles are applied to explicit binary sequences. No choice principle is used in either direction. □

Remark 12.20 (Reasoning by cases costs nothing for stable conclusions)**.** Every priced row has a conclusion that names a side. A conclusion that names no side can be reached by cases for free. Any two points satisfy $\neg\neg(x \le y \vee y \le x)$: if neither held, we would have $\neg\neg(y < x)$ and $\neg\neg(x < y)$, hence $\neg\neg(x < x)$, contrary to irreflexivity. An inequality $x \le y$ is itself a negation, so it is stable under double negation, and an equation is stable because it follows from two such inequalities. Hence every equation or $\le$-inequality proved by cases on the order of finitely many points holds outright. Identities such as $\min(x,y)\max(x,y) = xy$ and $|x|\,|x| = x\,x$ are proved in this way. Allowing the same argument for an arbitrary conclusion costs exactly LLPO.

Proof of the last sentence of Remark 12.20. Allowing the argument for an arbitrary conclusion means the following principle: for every finite list of points and every proposition P, if P follows from the assumption that any two points of the list are comparable, that is $x \le y$ or $y \le x$, then P holds. The remark proves this principle for every P with $\neg\neg P \to P$. Any two points are not not comparable, and double negation passes through finite conjunctions, since $\neg\neg A$ and $\neg\neg B$ give $\neg\neg(A \wedge B)$; so the assumption is not not true, hence $\neg\neg P$, hence P. The two identities of the remark are instances. If $x \le y$, then $\min(x,y) = x$ and $\max(x,y) = y$, as

in row 5 of Table 12.2, so $\min(x,y)\max(x,y) = xy$, and symmetrically if $y \le x$. If $0 \le x$, then $-x \le 0 \le x$ and $|x| = \max(x,-x) = x$; if $x \le 0$, then $|x| = -x$; in both cases $|x|\,|x| = x\,x$.

For an arbitrary conclusion the principle is exactly LLPO. If LLPO holds, any two points are comparable, by row 4 of Table 12.2, so the assumption holds outright and P follows. Conversely, apply the principle to the list x, y and the conclusion $x \le y \vee y \le x$, which follows from the assumption at once. Every two points are then comparable, and row 4 gives LLPO. Neither direction uses a choice principle. □

12.9 What completeness costs

Chapter 11 used completeness of the classical line as one resource: a bounded set of lower endpoints had a supremum, and the displayed value was defined from it. On $\mathbb{R}_\delta$ that resource comes apart. Some forms of completeness cost nothing. One, that every located cut is the cut of a point, costs only countable choice, applied once to select an approximating pair of ratios for each precision. The other forms that need nothing beyond countable choice follow from that one with no further choice, and the limit of a Cauchy sequence needs only a choice of representatives. Each of the others costs exactly one principle: LPO, WLPO or LLPO, or, for arbitrary sets of points, weak excluded middle or excluded middle.

Countable choice decides nothing (Section 12.9.1). Sections 12.9.2–12.9.3 build limits from located cuts and show that the line is determined by its task; Sections 12.9.4–12.9.10 prove the rows of Table 12.3; Sections 12.9.11–12.9.14 show what replaces countable choice and what does not; Sections 12.9.15–12.9.16 give prices away from the line and the split of LPO.

12.9.1 Countable choice decides nothing

A principle of a different kind enters here.

Two readings of maps matter from here on. In this book a map is a relation with exactly one output for each input (Appendix C), so a relation with exactly one witness for each number already defines a sequence: the *principle of unique choice* is part of that reading. With excluded middle, unique choice gives countable choice for numbers, because the least witness is unique. The formal theory of Theorem 12.63 has variables for sequences instead and does not contain unique choice: in its model of computable sequences, the halting relation of that proof has exactly one witness for each program, and no computable sequence collects the witnesses. There, excluded middle and countable choice are separate principles. The theory of Theorem 12.22 contains countable choice for numbers, and with it unique choice, its case of a relation with exactly one witness for each number. Chapter 14 shows where unique choice enters linear algebra on the line, and Chapter 16 shows, inside the computable calculus of δ's own objects, that without it omniscience decides each question but cannot collect the answers into a sequence (Theorem 16.27).

Definition 12.21 (Countable choice)**.** *Countable choice*, AC_ω, states: if for every natural number n there is some x with $R(n, x)$, then there is a sequence f with $R(n, f(n))$ for every n.

Countable choice selects witnesses; it decides nothing. The next theorem makes this exact.

Theorem 12.22 (Countable choice decides nothing)**.** *Consider intuitionistic arithmetic with variables for sequences, induction for every formula, and countable choice both for numbers and for sequences. In that theory none of LPO, WLPO, LLPO and* $\mathrm{MP}_{\mathrm{bin}}$ *is provable, and none is refutable. More generally, if it proves* $\forall x\,(A(x) \vee \neg A(x))$ *for a property* A *built from equations and* $\bot$ *by conjunction, implication and universal quantification over numbers, then* A *is decided by a computer program, with any other free variables of* A *read as* 0 *and its free sequence variables as the zero sequence. With* $\mathrm{MP}_{\mathrm{bin}}$ *added, none of WLPO, LLPO and LPO becomes provable. The proof reasons in a classical metatheory.*

Conditions and scope.

Base and premises
Intuitionistic arithmetic with variables for sequences, induction for every formula, and countable choice for numbers and for sequences at every formula (hence unique choice); the metatheory is classical.

Conclusion
None of LPO, WLPO, LLPO and $\mathrm{MP}_{\mathrm{bin}}$ is provable or refutable; a provably decided property built from equations and $\bot$ by $\wedge$, $\to$ and $\forall x$ is decided by a program, with its other free variables read as in the theorem; with $\mathrm{MP}_{\mathrm{bin}}$ added, none of WLPO, LLPO and LPO becomes provable.

Proof. We fix the theory, read its formulas in two ways as tasks for programs, show that every theorem passes each reading, and show that none of the four principles does. The arguments about programs and models are made in ordinary classical mathematics: they describe what programs compute and which statements are true in a model, and they ask nothing of the theory under study.

The theory. Number terms are built from number variables, 0, the successor S, $+$, $\cdot$ and the application $\alpha(t)$ of a sequence variable α to a number term t. Formulas are built from equations $t = s$ and $\bot$ by $\wedge$, $\vee$ and $\to$, by the number quantifiers $\forall x$, $\exists x$ and by the sequence quantifiers $\forall \alpha$, $\exists \alpha$; $\neg A$ abbreviates $A \to \bot$. The rules are those of intuitionistic natural deduction for these connectives and quantifiers, in which $\forall x$ is instantiated and $\exists x$ introduced at any number term, and $\forall \alpha$ is instantiated and $\exists \alpha$ introduced at any sequence variable; reflexivity $t = t$ and the substitution of equals into every formula; the axioms $\neg(St = 0)$, $St = Ss \to t = s$, $t + 0 = t$, $t + Ss = S(t + s)$, $t \cdot 0 = 0$ and $t \cdot Ss = t \cdot s + t$; the induction rule, which infers $\forall x\, A(x)$ from $A(0)$ and $\forall x\,(A(x) \to A(Sx))$ for every formula A, sequence variables and sequence quantifiers included; and, for every formula A with any parameters, the two choice schemas

$$\forall x \exists y\, A(x, y) \to \exists \alpha \forall x\, A(x, \alpha(x)),$$
$$\forall x \exists \beta\, A(x, \beta) \to \exists \alpha \forall x \exists \beta \big(\forall y\, \beta(y) = \alpha(\langle x, y\rangle) \wedge A(x, \beta)\big),$$

where $\langle x, y\rangle = (x + y) \cdot (x + y) + y$. The first is countable choice for numbers. The second is countable choice for sequences: the pairing term takes different values at different pairs, so

the chosen sequences are the sections $y \mapsto \alpha(\langle x, y\rangle)$ of a single sequence. Write $\mathrm{Bin}(\alpha)$ for $\forall n\,(\alpha(n) = 0 \vee \alpha(n) = 1)$. With the two bits read as 0 and 1, the principles of Definition 7.8 are the sentences

$$\begin{aligned}
\mathrm{LPO} &: \ \forall\alpha\big(\mathrm{Bin}(\alpha) \to \forall n\,\alpha(n) = 0 \vee \exists n\,\alpha(n) = 1\big),\\
\mathrm{WLPO} &: \ \forall\alpha\big(\mathrm{Bin}(\alpha) \to \forall n\,\alpha(n) = 0 \vee \neg\forall n\,\alpha(n) = 0\big),\\
\mathrm{MP}_{\mathrm{bin}} &: \ \forall\alpha\big(\mathrm{Bin}(\alpha) \to \neg\forall n\,\alpha(n) = 0 \to \exists n\,\alpha(n) = 1\big),\\
\mathrm{LLPO} &: \ \forall\alpha\big(\mathrm{Bin}(\alpha) \to \forall m\,\forall n\,(\alpha(m) = 1 \to \alpha(n) = 1 \to m = n)\\
&\qquad\qquad \to \forall k\,\alpha(2k) = 0 \vee \forall k\,\alpha(2k+1) = 0\big).
\end{aligned}$$

None of the four is refutable. Read numbers as the natural numbers and sequences as all functions from the natural numbers to themselves. Every rule preserves truth in this reading; induction holds because the numbers are the natural numbers; the first choice schema holds because, when every x has some y, a function choosing one y for each x exists; and the second holds because sequences β_x chosen for the numbers x are assembled into one sequence by $\alpha(\langle x, y\rangle) = \beta_x(y)$, with $\alpha = 0$ off the values of the pairing term. These choices are made in the classical mathematics in which the model is described, which is exactly what a model of a theory with choice requires. In this model each of the four principles is true, by excluded middle applied to the given sequence. A refutation would be true there as well, so none of the four is refutable, in the theory or in the theory with $\mathrm{MP}_{\mathrm{bin}}$ added, which the model also satisfies. In particular both theories are consistent.

Programs. Fix a numbering of the programs that compute partial functions of one natural number, and write $\{e\}(a)$ for the output of program e on input a when that run halts. A program is *total* when it halts on every input. We use three standard facts of computability [19, Chapter XII]: a function obtained from given partial recursive functions by the operations of Definition 10.5 has a program (Proposition 10.6); from a program for a function of two arguments one computes, uniformly in the first argument, a program for the resulting function of the second; and functions defined by primitive recursion from computable ones are computable. Fix a computable bijection π from pairs of numbers onto numbers, and write $(r)_0$ and $(r)_1$ for the components of the pair numbered r. We arrange that $\pi(0, 0) = 0$ and that program 0 returns 0 on every input. A *valuation* assigns a number to every number variable and a total program to every sequence variable; the variable assigned i stands for the sequence $n \mapsto \{i\}(n)$. Under a valuation every term has a value, and every formula is true or false in the model whose sequences are the total computable ones.

Modified realizability. This is Kreisel's interpretation [7]. Types are built from $\mathbb{N}$ by $\sigma \to \rho$, $\sigma \times \rho$ and $\sigma + \rho$. A formula A has the type $\tau(A)$ given by

$$\begin{aligned}
&\tau(t = s) = \tau(\bot) = \mathbb{N}, && \tau(A \wedge B) = \tau(A) \times \tau(B), && \tau(A \vee B) = \tau(A) + \tau(B),\\
&\tau(A \to B) = \tau(A) \to \tau(B), && \tau(\forall x\,A) = \mathbb{N} \to \tau(A), && \tau(\exists x\,A) = \mathbb{N} \times \tau(A),\\
&\tau(\forall\alpha\,A) = (\mathbb{N} \to \mathbb{N}) \to \tau(A), && \tau(\exists\alpha\,A) = (\mathbb{N} \to \mathbb{N}) \times \tau(A).
\end{aligned}$$

The *hereditarily total operations* of each type form a set HRO_σ of numbers: $\mathrm{HRO}_{\mathbb{N}}$ contains every number; $\mathrm{HRO}_{\sigma\to\rho}$ contains the programs e such that $\{e\}(a)$ halts with a value in HRO_ρ for every a in HRO_σ; $\mathrm{HRO}_{\sigma\times\rho}$ contains the r with $(r)_0 \in \mathrm{HRO}_\sigma$ and $(r)_1 \in \mathrm{HRO}_\rho$; and $\mathrm{HRO}_{\sigma+\rho}$ contains the r with $(r)_0 = 0$ and $(r)_1 \in \mathrm{HRO}_\sigma$, or $(r)_0 \neq 0$ and $(r)_1 \in \mathrm{HRO}_\rho$. Thus $\mathrm{HRO}_{\mathbb{N}\to\mathbb{N}}$

is the set of total programs, and an induction on the type shows that 0 lies in every HRO_σ. Under a valuation, *r realizes* A, written $r \Vdash_{\mathrm{m}} A$, is defined by recursion on A:

- $r \Vdash_{\mathrm{m}} t = s$ when $t = s$ is true; no number realizes $\bot$;
- $r \Vdash_{\mathrm{m}} A \wedge B$ when $(r)_0 \Vdash_{\mathrm{m}} A$ and $(r)_1 \Vdash_{\mathrm{m}} B$;
- $r \Vdash_{\mathrm{m}} A \vee B$ when $(r)_0 = 0$ and $(r)_1 \Vdash_{\mathrm{m}} A$, or $(r)_0 \neq 0$ and $(r)_1 \Vdash_{\mathrm{m}} B$;
- $r \Vdash_{\mathrm{m}} A \to B$ when $r \in \mathrm{HRO}_{\tau(A)\to\tau(B)}$ and, for every $s \Vdash_{\mathrm{m}} A$, the value $\{r\}(s)$ realizes B;
- $r \Vdash_{\mathrm{m}} \forall x\, A(x)$ when, for every n, $\{r\}(n)$ halts with a value realizing $A(n)$;
- $r \Vdash_{\mathrm{m}} \exists x\, A(x)$ when $(r)_1 \Vdash_{\mathrm{m}} A((r)_0)$;
- $r \Vdash_{\mathrm{m}} \forall \alpha\, A(\alpha)$ when, for every total program i, $\{r\}(i)$ halts with a value realizing $A(i)$;
- $r \Vdash_{\mathrm{m}} \exists \alpha\, A(\alpha)$ when $(r)_0$ is total and $(r)_1 \Vdash_{\mathrm{m}} A((r)_0)$.

Here $A(n)$ is read with its variable assigned n, and $A(i)$ with its sequence variable assigned i. An induction on A shows that every realizer of A lies in $\mathrm{HRO}_{\tau(A)}$. The implication clause makes the reading *modified*: a realizer of $A \to B$ must be an operation of type $\tau(A) \to \tau(B)$, so it must answer on every input of that type, whether or not the input realizes A.

Kleene realizability. The relation $r \Vdash_{\mathrm{k}} A$ has the same clauses, except that $r \Vdash_{\mathrm{k}} A \to B$ asks only that $\{r\}(s)$ halt with a realizer of B for every $s \Vdash_{\mathrm{k}} A$. Nothing is asked about other inputs. This is the reading used in Chapter 6, extended to sequences.

Every theorem is realized. For a derivation of A from hypotheses $B_1, \dots, B_m$ we find one program c with two properties. Feed c the values of the free number variables, the total programs assigned to the free sequence variables, and numbers $s_1, \dots, s_m$ with $s_j \in \mathrm{HRO}_{\tau(B_j)}$. Then c halts with a value in $\mathrm{HRO}_{\tau(A)}$, and that value realizes A whenever each s_j realizes B_j. For Kleene realizability we ask only for the second property, on inputs whose s_j realize the B_j. The program is built by induction on the derivation; Appendix F.1 lists it rule by rule. Four steps carry the argument.

Implication introduction turns the program c for B, with the extra hypothesis A, into the program that receives the inputs and returns a program for $s \mapsto c(\dots, s)$. By the first property of c, this program halts with a value in $\mathrm{HRO}_{\tau(B)}$ on every s in $\mathrm{HRO}_{\tau(A)}$, so it lies in $\mathrm{HRO}_{\tau(A)\to\tau(B)}$, which is what the modified implication clause asks. The first property is carried through the induction for this step.

The induction rule is realized by primitive recursion. From realizers r_0 of $A(0)$ and r_1 of $\forall x(A(x) \to A(Sx))$ put $R(0) = r_0$ and $R(n+1) = \{\{r_1\}(n)\}(R(n))$. Each $\{r_1\}(n)$ lies in $\mathrm{HRO}_{\tau(A)\to\tau(A)}$, so by induction on n every $R(n)$ is defined and lies in $\mathrm{HRO}_{\tau(A)}$; when r_0 and r_1 are realizers, a second induction on n shows that $R(n)$ realizes $A(n)$.

The first choice schema is realized by the program E that sends e to $\pi(f_e, g_e)$, where f_e is a program for $n \mapsto (\{e\}(n))_0$ and g_e one for $n \mapsto (\{e\}(n))_1$, both computed from e. If e lies in $\mathrm{HRO}_{\mathbb{N}\to(\mathbb{N}\times\tau(A))}$, then f_e is total and g_e lies in $\mathrm{HRO}_{\mathbb{N}\to\tau(A)}$, which gives the first property. If e realizes $\forall x \exists y\, A(x,y)$, then for every n the value $r_n = \{e\}(n)$ has $(r_n)_1$ realizing $A(n, (r_n)_0)$, that

is $A(n, \{f_e\}(n))$. So g_e realizes $\forall x\, A(x, \alpha(x))$ with α assigned f_e, and $\pi(f_e, g_e)$ realizes the conclusion. The second schema is realized by $e \mapsto \pi(a_e, h_e)$, where a_e computes $\langle x, y\rangle \mapsto \{(\{e\}(x))_0\}(y)$, recovering x and y from the value of the pairing term by a bounded search, and returns 0 on numbers that are not such values; and h_e computes $x \mapsto \pi\big((\{e\}(x))_0, \pi(0, (\{e\}(x))_1)\big)$. If e lies in the type of the premise, every $(\{e\}(x))_0$ is total, so a_e is total and h_e lies in the type of the body; this is the first property. When e realizes $\forall x \exists \beta\, A(x, \beta)$, and with β assigned $(\{e\}(x))_0$ every equation $\beta(y) = \alpha(\langle x, y\rangle)$ is true, so program 0 realizes $\forall y\, \beta(y) = \alpha(\langle x, y\rangle)$ and $\{h_e\}(x)$ realizes the body of the conclusion. Neither program decides anything: each returns, rearranged, what the realizer of the premise supplies. This is the formal content of the sentence that countable choice selects. The same programs realize both schemas in Kleene's reading.

Finally, Kleene's reading also realizes $\mathrm{MP}_{\mathrm{bin}}$, by search. Let M send i to a program that sends b to a program that sends d to $\pi(\mu, 0)$, where μ is the first n with $\{i\}(n) = 1$. Suppose $b \Vdash_{\mathrm{k}} \mathrm{Bin}(\alpha)$ and $d \Vdash_{\mathrm{k}} \neg\forall n\, \alpha(n) = 0$, with α assigned i. Then α is binary, and it is not everywhere 0: otherwise program 0 would realize $\forall n\, \alpha(n) = 0$ and $\{d\}(0)$ would realize $\bot$. Hence some value is 1, the search stops at the first such n, and $\pi(\mu, 0)$ realizes $\exists n\, \alpha(n) = 1$.

Applied to derivations without hypotheses, under the valuation that assigns 0 to every number variable and program 0 to every sequence variable, this gives: every theorem of the theory has a modified realizer, and every theorem of the theory with $\mathrm{MP}_{\mathrm{bin}}$ added has a Kleene realizer.

Two problems that no program solves. Let $h(e, n) = 1$ if program e halts on input 0 within n steps, and $h(e, n) = 0$ otherwise. The function h is computable, because n steps of a run can be simulated, and program e halts on input 0 exactly when some $h(e, n)$ is 1. No total program decides, for every e, whether program e halts on input 0 [21]. Next let A_0 be the set of programs e with $\{e\}(0) = 0$ and A_1 the set with $\{e\}(0) = 1$. No total program d with values in $\{0, 1\}$ has $d(e) = 1$ for every $e \in A_0$ and $d(e) = 0$ for every $e \in A_1$. Indeed, by Kleene's recursion theorem [19, Chapter XII] there is a program c that returns 1 on every input if $d(c) = 1$, and 0 if $d(c) = 0$. If $d(c) = 1$, then $c \in A_1$, so $d(c) = 0$; if $d(c) = 0$, then $c \in A_0$, so $d(c) = 1$. Both cases are contradictory. The two sets are joined by one sequence for each program e. Put $\ell_e(2K) = 1$ when the run of e on input 0 halts after exactly K steps with output 0, put $\ell_e(2K + 1) = 1$ when it halts after exactly K steps with output 1, and put $\ell_e(n) = 0$ otherwise. Whether a run halts after exactly K steps is decided by running it for K steps, so $\ell_e(n)$ is computable from e and n. The sequence has at most one entry 1, since a run has only one halting time; it has an entry 1 at an even place exactly when $e \in A_0$, and at an odd place exactly when $e \in A_1$.

From a realizer to a program. Each of the four principles has the form $\forall \alpha(\mathrm{Bin}(\alpha) \to B(\alpha))$. Suppose r realizes such a principle, in either reading, and let $a(c, n)$ be a computable function with values in $\{0, 1\}$. A program i_c for $n \mapsto a(c, n)$ is computed from c, and it is total. The program b_c computing $n \mapsto \pi(a(c, n), 0)$ realizes $\mathrm{Bin}(\alpha)$ with α assigned i_c: its tag at n names the true side, and 0 realizes the true equation. Therefore

$$G(c) = \{\{r\}(i_c)\}(b_c)$$

halts for every c with a realizer of $B(\alpha)$, α assigned i_c, and G is computed by one program.

LPO is not realized. Take $a = h$, so that the sequence of c records the halting of program c. The tag $t(c) = (G(c))_0$ is a total computable function of c. If $t(c) = 0$, then $(G(c))_1$ realizes $\forall n\, \alpha(n) = 0$, so every $h(c, n)$ is 0 and program c does not halt. If $t(c) \neq 0$, then $(G(c))_1$ realizes

$\exists n\,\alpha(n) = 1$, so some $h(c,n)$ is 1 and program c halts. The tag decides halting, which no program does.

WLPO is not realized. With the same sequences, a tag $t(c) \neq 0$ now comes with a realizer of $\neg\forall n\,\alpha(n) = 0$. If every $h(c,n)$ were 0, program 0 would realize $\forall n\,\alpha(n) = 0$, and the realizer of the negation would turn it into a realizer of $\bot$. So not every $h(c,n)$ is 0, and program c halts. Again the tag decides halting. Both arguments use only the clauses that the two readings share.

$\mathrm{MP}_{\mathrm{bin}}$ *is not realized in the modified reading.* Again take $a = h$. Now $G(c)$ realizes $\neg\forall n\,\alpha(n) = 0 \to \exists n\,\alpha(n) = 1$, so it lies in $\mathrm{HRO}_{\sigma\to(\mathbb{N}\times\mathbb{N})}$ with $\sigma = \tau(\neg\forall n\,\alpha(n) = 0)$. Since 0 lies in HRO_σ, the run $\{G(c)\}(0)$ halts for every c, and $m(c) = (\{G(c)\}(0))_0$ is a total computable function of c. Suppose program c halts. Then $\forall n\,\alpha(n) = 0$ is false and has no realizer, so every element of HRO_σ realizes its negation, 0 included. Hence $\{G(c)\}(0)$ realizes $\exists n\,\alpha(n) = 1$, which says $h(c, m(c)) = 1$. So program c halts exactly when $h(c, m(c)) = 1$, a test that a program performs. This contradiction is where the two readings part. A Kleene realizer of the implication need not halt on the input 0 when program c never halts, because then the premise has no realizer; the search of the previous paragraph is such a realizer, and its m is not total.

LLPO is not realized. Take $a(c,n) = \ell_c(n)$. The formula $\forall m\,\forall n\,(\alpha(m) = 1 \to \alpha(n) = 1 \to m = n)$ is true for this sequence, and program 0 realizes it in both readings: on all arguments it returns 0, which lies in every HRO_σ and realizes the final equation, true whenever the premises are realized. So $z(c) = \{G(c)\}(0)$ halts for every c with a realizer of $\forall k\,\alpha(2k) = 0 \vee \forall k\,\alpha(2k+1) = 0$. Put $d(c) = 1$ if $(z(c))_0 \neq 0$ and $d(c) = 0$ otherwise. If $c \in A_0$, the sequence has an entry 1 at an even place, so the first side is false and unrealized; hence $(z(c))_0 \neq 0$ and $d(c) = 1$. If $c \in A_1$, the second side is false, so $(z(c))_0 = 0$ and $d(c) = 0$. The total program d separates A_0 from A_1, which no program does.

So none of the four principles has a modified realizer, while every theorem has one. None is provable, and none is refutable, as shown first.

Decided properties. Call a formula *negative* when it is built from equations and $\bot$ by $\wedge$, $\to$ and $\forall x$. For negative A, under every valuation, $r \Vdash_{\mathrm{m}} A$ holds exactly when $r \in \mathrm{HRO}_{\tau(A)}$ and A is true. This follows by induction on A. Equations and $\bot$ are immediate, and so are $\wedge$ and $\forall x$. If r realizes $A \to B$ and A is true, then 0 realizes A by the induction hypothesis, so $\{r\}(0)$ realizes B and B is true. Conversely, if $r \in \mathrm{HRO}_{\tau(A)\to\tau(B)}$ and $A \to B$ is true, a realizer s of A lies in $\mathrm{HRO}_{\tau(A)}$ and makes A true, so $\{r\}(s)$ lies in $\mathrm{HRO}_{\tau(B)}$ and B is true, and $\{r\}(s)$ realizes B. Now let $A(x)$ be negative, any other free variables read as in the valuation fixed above, and suppose the theory proves $\forall x(A(x) \vee \neg A(x))$. A realizer r gives, for every n, a value $z_n = \{r\}(n)$ realizing $A(n) \vee \neg A(n)$, and $d(n) = (z_n)_0$ is a total computable function. If $d(n) = 0$, then $(z_n)_1$ realizes $A(n)$, so $A(n)$ is true. If $d(n) \neq 0$, then $(z_n)_1$ realizes the negative formula $\neg A(n)$, so $A(n)$ is false. Thus $A(n)$ holds exactly when $d(n) = 0$, and the program computing d decides A.

With $\mathrm{MP}_{\mathrm{bin}}$ *added.* Every theorem of the extended theory has a Kleene realizer. The arguments for LPO, WLPO and LLPO above used only clauses that Kleene's reading shares with the modified one, and the realizer 0 of the true premise of LLPO is a Kleene realizer as well. So none of WLPO, LLPO and LPO has a Kleene realizer, and none is provable with $\mathrm{MP}_{\mathrm{bin}}$; the classical model shows that none is refutable there either. □

Below countable choice appears only as a stated hypothesis, and each result says where it is used. Every such use in Table 12.3 is countable choice for numbers or for sequences, so all choice used in that table lies in this theory, which proves none of the four principles.

12.9.2 Limits and located cuts: where countable choice enters

Distances are order statements. Say that x and y are *within* $1/(k+1)$ when $x \le y+\eta(1/(k+1))$ and $y \le x+\eta(1/(k+1))$. A sequence of points (x_n) *converges* to L if for every k there is an N such that x_m is within $1/(k+1)$ of L for all $m \ge N$. It is *Cauchy* if for every k there is an N such that x_m and x_n are within $1/(k+1)$ for all $m, n \ge N$. On sequences that name the points, "within" becomes a bound at every stage.

Lemma 12.23 (Two readings of "within")**.** *Let s and t be regular sequences naming the points x and y, and let $\varepsilon = 1/(k+1)$. Then x and y are within ε exactly when*

$$|s_n - t_n| \le \varepsilon + \frac{2}{n+1} \qquad \text{for every } n.$$

No choice principle is used.

Proof. By the definitions of sum and negation, the point $x-(y+\eta(\varepsilon))$ is named by the regular sequence $u_j = s_{2j+1} - t_{4j+3} - \varepsilon$. Regularity of s and t compares u_j with any stage n:

$$\left|u_j - (s_n - t_n - \varepsilon)\right| \le \frac{1}{2j+2} + \frac{1}{4j+4} + \frac{2}{n+1} = \frac{3}{4j+4} + \frac{2}{n+1}. \tag{12.4}$$

Suppose the stagewise bound holds, and suppose $y+\eta(\varepsilon) < x$. Positivity does not depend on the naming sequence, so $u_N > 2/(N+1)$ for some N. At the stage $n = 4N+3$, (12.4) with $j = N$ gives

$$s_n - t_n \ge u_N + \varepsilon - \frac{5}{4N+4} > \varepsilon + \frac{8}{4N+4} - \frac{5}{4N+4} > \varepsilon + \frac{2}{n+1},$$

contrary to the bound. So $x \le y+\eta(\varepsilon)$; exchanging the roles of s and t gives $y \le x+\eta(\varepsilon)$.

Conversely, suppose $x \le y+\eta(\varepsilon)$ and fix n. The comparison $s_n - t_n \le \varepsilon + 2/(n+1)$ is decidable, so it suffices to refute $s_n - t_n = \varepsilon + 2/(n+1) + \delta$ with a positive ratio δ. In that case (12.4) gives $u_j \ge \delta - 3/(4j+4)$ for every j, and for j with $4j+4 > 11/\delta$ this exceeds $8/(4j+4) = 2/(j+1)$. So u has a positive stage and $y+\eta(\varepsilon) < x$, contrary to the hypothesis. In the same way $y \le x+\eta(\varepsilon)$ gives $t_n - s_n \le \varepsilon + 2/(n+1)$. □

Corollary 12.24 (Equality from every tolerance)**.** *Two points are equal exactly when they are within $1/(k+1)$ of each other for every k. No choice principle is used.*

Proof. Let s and t name x and y. If the points are within every $1/(k+1)$, Lemma 12.23 gives $|s_n - t_n| \le 1/(k+1) + 2/(n+1)$ for all k and n, and the Archimedean step leaves $|s_n - t_n| \le 2/(n+1)$ at every stage. Then every $n \ge 2k+1$ has $|s_n - t_n| \le 1/(k+1)$, as in the first half of Lemma 12.15, so $s \approx t$ and $x = y$. Conversely, a point is within every $1/(k+1)$ of itself: $x+\eta(1/(k+1)) < x$ would give, after adding $-x$, $\eta(1/(k+1)) < \eta(0)$, and η reflects the order. □

A sequence of points is a sequence of classes. To calculate with it we want stages: for each k, a regular sequence naming a term x_N at an index N from which on the Cauchy condition holds at every tolerance $1/(j+1)$ with $j \le k$. Producing infinitely many such representatives at once is an application of AC_ω; the indices themselves are never selected. Once these representatives are supplied, the limit is explicit. A representative of every term is not enough by itself: the rational points c_s in the proof of Theorem 12.63 have evident representatives, and that sequence has no limit in the model used there.

Theorem 12.25 (The diagonal limit)**.** *Call regular sequences $s^{(0)}, s^{(1)}, \ldots$ a* Cauchy family *when their points are within $1/(k+1)$ of one another whenever both indices are at least k. The diagonal $d_n = s^{(2n+1)}_{2n+1}$ of a Cauchy family is a regular sequence, and the point of $s^{(m)}$ is within $1/(k+1)$ of the point of d whenever $k \le m$. So the points of the family converge to the point of d. No choice principle and no omniscience principle is used.*

Proof. By Lemma 12.23, the hypothesis says that $|s^{(i)}_p - s^{(j)}_p| \le 1/(c+1) + 2/(p+1)$ at every stage p whenever $i, j \ge c$.

Write $a = 2m+1$ and $b = 2n+1$. Compare $d_m = s^{(a)}_a$ with $d_n = s^{(b)}_b$ through an arbitrary stage p:

$$|d_m - d_n| \le |s^{(a)}_a - s^{(a)}_p| + |s^{(a)}_p - s^{(b)}_p| + |s^{(b)}_p - s^{(b)}_b|.$$

Regularity bounds the outer terms by $1/(a+1) + 1/(p+1)$ and $1/(b+1) + 1/(p+1)$. The hypothesis at $c = \min(a,b)$ bounds the middle term by $1/(c+1) + 2/(p+1)$, and $1/(c+1) \le 1/(a+1) + 1/(b+1)$. The total is

$$\frac{2}{a+1} + \frac{2}{b+1} + \frac{4}{p+1} = \frac{1}{m+1} + \frac{1}{n+1} + \frac{4}{p+1}.$$

Since p is arbitrary, the Archimedean step removes the last term, and this is the regularity of d.

For the second assertion, let $k \le m$, put $a = 2n+1$, and compare $s^{(m)}_n$ with $d_n = s^{(a)}_a$ through a stage p. Regularity of $s^{(m)}$ and of $s^{(a)}$ contributes $1/(n+1) + 1/(p+1)$ and $1/(p+1) + 1/(a+1)$. Neither m nor a is below $c = \min(k,a)$, so the hypothesis at c bounds $|s^{(m)}_p - s^{(a)}_p|$ by $1/(c+1) + 2/(p+1)$, and $1/(c+1) \le 1/(k+1) + 1/(a+1)$. Since $2/(a+1) = 1/(n+1)$, the total is $1/(k+1) + 2/(n+1) + 4/(p+1)$, and the Archimedean step leaves $|s^{(m)}_n - d_n| \le 1/(k+1) + 2/(n+1)$ at every stage n. By Lemma 12.23 the two points are within $1/(k+1)$, and the index $N = k$ witnesses convergence at the tolerance $1/(k+1)$. Every step is an integer estimate or the Archimedean step; nothing is chosen and nothing is decided. □

Theorem 12.26 (Cauchy sequences of points)**.** *A sequence of points has at most one limit; this uses no choice principle. Assuming AC_ω, every Cauchy sequence of points of $\mathbb{R}_\delta$ converges. Countable choice is used once, for regular sequences, to select representatives; no omniscience principle is used.*

Proof. Let L and L' be limits of (x_n), and fix k. Convergence at the tolerance $1/(2k+2)$ supplies indices for both; at an index m beyond the two, L is within $1/(2k+2)$ of x_m, which is within

$1/(2k+2)$ of L'. Adding the two order statements (if $a \le b$ then $a+c \le b+c$, since $b+c < a+c$ would give $b < a$ after adding $-c$, by Proposition 12.19(1); then use transitivity of $\le$ and $\eta(1/(2k+2)) + \eta(1/(2k+2)) = \eta(1/(k+1))$), L and L' are within $1/(k+1)$. This holds for every k, so $L = L'$ by Corollary 12.24. No choice is involved.

Now let (x_n) be a Cauchy sequence of points. Call an index N *good up to* k when the Cauchy condition holds from N on at every tolerance $1/(j+1)$ with $j \le k$. Every k has an index good up to k: by induction on k, the largest of an index good up to k and an index supplied by the Cauchy condition at $k+1$ is good up to $k+1$, since an index beyond a good one is good. For each k some regular sequence names x_N for some index N good up to k. Countable choice, applied once, supplies for each k such a regular sequence $s^{(k)}$; the index itself is never selected.

For $m, m' \ge k$ the indices behind $s^{(m)}$ and $s^{(m')}$ are both good at the tolerance $1/(k+1)$, and the condition at the smaller of them covers both, so the points of $s^{(m)}$ and $s^{(m')}$ are within $1/(k+1)$. These sequences therefore form a Cauchy family, so by Theorem 12.25 their diagonal names a point L, and the point of $s^{(k)}$ is within $1/(k+1)$ of L for every k. Given k, let N be an index behind $s^{(2k+1)}$. For $m \ge N$, the point x_m is within $1/(2k+2)$ of x_N, which is within $1/(2k+2)$ of L; adding the two order statements as in the first paragraph, x_m is within $1/(k+1)$ of L. So (x_n) converges to L. The indices are used only inside the proofs of these propositions. □

The proof uses countable choice once, to pick representatives; the limit itself is computed from the data. A second description of the continuum avoids even that step.

Definition 12.27 (Located cuts)**.** A *located cut* is a pair $C = (\mathscr{L}, \mathscr{U})$ of sets of ratios, both inhabited, with $\mathscr{L}$ closed downward and without a greatest element, $\mathscr{U}$ closed upward and without a least element, the two disjoint, and *located*: whenever $q < r$, either $q \in \mathscr{L}$ or $r \in \mathscr{U}$. The *cut of* a point x is $C_x = (\mathscr{L}_x, \mathscr{U}_x)$, where $\mathscr{L}_x = \{q : \eta(q) < x\}$ and $\mathscr{U}_x = \{r : x < \eta(r)\}$. For located cuts C and D and a positive ratio ε, write $C \preceq_\varepsilon D$ when every member of the lower set of C lies less than ε above every member of the upper set of D, that is, $q - r < \varepsilon$ whenever q is in the lower set of C and r in the upper set of D.

Lemma 12.28 (Laws of located cuts)**.** *Let $C = (\mathscr{L}, \mathscr{U})$, D and E be located cuts.*

1. *Every member of $\mathscr{L}$ lies below every member of $\mathscr{U}$.*
2. *A ratio r lies in $\mathscr{U}$ exactly when some $r' < r$ is not in $\mathscr{L}$. Hence two located cuts with the same lower set are equal.*
3. *If $C \preceq_\varepsilon D$ and $D \preceq_\delta E$, then $C \preceq_{\varepsilon+\delta} E$.*
4. *If $D \preceq_{1/(k+1)} E$ for every k, then every member of the lower set of D lies in the lower set of E.*

No choice principle is used.

Proof. 1. Let $q \in \mathscr{L}$ and $r \in \mathscr{U}$. If $r \le q$, take $q' \in \mathscr{L}$ with $q' > q$; then $r < q'$, so $r \in \mathscr{L}$, and r would lie in both sets. Comparisons of ratios are decidable, so $q < r$.

2. If $r \in \mathscr{U}$, take $r' \in \mathscr{U}$ with $r' < r$; it is not in $\mathscr{L}$, because the two sets are disjoint. Conversely, if $r' < r$ and $r' \notin \mathscr{L}$, locatedness at $r' < r$ gives $r \in \mathscr{U}$. So the upper set is determined by the lower set.

3. Let q be in the lower set of C and r in the upper set of E, and suppose $q - r \geq \varepsilon + \delta$. Take $q' > q$ in the lower set of C. Then $r + \delta < q' - \varepsilon$, and locatedness of D at this pair puts $r + \delta$ in the lower set of D or $q' - \varepsilon$ in its upper set. The first contradicts $D \preceq_\delta E$ at the pair $r + \delta$ and r, whose difference is δ; the second contradicts $C \preceq_\varepsilon D$ at the pair q' and $q' - \varepsilon$, whose difference is ε. Comparisons of ratios are decidable, so $q - r < \varepsilon + \delta$.

4. Let q be in the lower set of D, and take $q < q' < q''$ in it. Locate E at $q < q'$. If q' were in the upper set of E, then $q'' - q' < 1/(k+1)$ for every k, which fails once $k + 1 > 1/(q'' - q')$. So q is in the lower set of E. □

Call a sequence $C_0, C_1, \ldots$ of located cuts, with $C_n = (\mathscr{L}_n, \mathscr{U}_n)$, *Cauchy* when for every k there is an N such that $C_m \preceq_{1/(k+1)} C_n$ whenever $m, n \geq N$, and *regular* when $C_m \preceq_{1/(m+1)+1/(n+1)} C_n$ for all m and n. A located cut D is a *limit* of the sequence when for every k there is an N such that $C_n \preceq_{1/(k+1)} D$ and $D \preceq_{1/(k+1)} C_n$ for all $n \geq N$: the cuts approach D in the sense of the Cauchy condition, with D in place of either of the two cuts.

Theorem 12.29 (Cauchy sequences of located cuts)**.** *Every Cauchy sequence of located cuts has exactly one limit D. A ratio q lies in the lower set of D exactly when, for some k, $q + 1/(k+1) \in \mathscr{L}_m$ for every m from some index on; a ratio r lies in its upper set exactly when, for some k, $r - 1/(k+1) \in \mathscr{U}_m$ for every m from some index on. Every regular sequence of located cuts is Cauchy. No choice principle and no omniscience principle is used.*

Proof. Call an index N *good at* k when $C_m \preceq_{1/(k+1)} C_n$ for all $m, n \geq N$; the hypothesis says that every k has a good index. Let $\mathscr{L}^*$ consist of the ratios q for which there are k, an index N good at k, and $q' \in \mathscr{L}_N$ with $q \leq q' - 2/(k+1)$; let $\mathscr{U}^*$ consist of the ratios r for which there are k, an index N good at k, and $r' \in \mathscr{U}_N$ with $r \geq r' + 2/(k+1)$. We show that $D = (\mathscr{L}^*, \mathscr{U}^*)$ has the stated properties.

Inhabited. Let N be good at 0. A member a of $\mathscr{L}_N$ gives $a - 2 \in \mathscr{L}^*$, and a member b of $\mathscr{U}_N$ gives $b + 2 \in \mathscr{U}^*$.

Closed, and without end points. If $q \in \mathscr{L}^*$ and $p < q$, the same k, N and q' show $p \in \mathscr{L}^*$. If $q \in \mathscr{L}^*$ by k, N and q', take $q'' > q'$ in $\mathscr{L}_N$; then $q'' - 2/(k+1)$ lies in $\mathscr{L}^*$ by k, N and q'', and exceeds q. The upper set is treated in the same way.

Disjoint. Suppose $q \in \mathscr{L}^*$ by k, N, q' and $q \in \mathscr{U}^*$ by k', N', r'. Then $q' - r' \geq 2/(k+1) + 2/(k'+1)$. If $N \leq N'$, goodness of N at k, applied to the cuts C_N and $C_{N'}$, gives $q' - r' < 1/(k+1)$; if $N' \leq N$, goodness of N' at k' gives $q' - r' < 1/(k'+1)$. Both are impossible.

Located. Let $q < r$. Choose k with $4/(k+1) < r - q$ and an index N good at k. Since $q + 2/(k+1) < r - 2/(k+1)$, locatedness of C_N gives $q + 2/(k+1) \in \mathscr{L}_N$, so that $q \in \mathscr{L}^*$, or $r - 2/(k+1) \in \mathscr{U}_N$, so that $r \in \mathscr{U}^*$. The index N is used inside the proof of this disjunction and is never selected.

D is a limit. Given k, let N be good at k and let $n \geq N$. Take $q \in \mathscr{L}_n$ and $r \in \mathscr{U}^*$ by k', N', r', and suppose $q - r \geq 1/(k+1)$. Then $q - r' \geq 1/(k+1) + 2/(k'+1)$. If $N' \leq n$, goodness of N' at k', applied to C_n and $C_{N'}$, gives $q - r' < 1/(k'+1)$; if $n \leq N'$, then n and N' are at least N, and goodness of N gives $q - r' < 1/(k+1)$. Either way we have a contradiction, so $C_n \preceq_{1/(k+1)} D$. In the same way $D \preceq_{1/(k+1)} C_n$.

Uniqueness. Let D and E both be limits. Given k, take n beyond the indices that the limit property supplies for D and for E at the tolerance $1/(2k+2)$. Then $D \preceq_{1/(2k+2)} C_n$ and $C_n \preceq_{1/(2k+2)} E$, so $D \preceq_{1/(k+1)} E$ by Lemma 12.28(3). By Lemma 12.28(4) the lower set of D lies in that of E; by symmetry the two lower sets are equal, and $D = E$ by Lemma 12.28(2).

The lower set. Let D be the limit. If q lies in its lower set, take $q'' > q$ in it, choose k with $3/(k+1) < q'' - q$, and N with $D \preceq_{1/(k+1)} C_m$ for $m \geq N$. For $m \geq N$, locate C_m at $q + 1/(k+1) < q + 2/(k+1)$. If $q + 2/(k+1) \in \mathscr{U}_m$, then $q'' - (q + 2/(k+1)) < 1/(k+1)$, that is $q'' - q < 3/(k+1)$, which is false. So $q + 1/(k+1) \in \mathscr{L}_m$ for every $m \geq N$. Conversely, suppose $q + 1/(k+1) \in \mathscr{L}_m$ for every $m \geq N$. Locate D at $q < q + 1/(2k+2)$. If $q + 1/(2k+2)$ lay in the upper set of D, take N' with $C_m \preceq_{1/(2k+2)} D$ for $m \geq N'$; at $m = N + N'$ the pair $q + 1/(k+1) \in \mathscr{L}_m$ and $q + 1/(2k+2)$ would have difference exactly $1/(2k+2)$, which is not less than $1/(2k+2)$. So q lies in the lower set of D.

The upper set. If r lies in the upper set of D, take $r'' < r$ in it, choose k with $3/(k+1) < r - r''$, and N with $C_m \preceq_{1/(k+1)} D$ for $m \geq N$. For $m \geq N$, locate C_m at $r - 2/(k+1) < r - 1/(k+1)$. If $r - 2/(k+1) \in \mathscr{L}_m$, then $(r - 2/(k+1)) - r'' < 1/(k+1)$, that is $r - r'' < 3/(k+1)$, which is false. So $r - 1/(k+1) \in \mathscr{U}_m$ for every $m \geq N$. Conversely, suppose $r - 1/(k+1) \in \mathscr{U}_m$ for every $m \geq N$, and locate D at $r - 1/(2k+2) < r$. If $r - 1/(2k+2)$ lay in the lower set of D, take N' with $D \preceq_{1/(2k+2)} C_m$ for $m \geq N'$; at $m = N + N'$ the pair $r - 1/(2k+2)$ and $r - 1/(k+1) \in \mathscr{U}_m$ would have difference exactly $1/(2k+2)$. So r lies in the upper set of D.

Regular sequences. If $C_m \preceq_{1/(m+1)+1/(n+1)} C_n$ for all m and n, the index $2k+1$ is good at k, because $1/(m+1) + 1/(n+1) \leq 1/(k+1)$ when $m, n \geq 2k+1$.

Every step compares two indices or two ratios, which is decidable, or uses an index whose existence the hypothesis states, inside the proof of a proposition. Nothing is selected. □

The limit is read off from the sets alone: its lower and upper sets are described by the cuts of the sequence, with no choice principle at all. The properties of the limit that need an index from the Cauchy condition (disjointness, locatedness and the limit property) use that index only inside the proof of a proposition, so no index is ever selected. To compare cuts with points we need one more fact about the line: there is a ratio between any two points.

Lemma 12.30 (Ratios are dense)**.** *If $x < y$, there is a ratio q with $x < \eta(q) < y$. No choice principle is used.*

Proof. Let s and t name x and y. The point $y - x$ is named by $u_n = t_{2n+1} - s_{2n+1}$, and it is positive, so $u_N > 2/(N+1)$ for some N. By Lemma 12.16, $u_M > 1/(2N+2) = 4/(M+1)$ at $M = 8N+7$. Let q be the mean of s_{2M+1} and t_{2M+1}. Then $t_{2M+1} - q = q - s_{2M+1} = u_M/2 > 2/(M+1)$. These are the stages at M of the sequences $(t_{2j+1} - q)_j$ and $(q - s_{2j+1})_j$, which name $y - \eta(q)$ and $\eta(q) - x$, so both points are positive. □

Lemma 12.31 (The cut of a point)**.** *For every point x, the cut C_x is a located cut. Moreover $x \leq y$ exactly when $\mathscr{L}_x \subseteq \mathscr{L}_y$, so different points have different cuts. No choice principle is used.*

Proof. By Proposition 12.19(4), $x < \eta(n)$ and $-x < \eta(n')$ for some natural numbers n and n'; so $n \in \mathscr{U}_x$ and, adding $x - \eta(n')$ to the second inequality, $-n' \in \mathscr{L}_x$. If $p < q \in \mathscr{L}_x$, then

$\eta(p) < \eta(q) < x$, so $p \in \mathscr{L}_x$. By Lemma 12.30, $\eta(q) < x$ gives a ratio q' with $\eta(q) < \eta(q') < x$, and then $q < q' \in \mathscr{L}_x$, so $\mathscr{L}_x$ has no greatest element. The upper set is treated in the same way. A ratio in both sets would give $\eta(q) < x < \eta(q)$. If $q < r$, then $\eta(q) < \eta(r)$, and cotransitivity gives $\eta(q) < x$ or $x < \eta(r)$: the cut is located.

If $x \le y$ and $\eta(q) < x$, cotransitivity gives $\eta(q) < y$ or $y < x$, and the second is excluded. Conversely, if $\mathscr{L}_x \subseteq \mathscr{L}_y$ and $y < x$, Lemma 12.30 gives q with $y < \eta(q) < x$; then $q \in \mathscr{L}_x \subseteq \mathscr{L}_y$ and $\eta(q) < y < \eta(q)$, which is impossible. So $x \le y$. Equal cuts therefore give $x \le y \le x$, and $x = y$ by Proposition 12.19(2). □

A cut is the cut of a point exactly when it can be approximated by a sequence of pairs of ratios. Each single pair can be found without choice; assembling all of them into one sequence is exactly an instance of AC_ω at pairs of ratios, and nothing else is needed.

Lemma 12.32 (One approximating pair needs no choice)**.** *Let $(\mathscr{L}, \mathscr{U})$ be a located cut and n a natural number. There are $q \in \mathscr{L}$ and $r \in \mathscr{U}$ with $r - q < 1/(n+1)$. No choice principle is used.*

Proof. Take $a \in \mathscr{L}$ and $b \in \mathscr{U}$; then $a < b$ by Lemma 12.28(1). Choose a positive integer $G \ge 4(n+1)$ for which $K = (b-a)G$ is a natural number, for instance the product of the two denominators and $4(n+1)$, and put $p_j = a + j/G$. We prove by induction on j: either $p_j \in \mathscr{L}$, or there is an i with $p_i \in \mathscr{L}$ and $p_{i+2} \in \mathscr{U}$. For $j = 0$, $p_0 = a \in \mathscr{L}$. If $p_j \in \mathscr{L}$, locatedness at $p_{j+1} < p_{j+2}$ gives $p_{j+1} \in \mathscr{L}$, or $p_{j+2} \in \mathscr{U}$, and then $i = j$ serves; if the second alternative already holds for j, it holds for $j+1$. At $j = K$ we have $p_K = b \in \mathscr{U}$, so $p_K \notin \mathscr{L}$, and the second alternative holds: $q = p_i$ and $r = p_{i+2}$ satisfy $r - q = 2/G \le 1/(2n+2) < 1/(n+1)$. The induction proves a proposition at each step and selects nothing. □

Theorem 12.33 (Located cuts and points)**.** *A located cut $(\mathscr{L}, \mathscr{U})$ is the cut of a point exactly when it has an* approximation sequence*: a sequence of pairs $q_n \in \mathscr{L}$, $r_n \in \mathscr{U}$ with $r_n - q_n < 1/(n+1)$ for every n. Neither direction uses a choice principle. Assuming AC_ω for pairs of ratios, every located cut is the cut of exactly one point, and $x \mapsto C_x$ is a bijection from $\mathbb{R}_\delta$ onto the located cuts; countable choice is used once, at pairs of ratios, and no omniscience principle is used.*

Proof. Let x be named by s. For each n put $m = 4n+4$, $q_n = s_m - 2/(m+1)$ and $r_n = s_m + 2/(m+1)$. The point $x - \eta(q_n)$ is named by $(s_{2j+1} - q_n)_j$, and at $j = 3m+2$ regularity gives

$$s_{6m+5} - q_n \ge \frac{2}{m+1} - \frac{1}{m+1} - \frac{1}{6m+6} = \frac{5}{6m+6} > \frac{2}{j+1},$$

so $\eta(q_n) < x$; in the same way $x < \eta(r_n)$. And $r_n - q_n = 4/(4n+5) < 1/(n+1)$. Only the one sequence s naming the one point x is used.

Conversely, let (q_n, r_n) be an approximation sequence. Since $q_m < r_n$ (Lemma 12.28(1)) and $r_n - q_n < 1/(n+1)$, we have $q_m - q_n < 1/(n+1)$, and symmetrically $q_n - q_m < 1/(m+1)$; so (q_n) is a regular sequence. Let x be its point; we show $\mathscr{L} = \mathscr{L}_x$. If $\eta(q) < x$, the sequence $(q_{2j+1} - q)_j$ naming $x - \eta(q)$ has a positive stage, so $q < q_{2N+1} \in \mathscr{L}$ for some N, and $q \in \mathscr{L}$. If $q \in \mathscr{L}$, take $q' > q$ in $\mathscr{L}$ and put $\delta = q' - q$. Every k has $q' < r_k$, hence $q_k > q' - 1/(k+1)$, and so $q_{2j+1} - q > \delta - 1/(2j+2)$; for j with $2j + 2 > 5/\delta$ this exceeds $2/(j+1)$, so $\eta(q) < x$. The located cuts $(\mathscr{L}, \mathscr{U})$ and C_x have the same lower set, so they are equal by Lemma 12.28(2).

For the last sentence, Lemma 12.32 gives, for every n, some pair approximating the cut at precision n. Countable choice for pairs of ratios, applied once to this relation, gives an approximation sequence, and the first part gives the point. The point is unique by Lemma 12.31, which also makes $x \mapsto C_x$ injective. □

The cuts of the points of a Cauchy sequence of points form a Cauchy sequence of located cuts. This rests on reading "within" from the cuts.

Lemma 12.34 (Distances read from cuts)**.** *Let $\varepsilon = 1/(k+1)$. Points x and y are within ε exactly when $C_x \preceq_\varepsilon C_y$ and $C_y \preceq_\varepsilon C_x$. No choice principle is used.*

Proof. We show that $x \le y + \eta(\varepsilon)$ implies $C_x \preceq_\varepsilon C_y$, and that $C_x \preceq_\varepsilon C_y$ implies $x \le y + \eta(\varepsilon)$; exchanging x and y gives the lemma. Recall that $u \le v < w$ and $u < v \le w$ each give $u < w$, by cotransitivity.

Suppose $x \le y+\eta(\varepsilon)$, $\eta(q) < x$, $y < \eta(r)$ and $q-r \ge \varepsilon$. Then $y+\eta(\varepsilon) < \eta(r)+\eta(\varepsilon) = \eta(r+\varepsilon) \le \eta(q)$, so $x < \eta(q)$, contrary to $\eta(q) < x$. Comparisons of ratios are decidable, so $q - r < \varepsilon$.

Suppose $C_x \preceq_\varepsilon C_y$ and $y + \eta(\varepsilon) < x$. Lemma 12.30 gives q with $y + \eta(\varepsilon) < \eta(q) < x$; then $y < \eta(q - \varepsilon)$, so $q \in \mathscr{L}_x$ and $q - \varepsilon \in \mathscr{U}_y$, and their difference is ε, which is not less than ε. So $x \le y + \eta(\varepsilon)$. □

Corollary 12.35 (The limit of a Cauchy sequence as a cut)**.** *Let (x_n) be a Cauchy sequence of points. With no choice principle: the cuts of its terms form a Cauchy sequence of located cuts and so have exactly one limit D; a point L is a limit of (x_n) exactly when $C_L = D$. Hence (x_n) converges exactly when D is the cut of a point, and if every located cut is the cut of a point, every Cauchy sequence of points converges with no further choice. In particular, countable choice for pairs of ratios, applied once, makes every Cauchy sequence of points converge.*

Proof. By Lemma 12.34, the Cauchy condition for the points gives the Cauchy condition for their cuts, so Theorem 12.29 supplies the unique limit D. By the same lemma, "x_n is within $1/(k+1)$ of L for $n \ge N$" says that $C_{x_n} \preceq_{1/(k+1)} C_L$ and $C_L \preceq_{1/(k+1)} C_{x_n}$ for $n \ge N$. So L is a limit of (x_n) exactly when C_L is a limit of the cuts, that is, by uniqueness, exactly when $C_L = D$. The remaining assertions follow from Theorem 12.33. □

So the cuts of the points of any Cauchy sequence of points have a unique limit cut, with no choice; countable choice is used only to make that cut a point, and Theorem 12.63 shows that excluded middle, without unique choice, cannot replace it.

The same rung has an order form. A *set of points* is any property of points; it is *inhabited* if some point has it, and *bounded above* if some point lies at or above every member, an *upper bound*. A *least upper bound* of a set of points is an upper bound lying below every upper bound. Call a set of points *order-located* if, whenever $q < r$, either $\eta(r)$ is an upper bound of the set or some member exceeds $\eta(q)$.

Theorem 12.36 (Least upper bounds of order-located sets)**.** *Every inhabited, order-located set of points that is bounded above has a least upper bound exactly when every located cut is the cut of a point. Neither direction uses a choice principle. A set of points has at most one least upper bound, and if x is a least upper bound of an order-located set S, every ratio q with $\eta(q) < x$ has $\eta(q) < s$ for some $s \in S$.*

Proof. Two least upper bounds lie below each other, so they are equal by Proposition 12.19(2). Let x be a least upper bound of an order-located set S, and let $\eta(q) < x$. Lemma 12.30 gives a ratio q' with $\eta(q) < \eta(q') < x$. At $q < q'$, either $\eta(q')$ is an upper bound of S, and then $x \le \eta(q')$, which denies $\eta(q') < x$, or some member exceeds $\eta(q)$. Hence

$$\mathscr{L}_x = \bigcup_{s \in S} \mathscr{L}_s, \tag{12.5}$$

the inclusion $\supseteq$ holding because $s \le x$ for $s \in S$ (Lemma 12.31).

Suppose every located cut is the cut of a point, and let S be inhabited, order-located and bounded above by a point b. By Proposition 12.19(4) there is a ratio b' with $b < \eta(b')$, and $\eta(b')$ is also an upper bound. Let $\mathscr{L}^*$ be the set of ratios q with $\eta(q) < s$ for some $s \in S$, and $\mathscr{U}^*$ the set of ratios r above some ratio r' for which $\eta(r')$ is an upper bound of S. These sets form a located cut. A member of S has a ratio below it, and every $r > b'$ lies in $\mathscr{U}^*$. The lower set is closed downward and has no greatest element, because each $\mathscr{L}_s$ has these properties. The upper set is closed upward, and if $r' < r$ with $\eta(r')$ an upper bound, the mean of r' and r is a smaller member of $\mathscr{U}^*$. A ratio q in both sets would give $s \in S$ and $r' < q$ with $s \le \eta(r') < \eta(q) < s$. Finally, if $q < r$, order-locatedness at q and the mean m of q and r says either that $\eta(m)$ is an upper bound, so $r \in \mathscr{U}^*$, or that some member exceeds $\eta(q)$, so $q \in \mathscr{L}^*$. Let x be the point whose cut is $(\mathscr{L}^*, \mathscr{U}^*)$. For $s \in S$, $\mathscr{L}_s \subseteq \mathscr{L}_x$, so $s \le x$ by Lemma 12.31. If y is an upper bound and $q \in \mathscr{L}_x$, then $\eta(q) < s \le y$ for some $s \in S$, so $\mathscr{L}_x \subseteq \mathscr{L}_y$ and $x \le y$. Thus x is a least upper bound.

Conversely, suppose the least-upper-bound property, and let $(\mathscr{L}, \mathscr{U})$ be a located cut. The set $S = \{\eta(q) : q \in \mathscr{L}\}$ is inhabited, and $\eta(r)$ is an upper bound of it for every $r \in \mathscr{U}$. It is order-located: if $a < b$, then either $a \in \mathscr{L}$, and some $a' > a$ in $\mathscr{L}$ gives the member $\eta(a') > \eta(a)$, or $b \in \mathscr{U}$, and $\eta(b)$ is an upper bound. Let x be its least upper bound. By (12.5), $q \in \mathscr{L}_x$ exactly when $q < q'$ for some $q' \in \mathscr{L}$, that is, exactly when $q \in \mathscr{L}$, since $\mathscr{L}$ is closed downward and has no greatest element. So C_x and $(\mathscr{L}, \mathscr{U})$ have the same lower set, and they are equal by Lemma 12.28(2). No step selects anything. □

A finite set needs neither choice nor any decision. Call a set of points *finite and inhabited* when it is given by a list $x_0, x_1, \dots, x_n$ of points, $n \ge 0$, repetitions allowed.

Proposition 12.37 (Finite sets have least upper bounds)**.** *Let $x_0, x_1, \dots, x_n$ be points. Put $M_0 = x_0$ and $M_i = \max(x_i, M_{i-1})$ for $1 \le i \le n$. Then M_n is a least upper bound of $\{x_0, \dots, x_n\}$. Moreover, if $\eta(q) < M_n$ for a ratio q, then $\eta(q) < x_i$ for some $i \le n$. No choice principle and no omniscience principle is used.*

Proof. First, $a < \max(x, y)$ implies $a < x$ or $a < y$. Let c, s and t name a, x and y. The maximum is computed stagewise, so the point $\max(x, y) - a$ is named by $\max(s_{2j+1}, t_{2j+1}) - c_{2j+1}$, and

it has a stage N above $2/(N+1)$. Comparing the ratios s_{2N+1} and t_{2N+1}, the larger one, say s_{2N+1}, gives $s_{2N+1} - c_{2N+1} > 2/(N+1)$, a positive stage of $x - a$; so $a < x$.

Now induct on n. For $n = 0$, $x_0 \le x_0$, every upper bound of $\{x_0\}$ lies above x_0, and $\eta(q) < M_0$ is $\eta(q) < x_0$. Suppose the assertions hold for M_{n-1} and $\{x_0, \dots, x_{n-1}\}$. By Proposition 12.19(5), $x_n \le M_n$ and $M_{n-1} \le M_n$, so every x_i with $i < n$ satisfies $x_i \le M_{n-1} \le M_n$, and M_n is an upper bound. If y is an upper bound of $\{x_0, \dots, x_n\}$, it is one of $\{x_0, \dots, x_{n-1}\}$, so $M_{n-1} \le y$, and also $x_n \le y$; since $\max(x_n, M_{n-1})$ is the least upper bound of these two points, $M_n \le y$. Finally, $\eta(q) < M_n$ gives $\eta(q) < x_n$ or $\eta(q) < M_{n-1}$ by the first paragraph, and in the second case $\eta(q) < x_i$ for some $i < n$. □

With countable choice the two descriptions of the continuum coincide, and the price of identifying them is that single selection.

12.9.3 The line is determined by its task

The same selection settles a question asked of every stage of the number tower in Chapter 4: is the line the unique solution of its task? Its task is to receive exactly one map, preserving the arithmetic and the order, from every Archimedean ordered field: the structure that the next theorem defines by laws that Proposition 12.19 proves for the line.

Theorem 12.38 (The line is determined by its task)**.** *Call a commutative ring with a strict order $<$ an* Archimedean ordered field *when $0 < 1$, the order is irreflexive, transitive and cotransitive, two elements neither of which lies below the other are equal, adding an element preserves $<$, a product of positive elements is positive, every positive element has an inverse, and every element lies below some natural number. Then $\mathbb{R}_\delta$ is an Archimedean ordered field, and:*

1. *from every Archimedean ordered field there is at most one map into $\mathbb{R}_\delta$ that preserves 0, 1, addition, multiplication and $<$, and the only such map from $\mathbb{R}_\delta$ to itself is the identity;*
2. *every Archimedean ordered field has such a map into $\mathbb{R}_\delta$ exactly when every located cut is the cut of a point.*

Neither assertion uses countable choice. The forward direction of the second reads a relation with exactly one output for each input as a map, as Appendix C does; this reading is the principle of unique choice. With countable choice, therefore, every Archimedean ordered field maps into $\mathbb{R}_\delta$ in exactly one such way.

Conditions and scope.

Base and premises

The line $\mathbb{R}_\delta$ of this chapter and an Archimedean ordered field as defined in the statement. Neither part uses countable choice; the forward direction of part 2 uses unique choice, the book's reading of maps.

Conclusion

$\mathbb{R}_\delta$ is an Archimedean ordered field; from every Archimedean ordered field there is at most one structure-preserving map into $\mathbb{R}_\delta$, and the identity is the only one from $\mathbb{R}_\delta$ to

itself; every such field has one exactly when every located cut is the cut of a point. With countable choice every such field has exactly one.

Proof. Every map in the theorem is compared with one canonical passage: from an element of an Archimedean ordered field to its located cut. We place the ratios inside such a field, define the cut of an element, give the located cuts the arithmetic and the order read from their sets, and show that a map into the located cuts preserving the structure is unique. The two assertions then follow. The routine verifications are collected in Appendix F.2; the steps that carry the argument are here.

The line is an Archimedean ordered field. By Proposition 12.19, $\mathbb{R}_\delta$ is a commutative ring, and by its item 1 the order is irreflexive, transitive and cotransitive, and adding a point preserves it. Multiplying by a positive point y preserves $<$, so $0 < x$ gives $0 = 0 \cdot y < xy$: a product of positive points is positive. If neither of x, y lies below the other, then $x \le y$ and $y \le x$, and item 2 gives $x = y$. Positive points are invertible by item 3, every point lies below some $\eta(n)$ by item 4, and $\eta(0) < \eta(1)$ because η preserves the order of the ratios.

The ratios in an Archimedean ordered field. Let F be an Archimedean ordered field. Corollary 4.14 gives exactly one map from $\mathbb{Z}_\delta$ into F preserving 1, sums and products; write u_F for the image of the integer u. The axioms alone give three facts, proved in Lemma F.3: $u_F < v_F$ exactly when $u < v$; the inverse of a positive element is positive; and multiplying by a positive element preserves and reflects $<$. For a positive integer d the element d_F is therefore positive, so it has an inverse, which is unique because inverses in a commutative ring are. For the ratio $q = \langle u; d\rangle$ with $d > 0$ put $q_F = u_F d_F^{-1}$. Cross-equal records give the same element, the assignment $q \mapsto q_F$ preserves sums and products, and $q < r$ exactly when $q_F < r_F$. In $\mathbb{R}_\delta$ the image of q is $\eta(q)$, because η preserves sums and products and $\eta(\langle d; 1\rangle)\,\eta(\langle 1; d\rangle) = \eta(1)$.

The cut of an element. For x in F let $\kappa_F(x)$ be the pair of sets

$$\{q \,:\, q_F < x\}, \qquad \{r \,:\, x < r_F\}.$$

This is a located cut. Its lower set has no greatest element: if $q_F < x$, the positive element $x - q_F$ has an inverse e, the Archimedean condition gives a natural number N with $e < N_F$, so $1 < N_F(x - q_F)$, and the ratio $q + \langle 1; N\rangle$ still lies below x. Its lower and upper sets are located by cotransitivity: if $q < r$, then $q_F < r_F$, so $q_F < x$ or $x < r_F$. The remaining laws, and the facts that κ_F preserves and reflects $<$ and is injective, are proved in Lemma F.5. For $F = \mathbb{R}_\delta$ the pair $\kappa_F(x)$ is the cut C_x of the point x (Definition 12.27), since the image of q is $\eta(q)$; we write it $\kappa(x)$. The ratios themselves form an Archimedean ordered field, in which the order is decided and hence cotransitive; there $\kappa(q)$ is the pair $\{p \,:\, p < q\}, \{p \,:\, q < p\}$, the *cut of the ratio* q, which is also the cut of the point $\eta(q)$.

The arithmetic of located cuts. For located cuts $C = (\mathscr{L}_C, \mathscr{U}_C)$ and $D = (\mathscr{L}_D, \mathscr{U}_D)$ define $C + D$, $-C$ and CD by their lower and upper sets:

$$\begin{aligned}
C + D: &\quad \{q \,:\, q < a + b\}, \qquad \{r \,:\, a' + b' < r\},\\
-C: &\quad \{q \,:\, -q \in \mathscr{U}_C\}, \qquad \{r \,:\, -r \in \mathscr{L}_C\},\\
CD: &\quad \{q \,:\, q < ab,\ q < ab',\ q < a'b,\ q < a'b'\},\\
&\quad \{r \,:\, ab < r,\ ab' < r,\ a'b < r,\ a'b' < r\},
\end{aligned}$$

where in each set a ranges over $\mathscr{L}_C$, a' over $\mathscr{U}_C$, b over $\mathscr{L}_D$ and b' over $\mathscr{U}_D$, and the condition asks for some such ratios. Let $C < D$ mean that some ratio lies in $\mathscr{U}_C$ and in $\mathscr{L}_D$, and let zero and one be the cuts of the ratios 0 and 1. The product compares a ratio with all four corners of the brackets $[a, a']$ and $[b, b']$, so it never asks for the sign of a cut. Lemma F.6 proves that with these operations and this order the located cuts form an Archimedean ordered field, and that κ_F carries 0, 1, sums and products of F to those of the cuts. Two tools carry these verifications. Two located cuts are equal as soon as no lower member of either is an upper member of the other (Lemma F.1). And for every n a located cut has a lower member q and an upper member r with $r - q < 1/(n+1)$ (Lemma 12.32), between any given lower and upper member (Lemma F.2): starting from one lower and one upper member, the ratios of a fine grid between them are compared with the cut by locatedness, one after another, and an induction on the number of grid points proves that two grid points two steps apart lie on opposite sides. That proof establishes a disjunction step by step and selects nothing.

The cut of the ratio q is the image of q in this field: by the lemma for the field of ratios, cuts of ratios add and multiply as the ratios do. So the cut of an element C of the field of located cuts is C itself. Indeed, $\kappa(q) < C$ means that some ratio $p > q$ lies in $\mathscr{L}_C$, and this holds exactly when $q \in \mathscr{L}_C$, because $\mathscr{L}_C$ is closed downward and has no greatest element.

A map into the located cuts is unique. Let h send F into the located cuts preserving 0, 1, sums, products and $<$. We show $h(x) = \kappa_F(x)$ for every x. First, h sends q_F to the cut of q. For natural numbers this follows by induction, since $h(n_F + 1_F) = h(n_F) + h(1_F)$ and cuts of ratios add as ratios do. Since $h(y) + h(-y) = h(0)$ and negatives in a ring are unique, $h(-y) = -h(y)$, which covers the integers. For $q = \langle u; d\rangle$ we have $d_F\, q_F = u_F$, so $\kappa(d)\, h(q_F) = \kappa(u)$; multiplying by $\kappa(\langle 1; d\rangle)$ and using $\kappa(\langle 1; d\rangle)\kappa(d) = \kappa(1)$ gives $h(q_F) = \kappa(q)$. Now compare lower sets. If $q_F < x$, then $\kappa(q) = h(q_F) < h(x)$, so some ratio $p > q$ lies in the lower set of $h(x)$, and then so does q. Conversely, let q lie in the lower set of $h(x)$, and choose a larger ratio q' in that lower set. Cotransitivity in F, applied to $q_F < q'_F$, gives $q_F < x$ or $x < q'_F$. In the second case $h(x) < h(q'_F) = \kappa(q')$, so some ratio $s < q'$ lies in the upper set of $h(x)$; but $s < q'$ also puts s in the lower set of $h(x)$, and the two sets are disjoint. Hence $q_F < x$. The lower sets of $h(x)$ and $\kappa_F(x)$ agree, and a located cut is determined by its lower set, so $h(x) = \kappa_F(x)$.

The first assertion. Let f send F into $\mathbb{R}_\delta$ preserving 0, 1, sums, products and $<$. The composite $x \mapsto \kappa(f(x))$ preserves the same structure, because the cut of a point does, by Lemmas F.5 and F.6(b) for $F = \mathbb{R}_\delta$. By the uniqueness just proved, $\kappa(f(x)) = \kappa_F(x)$ for every x. A point is determined by its cut, so $f(x)$ is determined by x, and any two such maps agree. The identity of $\mathbb{R}_\delta$ is such a map, so it is the only one.

The second assertion. Suppose first that every located cut is the cut of a point, and let F be an Archimedean ordered field. For each x in F, the located cut $\kappa_F(x)$ is the cut of a point, and of only one, since different points have different cuts. Send x to the point $f(x)$ with that cut. This prescription specifies exactly one output for each input, which is what a map is (Appendix C); nothing is selected, since there is only one candidate. If maps are required instead to be operations given in advance, this sentence is the one place where the principle of unique choice is used: a relation with exactly one output for each input defines a map, here from the located cuts into $\mathbb{R}_\delta$. No other step needs it, because the first assertion and the converse below concern maps that are already given. The map f preserves the structure. For

sums,

$$\kappa\big(f(x+y)\big) = \kappa_F(x+y) = \kappa_F(x) + \kappa_F(y) = \kappa\big(f(x)\big) + \kappa\big(f(y)\big) = \kappa\big(f(x)+f(y)\big),$$

so $f(x+y) = f(x) + f(y)$ because points are determined by their cuts. Products, 0 and 1 are the same. If $x < y$, then $\kappa(f(x)) = \kappa_F(x) < \kappa_F(y) = \kappa(f(y))$, and the cut of a point reflects $<$, so $f(x) < f(y)$.

Conversely, suppose that every Archimedean ordered field has such a map into $\mathbb{R}_\delta$. Apply this to the field of located cuts, and call the map g. The composite $C \mapsto \kappa(g(C))$ sends the located cuts into themselves preserving 0, 1, sums, products and $<$. By the uniqueness of maps into the cuts, it is the cut map of that field, which is the identity. So $\kappa(g(C)) = C$: every located cut is the cut of the point $g(C)$.

Every step above is an explicit construction from given data, a comparison of ratios, an application of cotransitivity, or the approximation lemma, which proves a disjunction by induction. No choice principle is used. With countable choice, every located cut is the cut of a point (Theorem 12.33); by the second assertion every Archimedean ordered field then has such a map, and by the first it has exactly one. □

With countable choice the line is therefore determined by this task up to exactly one isomorphism. If an Archimedean ordered field T also receives exactly one such map from every Archimedean ordered field, the maps $\mathbb{R}_\delta \to T$ and $T \to \mathbb{R}_\delta$ compose to such maps of $\mathbb{R}_\delta$ and of T into themselves, and the first assertion, with the same uniqueness for T, makes both composites identities. No other isomorphism exists, since T receives only one such map from $\mathbb{R}_\delta$.

12.9.4 The table of completeness prices

Table 12.3 collects the prices of the familiar forms of completeness. Its terms have their usual meanings, read in the order of $\mathbb{R}_\delta$; recall that a least upper bound of a set of points is an upper bound lying below every upper bound. In the table, f is a function on the points of $\mathbb{R}_\delta$, and $[0,1]$ is the set of points x with $\eta(0) \le x \le \eta(1)$; the set $[-1,1]$ is defined in the same way. Such an f is *uniformly continuous on* $[0,1]$ when for every k there is a j such that points of $[0,1]$ within $1/(j+1)$ have values within $1/(k+1)$. A *root* of f is a point x with $f(x) = \eta(0)$. The function is *strictly increasing* on $[0,1]$ when $x < y$ in $[0,1]$ gives $f(x) < f(y)$, and it *attains a maximum* when some x in $[0,1]$ has $f(y) \le f(x)$ for every y in $[0,1]$. A *supremum* of f is an upper bound of its values on $[0,1]$ such that, for every k, some value $f(y)$ with y in $[0,1]$ lies within $1/(k+1)$ of it. Write $c_n = \sum_{i<n} e_i 2^{-(i+1)}$ for the nth partial sum of a digit sequence (e_i). A *binary expansion* of x has digits in $\{0,1\}$ and $\eta(c_n) \le x \le \eta(c_n + 2^{-n})$ for every n; a *signed-digit expansion* has digits in $\{-1,0,1\}$ and $\eta(c_n - 2^{-n}) \le x \le \eta(c_n + 2^{-n})$ for every n.

We now prove the rows of Table 12.3 priced LPO, WLPO, weak excluded middle and excluded middle, in both directions. Every passage from an assertion to its principle uses only the arithmetic and order of Proposition 12.19, and no choice principle. Every passage back says where countable choice enters. For exact roots and binary expansions, countable choice in the converse cannot be weakened to choice for the relations whose witnesses a search can find (Theorem 12.70). For the cut row it is replaced neither by excluded middle with such choice (Theorem 12.63) nor by unique choice (Theorem 12.66).

Assertion on $\mathbb{R}_\delta$	Price	Countable choice
The diagonal of a Cauchy family of regular sequences names the limit of their points (Theorem 12.25)	none	not used
Every Cauchy sequence of points converges (Theorem 12.26)	none	used once, to select representatives
Every Cauchy sequence of located cuts has a limit cut (Theorem 12.29)	none	not used
Every located cut is the cut of a point (Theorem 12.33)	none	used once, at pairs of ratios
Every bounded nondecreasing sequence converges (Theorem 12.45)	LPO	representatives; once at pairs of ratios
Every bounded nondecreasing sequence, given by regular sequences, is Cauchy (Theorem 12.46)	LPO	not used
Every bounded sequence has a convergent subsequence; every bounded sequence has a cluster point; every sequence has a monotone subsequence (Theorem 12.47)	LPO	representatives, decisions and indices; limits as in Theorem 12.45
Every sequence bounded above has a least upper bound (Theorem 12.48)	WLPO	representatives; once at pairs of ratios
… one that every smaller ratio is exceeded by some term (Theorem 12.49)	LPO	representatives; once at pairs of ratios
Every finite inhabited set has a least upper bound (Proposition 12.37)	none	not used
Every inhabited set of points bounded above has a least upper bound (Theorem 12.50)	WEM	once, at pairs of ratios
… one that every smaller ratio is exceeded by some member (Theorem 12.51)	EM	once, at pairs of ratios
A uniformly continuous f on $[0,1]$ with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$ has a root in $[0,1]$ (Theorem 12.54)	LLPO	once, one bit per dyadic ratio
such an f has, for each k, a point x of $[0,1]$ with $f(x)$ within $1/(k+1)$ of $\eta(0)$ (Theorem 12.55)	none	not used
such an f, strictly increasing, has a root in $[0,1]$ (Theorem 12.56)	none	used once, at pairs of ratios
A uniformly continuous f on $[0,1]$ attains a maximum (Theorem 12.60)	LLPO	bits for adjacent dyadic intervals; suprema as below
such an f has a supremum (Theorem 12.58)	none	used once, at pairs of ratios
Every point of $[0,1]$ has a binary expansion (Theorem 12.61)	LLPO	once, one bit per dyadic ratio
Every point of $[-1,1]$ has a signed-digit expansion (Proposition 12.62)	none	not used

Table 12.3. Completeness on the line built from ratios. "Price" is the principle equivalent to the assertion; "none" means that no omniscience principle is needed, so the assertion is proved outright, from countable choice where the last column says it is used. WEM is the weak excluded middle, $\neg P \vee \neg\neg P$ for every proposition P, and EM is excluded middle, $P \vee \neg P$ for every proposition P. In every priced row the passage from the assertion to the principle uses no choice principle, and the last column says where countable choice enters the passage back. Each row names the result that proves both directions.

For sequences and sets of points the terms are the following.

Definition 12.39 (Terms of the table)**.** Let (x_n) be a sequence of points of $\mathbb{R}_\delta$.

1. The sequence is *bounded above* if some point b satisfies $x_n \le b$ for every n, and *bounded* if, in addition, some point b' satisfies $b' \le x_n$ for every n. It is *nondecreasing* if $x_n \le x_{n+1}$ for every n, and then $x_m \le x_n$ whenever $m \le n$, by transitivity of $\le$; it is *nonincreasing* if $x_{n+1} \le x_n$ for every n; and it is *monotone* if it is nondecreasing or nonincreasing.

2. A *subsequence* is a sequence $(x_{\sigma(n)})$ with $\sigma(0) < \sigma(1) < \cdots$. By induction $\sigma(n) \ge n$ for every n.

3. A point L is a *cluster point* of (x_n) if for every k and every N some $m \ge N$ has x_m within $1/(k+1)$ of L.

4. The sequence is *given by regular sequences* when it is presented as a sequence $s^{(0)}, s^{(1)}, \ldots$ of regular sequences, its nth term being the point of $s^{(n)}$.

5. As before Theorem 12.36, a *set of points* is any property of points; it is *inhabited* if some point has it, and *bounded above* if some point b lies at or above every member. Upper bounds and least upper bounds of a sequence are those of the set of its terms.

6. A least upper bound L of a set S is *approached by its members* if every ratio q with $\eta(q) < L$ has a member s with $\eta(q) < s$. For a sequence we say *approached by its terms*.

The rows with the words "one that every smaller ratio is exceeded by some term" (or "member") ask for a least upper bound approached in the sense of item 6.

12.9.5 Order tools for the proofs of the table

Lemma 12.40 (Order tools)**.** *For points u, v, w, x, y, z and ratios q, r:*

(a) if $u \le v < w$ or $u < v \le w$, then $u < w$; and $u < v$ implies $u \le v$;

(b) if $x \le y$, then $x + z \le y + z$; consequently $x \le y$ exactly when $-y \le -x$;

(c) $\eta(q) + \eta(r) = \eta(q + r)$, and $\eta(q) < \eta(r)$ exactly when $q < r$, while $\eta(q) \le \eta(r)$ exactly when $q \le r$.

No omniscience principle and no choice principle is used.

Proof. (a) If $v < w$, cotransitivity gives $v < u$ or $u < w$, and $v < u$ denies $u \le v$. If $u < v$, cotransitivity gives $u < w$ or $w < v$, and $w < v$ denies $v \le w$. If $u < v$ and also $v < u$, transitivity gives $u < u$, contrary to irreflexivity; so $u < v$ gives $\neg(v < u)$, which is $u \le v$.

(b) If $y + z < x + z$, adding $-z$ gives $y < x$, which denies $x \le y$. Adding $-x - y$ to $x \le y$ gives $-y \le -x$, and adding $x + y$ reverses the step.

(c) This is the embedding of the ratios in Proposition 12.19, which preserves and reflects the order; the order of ratios is decidable, so $\neg(r < q)$ is $q \le r$. □

Two more facts about the order come from the located-cut material above. Between two points lies a ratio (Lemma 12.30): if $x < y$, then $x < \eta(q) < y$ for some ratio q. And $x \le y$ exactly when every ratio q with $\eta(q) < x$ also has $\eta(q) < y$ (Lemma 12.31). Distances are the order statements of "within", and four rules govern them.

Lemma 12.41 (Distances from order)**.** *Let a, c be ratios, y, z, w points and k a natural number.*

(a) If $\eta(a) \le y \le \eta(c)$ and $\eta(a) \le z \le \eta(c)$, where $c - a \le 1/(k+1)$, then y and z are within $1/(k+1)$.

(b) If $\eta(a) < y$ and $z < \eta(c)$, where $a - c \ge 1/(k+1)$, then y and z are not within $1/(k+1)$.

(c) If y, w and w, z are within $1/(2k+2)$, then y, z are within $1/(k+1)$.

(d) y and z are within $1/(k+1)$ exactly when $-y$ and $-z$ are.

No omniscience principle and no choice principle is used.

Proof. Write $\varepsilon = 1/(k+1)$.

(a) By Lemma 12.40(b),(c), $y \le \eta(c) = \eta(a) + \eta(c-a) \le z + \eta(c-a) \le z + \eta(\varepsilon)$, and in the same way $z \le y + \eta(\varepsilon)$.

(b) Suppose they were within $1/(k+1)$. Then $y \le z + \eta(\varepsilon)$. Adding $\eta(\varepsilon)$ preserves $<$, so $z + \eta(\varepsilon) < \eta(c) + \eta(\varepsilon)$, and $\eta(c) + \eta(\varepsilon) \le \eta(c) + \eta(a - c) = \eta(a)$. By Lemma 12.40(a), first $z + \eta(\varepsilon) < \eta(a)$ and then $y < \eta(a)$. Together with $\eta(a) < y$, transitivity gives $y < y$, contrary to irreflexivity.

(c) $y \le w + \eta(1/(2k+2)) \le z + \eta(1/(2k+2)) + \eta(1/(2k+2)) = z + \eta(\varepsilon)$, and symmetrically.

(d) Adding $-y - z$ to $y \le z + \eta(\varepsilon)$ gives $-z \le -y + \eta(\varepsilon)$, and adding $y + z$ reverses the step; Lemma 12.40(b) applies in both directions, and the same holds with y and z exchanged. □

In particular the points $\eta(0)$ and $\eta(1)$ are not both within $1/4$ of any point L: that would give $\eta(1) \le L + \eta(1/4) \le \eta(1/4) + \eta(1/4) = \eta(1/2)$, contrary to $\eta(1/2) < \eta(1)$.

12.9.6 Deciding a point against a ratio

An omniscience principle decides propositions about binary sequences. To use it on points, a question about points must be turned into a binary sequence, and for that the points need regular sequences naming them.

Lemma 12.42 (Deciding against a ratio)**.** *Let $s^{(0)}, s^{(1)}, \ldots$ be regular sequences naming the points $x_0, x_1, \ldots$, and let q be a ratio. Put $\beta_q(N) = 1$ if there are $n, j \le N$ with $s^{(n)}_{2j+1} - q > 2/(j+1)$, and $\beta_q(N) = 0$ otherwise. Then β_q is a binary sequence; it has an entry 1 exactly when $\eta(q) < x_n$ for some n, and it is all zero exactly when $x_n \le \eta(q)$ for every n. Consequently, with no choice principle:*

(a) LPO gives: $\eta(q) < x_n$ for some n, or $x_n \le \eta(q)$ for every n;

(b) WLPO gives: $x_n \le \eta(q)$ for every n, or not;

(c) $\mathrm{MP}_{\mathrm{bin}}$ *turns* $\neg(\forall n,\ x_n \le \eta(q))$ *into an* n *with* $\eta(q) < x_n$.

Proof. Each value $\beta_q(N)$ is a finite computation with ratios. The regular sequence $s^{(n)} + (-\eta(q))$ names the point $x_n - \eta(q)$, and its stage j is $s^{(n)}_{2j+1} - q$. Positivity belongs to the point, so $\eta(q) < x_n$ holds exactly when some stage j of this sequence exceeds $2/(j+1)$, and then $\beta_q(\max(n, j)) = 1$. Conversely, an entry $\beta_q(N) = 1$ exhibits such n and j. Since $x_n \le \eta(q)$ is $\neg(\eta(q) < x_n)$, the sequence β_q is all zero exactly when every $x_n \le \eta(q)$, and it is not all zero exactly when $\neg(\forall n,\ x_n \le \eta(q))$. Applying LPO, WLPO or $\mathrm{MP}_{\mathrm{bin}}$ to the one sequence β_q gives (a), (b) and (c). □

12.9.7 Two cuts that bound a set

The passages back build a candidate least upper bound as a located cut. There are two candidates, according to what can be decided.

Lemma 12.43 (The supremum cut)**.** *Let S be an inhabited set of points that is bounded above, and suppose that for every ratio q, either $\eta(q) < s$ for some member s or $s \le \eta(q)$ for every member s. Let $\mathscr{L}$ be the set of ratios q with $\eta(q) < s$ for some member s, and $\mathscr{U}$ the set of ratios r such that some ratio $r' < r$ has $s \le \eta(r')$ for every member s. Then $(\mathscr{L}, \mathscr{U})$ is a located cut, and every point whose cut is $(\mathscr{L}, \mathscr{U})$ is a least upper bound of S approached by its members. No choice principle is used.*

Proof. Let s_0 be a member and b an upper bound. By item 4 of Proposition 12.19 there are natural numbers n_0, n_1 with $-s_0 < \eta(n_0)$ and $b < \eta(n_1)$. The first gives $\eta(-n_0) < s_0$, so $-n_0 \in \mathscr{L}$. Every member satisfies $s \le b < \eta(n_1)$, hence $s < \eta(n_1)$ and $s \le \eta(n_1)$ by Lemma 12.40(a); so $n_1 + 1 \in \mathscr{U}$. If $q < q'$ and $\eta(q') < s$, then $\eta(q) < \eta(q') < s$, so $\mathscr{L}$ is closed downward; if $\eta(q) < s$, Lemma 12.30 gives a ratio q' with $\eta(q) < \eta(q') < s$, so $\mathscr{L}$ has no greatest element. $\mathscr{U}$ is closed upward by its definition, and if $r' < r$ witnesses $r \in \mathscr{U}$, the mean of r' and r is a smaller member of $\mathscr{U}$. If q lay in both sets, some member s and some ratio $r' < q$ would give $\eta(q) < s$ and $s \le \eta(r') < \eta(q)$, hence $\eta(q) < \eta(q)$ by Lemma 12.40(a) and transitivity. Finally let $q < r$. The hypothesis at q gives either a member with $\eta(q) < s$, and then $q \in \mathscr{L}$, or $s \le \eta(q)$ for every member, and then $r \in \mathscr{U}$ with $r' = q$. So the cut is located.

Let L have the cut $(\mathscr{L}, \mathscr{U})$, so that $\eta(q) < L$ exactly when some member exceeds $\eta(q)$. For a member s, every ratio q with $\eta(q) < s$ lies in $\mathscr{L}$, hence $\eta(q) < L$; by Lemma 12.31, $s \le L$. Let b be an upper bound and $\eta(q) < L$. Some member has $\eta(q) < s$, and cotransitivity gives $\eta(q) < b$ or $b < s$; the second denies $s \le b$. So $\eta(q) < b$, and Lemma 12.31 gives $L \le b$. Thus L is a least upper bound, and the description of $\mathscr{L}$ says that it is approached by the members. □

Lemma 12.44 (The least-upper-bound cut)**.** *Let S be an inhabited set of points that is bounded above, and suppose that for every ratio q, either $\eta(q)$ is an upper bound of S or it is not. Let $\mathscr{L}$ be the set of ratios q such that some ratio $q' > q$ has $\eta(q')$ not an upper bound of S, and $\mathscr{U}$ the set of ratios r such that some ratio $r' < r$ has $\eta(r')$ an upper bound of S. Then $(\mathscr{L}, \mathscr{U})$ is a located cut, and every point whose cut is $(\mathscr{L}, \mathscr{U})$ is a least upper bound of S. No choice principle is used.*

Proof. Let s be a member. As in Lemma 12.43, some ratio q has $\eta(q) < s$, and Lemma 12.30 gives q' with $\eta(q) < \eta(q') < s$. Then $\eta(q')$ is not an upper bound, so $q \in \mathscr{L}$. An upper bound

lies below some $\eta(n_1)$, which is then an upper bound, and $n_1 + 1 \in \mathcal{U}$. Both sets are closed in the right direction by their definitions, and neither has an end point: if $q' > q$ witnesses $q \in \mathcal{L}$, the mean of q and q' is a larger member of $\mathcal{L}$, and the mean of a witness $r' < r$ and r is a smaller member of $\mathcal{U}$. If q lay in both sets, there would be ratios $r' < q < q'$ with $\eta(r')$ an upper bound and $\eta(q')$ not; but every member satisfies $s \le \eta(r') \le \eta(q')$, so $\eta(q')$ is an upper bound. For $q < r$ let m be their mean. If $\eta(m)$ is an upper bound, then $r \in \mathcal{U}$; if it is not, then $q \in \mathcal{L}$. So the cut is located.

Let L have the cut $(\mathcal{L}, \mathcal{U})$. For a member s and a ratio q with $\eta(q) < s$, the first paragraph puts q in $\mathcal{L}$, so $\eta(q) < L$; by Lemma 12.31, $s \le L$. Let b be an upper bound and $\eta(q) < L$. Then $q \in \mathcal{L}$, so some $q' > q$ has $\eta(q')$ not an upper bound. Cotransitivity at $\eta(q) < \eta(q')$ gives $\eta(q) < b$ or $b < \eta(q')$, and the second would make $\eta(q')$ an upper bound, by Lemma 12.40(a). So $\eta(q) < b$, and Lemma 12.31 gives $L \le b$. □

12.9.8 Monotone sequences and sequential compactness cost LPO

Theorem 12.45 (Monotone convergence costs exactly LPO)**.** *Monotone convergence is equivalent to LPO, in the following sense.*

1. *If every bounded nondecreasing sequence of points of $\mathbb{R}_\delta$ converges, then LPO holds. The proof uses no choice principle.*

2. *Assume LPO and AC_ω. Then every nondecreasing sequence of points that is bounded above converges; in particular every bounded one does. Countable choice is used twice: to fix regular sequences naming the terms, and once at pairs of ratios, through Theorem 12.33.*

Proof. For the first statement, let α be a binary sequence. Put $t_n = \eta(1)$ if $\alpha(k) = 1$ for some $k \le n$, and $t_n = \eta(0)$ otherwise. Each term is fixed by a bounded search, so the sequence is given outright. It is nondecreasing, and it lies between $\eta(0)$ and $\eta(1)$, so it is bounded. By hypothesis it has a limit L; take N such that t_m is within $1/4$ of L for every $m \ge N$.

Search $\alpha(0), \dots, \alpha(N)$. If an event appears, the second alternative of LPO holds. Otherwise $t_N = \eta(0)$. Fix n. If $\alpha(n) = 1$, then $t_{N+n} = \eta(1)$, and $t_N = \eta(0)$ and $t_{N+n} = \eta(1)$ would both be within $1/4$ of L, which is impossible, as shown after Lemma 12.41. Since $\alpha(n)$ is binary, $\alpha(n) = 0$. This is the first alternative of LPO.

For the second, let (x_n) be nondecreasing and bounded above. Countable choice supplies regular sequences $s^{(n)}$ naming the points x_n. For every ratio q, LPO gives, through Lemma 12.42(a), either an n with $\eta(q) < x_n$ or $x_n \le \eta(q)$ for every n. So Lemma 12.43, applied to the set of terms, gives a located cut $(\mathcal{L}, \mathcal{U})$, and by Theorem 12.33, using countable choice at pairs of ratios, it is the cut of a point L. Thus $\eta(q) < L$ exactly when $q \in \mathcal{L}$, and $L < \eta(r)$ exactly when $r \in \mathcal{U}$.

Fix k. Lemma 12.32 gives $q \in \mathcal{L}$ and $r \in \mathcal{U}$ with $r - q < 1/(k+1)$. Since $q \in \mathcal{L}$, some N has $\eta(q) < x_N$; since $r \in \mathcal{U}$, some $r' < r$ has $x_n \le \eta(r')$ for every n. Let $m \ge N$. Then $x_N \le x_m$, so $\eta(q) < x_m$ by Lemma 12.40(a); and $x_m \le \eta(r') < \eta(r)$ gives $x_m < \eta(r)$. Hence $\eta(q) \le x_m \le \eta(r)$, and likewise $\eta(q) \le L \le \eta(r)$. By Lemma 12.41(a), x_m is within $1/(k+1)$ of L. So (x_n) converges to L. □

The proof of the first statement uses one limit point and one index N; it decides nothing about them beyond a bounded search.

When the terms come with regular sequences, the Cauchy condition costs the same principle, and then no choice is needed at all.

Theorem 12.46 (Monotone sequences are Cauchy exactly under LPO)**.** *The following are equivalent, and neither direction uses a choice principle:*

1. *every bounded nondecreasing sequence of points given by regular sequences is Cauchy;*
2. *LPO.*

Moreover, LPO makes every nondecreasing sequence given by regular sequences and bounded above Cauchy.

Proof. Assume the first statement, and let α be a binary sequence. Let $s^{(n)}$ be the constant sequence of the ratio 1 if $\alpha(k) = 1$ for some $k \le n$, and of the ratio 0 otherwise. Each $s^{(n)}$ is fixed by a bounded search, so the sequence of regular sequences is given outright. Its points are the terms t_n of the proof of Theorem 12.45: nondecreasing, and between $\eta(0)$ and $\eta(1)$. By hypothesis they form a Cauchy sequence; take N such that t_m and t_n are within $1/4$ whenever $m, n \ge N$. Search $\alpha(0), \dots, \alpha(N)$. If an event appears, the second alternative of LPO holds. Otherwise $t_N = \eta(0)$. Fix n. If $\alpha(n) = 1$, then $t_{N+n} = \eta(1)$, and $\eta(1)$ would be within $1/4$ of $\eta(0)$; then $\eta(1) \le \eta(0) + \eta(1/4) = \eta(1/4)$, contrary to $\eta(1/4) < \eta(1)$. Since $\alpha(n)$ is binary, $\alpha(n) = 0$. This is the first alternative of LPO.

Conversely, assume LPO, and let regular sequences $s^{(n)}$ be given whose points x_n are nondecreasing and bounded above. For every ratio q, LPO, through Lemma 12.42(a) applied to the given sequences, yields either an n with $\eta(q) < x_n$ or $x_n \le \eta(q)$ for every n. By Lemma 12.43 the sets $\mathscr{L}$ and $\mathscr{U}$ of that lemma form a located cut. Fix k, and take $q \in \mathscr{L}$ and $r \in \mathscr{U}$ with $r - q < 1/(k+1)$ (Lemma 12.32). Some N has $\eta(q) < x_N$, and some $r' < r$ has $x_n \le \eta(r')$ for every n. For $m \ge N$, monotonicity and Lemma 12.40(a) give $\eta(q) \le x_m \le \eta(r)$. So for $m, n \ge N$ the points x_m and x_n both lie between $\eta(q)$ and $\eta(r)$, and Lemma 12.41(a) puts them within $1/(k+1)$. The sequence is Cauchy.

No step selects anything: the regular sequences are given, each decision is one application of LPO to one binary sequence, the pair q, r is found inside the proof for one k, and the cut is never turned into a point. □

Theorem 12.47 (Sequential compactness costs exactly LPO)**.** *Consider the assertions*

(i) every bounded sequence of points of $\mathbb{R}_\delta$ has a convergent subsequence;

(ii) every bounded sequence of points has a cluster point;

(iii) every sequence of points has a monotone subsequence.

Each of them implies LPO, and the proof uses no choice principle; for (iii) the bounded sequences already suffice. Conversely, LPO and AC_ω imply all three. Countable choice is used in (iii) to fix regular sequences naming the terms and to collect three sequences of decisions and indices, and in (i) and (ii) through (iii) and Theorem 12.45.

Proof. (i) implies (ii). Let $(x_{\sigma(n)})$ converge to L, and let k and N be given. Take M such that $x_{\sigma(n)}$ is within $1/(k+1)$ of L for $n \geq M$. Then $m = \sigma(N+M) \geq N+M \geq N$, and x_m is within $1/(k+1)$ of L. So L is a cluster point. No choice is involved.

(ii) implies LPO. Let α be a binary sequence and (t_n) the test sequence of Theorem 12.45; it is bounded. Let L be a cluster point. With $k = 3$ and $N = 0$ there is an m with t_m within $1/4$ of L. Search $\alpha(0), \ldots, \alpha(m)$. If an event appears, the second alternative of LPO holds. Otherwise $t_m = \eta(0)$. Fix j. If $\alpha(j) = 1$, the cluster property with $k = 3$ and $N = j$ gives an $m' \geq j$ with $t_{m'}$ within $1/4$ of L, and $t_{m'} = \eta(1)$ because $j \leq m'$. Then $\eta(0)$ and $\eta(1)$ would both be within $1/4$ of L, which is excluded. Hence $\alpha(j) = 0$, the first alternative of LPO. With the first paragraph, (i) implies LPO as well.

(iii) implies LPO. Let α be a binary sequence. Put $z_n = \eta(1/(n+1))$ if $\alpha(k) = 1$ for some $k \leq n$, and $z_n = \eta(-1/(n+1))$ otherwise. Each term is fixed by a bounded search, and every term lies between $\eta(-1)$ and $\eta(1)$. Let $(z_{\sigma(n)})$ be a monotone subsequence.

If it is nondecreasing, every entry of α is 0. Indeed, if $\alpha(j) = 1$, an event occurs at or before $\sigma(j)$, since $\sigma(j) \geq j$, and hence at or before $\sigma(j+1)$. Then $z_{\sigma(j+1)} = \eta(1/(\sigma(j+1)+1)) < \eta(1/(\sigma(j)+1)) = z_{\sigma(j)}$, which denies $z_{\sigma(j)} \leq z_{\sigma(j+1)}$. Since each entry is binary, it is 0.

If it is nonincreasing, search $\alpha(0), \ldots, \alpha(\sigma(1))$. Should no event appear, none appears up to $\sigma(0) < \sigma(1)$ either, and $z_{\sigma(0)} = \eta(-1/(\sigma(0)+1)) < \eta(-1/(\sigma(1)+1)) = z_{\sigma(1)}$, which denies $z_{\sigma(1)} \leq z_{\sigma(0)}$. So the search finds an event, the second alternative of LPO.

LPO and AC_ω give (iii). Let (x_n) be a sequence of points, and use countable choice to fix regular sequences $s^{(n)}$ naming them. Call n a *peak* if $x_m \leq x_n$ for every $m > n$. For each n, $x_n < x_m$ holds exactly when some stage j of $s^{(m)} + (-s^{(n)})$, the ratio $s^{(m)}_{2j+1} - s^{(n)}_{2j+1}$, exceeds $2/(j+1)$. Let $\pi_n(N) = 1$ if some $i, j \leq N$ give such a stage for $m = n+i+1$, and $\pi_n(N) = 0$ otherwise. As in Lemma 12.42, π_n is all zero exactly when n is a peak, and has an entry 1 exactly when some $m > n$ has $x_n < x_m$; so LPO decides between the two. Countable choice collects these decisions into a binary sequence p, with $p(n) = 1$ when n is a peak and $p(n) = 0$ when a later term lies strictly above x_n. For each N, LPO applied to $p(N), p(N+1), \ldots$ decides whether a peak lies at or after N; countable choice collects these answers into a binary sequence c, with $c(N) = 0$ when some $n \geq N$ has $p(n) = 1$, and $c(N) = 1$ when $p(n) = 0$ for every $n \geq N$. Apply LPO to c.

If every $c(N)$ is 0, every index has a peak at or after it, and countable choice gives a sequence g with $g(N) \geq N$ and $p(g(N)) = 1$ for every N. Put $\sigma(0) = g(0)$ and $\sigma(i+1) = g(\sigma(i)+1)$. The indices increase, each is a peak, and so $x_{\sigma(i+1)} \leq x_{\sigma(i)}$: the subsequence is nonincreasing.

If $c(N) = 1$ for some N, every $n \geq N$ has a later term strictly above x_n, and countable choice gives a sequence g with $n < g(n)$ and $x_n < x_{g(n)}$ for every $n \geq N$. Put $\sigma(0) = N$ and $\sigma(i+1) = g(\sigma(i))$. The indices increase and stay at least N, and $x_{\sigma(i)} < x_{\sigma(i+1)}$, so $x_{\sigma(i)} \leq x_{\sigma(i+1)}$: the subsequence is nondecreasing.

LPO and AC_ω give (i), and hence (ii). Let (x_n) be bounded, with $b' \leq x_n \leq b$ for every n, and take a monotone subsequence $(y_n) = (x_{\sigma(n)})$ by (iii); it has the same bounds. If it is nondecreasing, Theorem 12.45 gives it a limit. If it is nonincreasing, $(-y_n)$ is nondecreasing and bounded above by $-b'$ (Lemma 12.40(b)), so it converges to some point M, and by Lemma 12.41(d) the subsequence (y_n) converges to $-M$. Then (ii) follows from the first paragraph of this proof. □

12.9.9 Least upper bounds cost WLPO, LPO, WEM or EM

Theorem 12.48 (Least upper bounds of sequences cost exactly WLPO)**.** *Least upper bounds of sequences are equivalent to WLPO, in the following sense.*

1. *If every bounded sequence of points of $\mathbb{R}_\delta$ has a least upper bound, then WLPO holds. The proof uses no choice principle.*
2. *Assume WLPO and AC_ω. Then every sequence of points that is bounded above has a least upper bound. Countable choice is used twice: to fix regular sequences naming the terms, and once at pairs of ratios, through Theorem 12.33.*

In particular "every sequence bounded above has a least upper bound" and "every bounded sequence has a least upper bound" are both equivalent to WLPO under AC_ω, and the passage to WLPO uses no choice.

Proof. For the first statement, let α be a binary sequence, and let $b_n = \eta(\alpha(n))$, reading each bit as the ratio 0 or 1. The sequence is bounded, below by $\eta(0)$ and above by $\eta(1)$; let L be a least upper bound. Since $\eta(0) < \eta(1)$, cotransitivity gives $\eta(0) < L$ or $L < \eta(1)$.

If $L < \eta(1)$, no entry of α is 1: an entry $\alpha(n) = 1$ would give $\eta(1) = b_n \leq L < \eta(1)$, hence $\eta(1) < \eta(1)$ by Lemma 12.40(a). Every entry is therefore 0.

If $\eta(0) < L$, then α is not all zero. Otherwise $\eta(0)$ would be an upper bound, and leastness would give $L \leq \eta(0)$, which denies $\eta(0) < L$.

These are the two alternatives of WLPO.

For the second, let (x_n) be bounded above, and use countable choice to fix regular sequences naming its terms. For every ratio q, WLPO decides, through Lemma 12.42(b), whether $\eta(q)$ is an upper bound of the terms. So Lemma 12.44, applied to the set of terms, gives a located cut, and every point with that cut is a least upper bound. By Theorem 12.33, using countable choice at pairs of ratios, the cut is the cut of a point. Finally, the assertion for sequences bounded above implies the assertion for bounded sequences, so statement 1 gives WLPO from either reading, and statement 2 gives both readings from WLPO. □

The proof of the first statement never decides whether L is $\eta(0)$ or $\eta(1)$; cotransitivity only places L away from one of them. If the least upper bound is also approached by the terms, the case $\eta(0) < L$ yields a term above $\eta(0)$, that is, an event, and the same argument gives LPO. The next theorem proves this and its converse.

Theorem 12.49 (Approached least upper bounds cost exactly LPO)**.** *Least upper bounds approached by the terms are equivalent to LPO, in the following sense.*

1. *If every sequence of points bounded above has a least upper bound approached by its terms, then LPO holds. The proof uses no choice principle.*
2. *Assume LPO and AC_ω. Then every sequence of points bounded above has a least upper bound approached by its terms. Countable choice is used to fix regular sequences naming the terms, and once at pairs of ratios, through Theorem 12.33.*

Proof. For the first statement, let α be a binary sequence and $b_n = \eta(\alpha(n))$, as in the proof of Theorem 12.48; the sequence is bounded above by $\eta(1)$. Let L be a least upper bound approached by the terms. Cotransitivity at $\eta(0) < \eta(1)$ gives $\eta(0) < L$ or $L < \eta(1)$. If $L < \eta(1)$, every entry of α is 0, exactly as in that proof. If $\eta(0) < L$, the ratio 0 is exceeded by some term: $\eta(0) < b_n$ for some n. If $\alpha(n)$ were 0, then $b_n = \eta(0)$ and $\eta(0) < \eta(0)$, which is impossible; so $\alpha(n) = 1$. These are the two alternatives of LPO.

For the second, let (x_n) be bounded above, and use countable choice to fix regular sequences naming its terms. LPO gives, through Lemma 12.42(a) and for every ratio q, an n with $\eta(q) < x_n$ or $x_n \le \eta(q)$ for every n. So the sets $\mathscr{L}$ and $\mathscr{U}$ of Lemma 12.43, for the set of terms, form a located cut. By Theorem 12.33, using countable choice at pairs of ratios, it is the cut of a point L, and by Lemma 12.43, L is a least upper bound approached by the terms. □

For arbitrary sets of points no binary sequence is available, and the decisions must be made about propositions. The prices become the weak and the full excluded middle.

Theorem 12.50 (Least upper bounds of sets cost exactly WEM)**.** *Least upper bounds of sets of points are equivalent to weak excluded middle, in the following sense.*

1. *If every inhabited set of points of $\mathbb{R}_\delta$ that is bounded above has a least upper bound, then $\neg P \vee \neg\neg P$ for every proposition P. The proof uses no choice principle.*

2. *Assume weak excluded middle and AC_ω. Then every inhabited set of points that is bounded above has a least upper bound. Countable choice is used once, at pairs of ratios, through Theorem 12.33.*

Proof. For the first statement, let P be a proposition and let T_P be the set of points s with $s = \eta(0)$, or with P and $s = \eta(1)$. It is inhabited by $\eta(0)$ and bounded above by $\eta(1)$; let L be a least upper bound. Since $\eta(0) < \eta(1/2)$, cotransitivity gives $\eta(0) < L$ or $L < \eta(1/2)$. If $L < \eta(1/2)$, then $\neg P$: from P we would get $\eta(1) \in T_P$, so $\eta(1) \le L < \eta(1/2) < \eta(1)$, and Lemma 12.40(a) with transitivity gives $\eta(1) < \eta(1)$. If $\eta(0) < L$, then $\neg\neg P$: from $\neg P$, the only member of T_P is $\eta(0)$, so $\eta(0)$ is an upper bound and leastness gives $L \le \eta(0)$, which denies $\eta(0) < L$.

For the second, let S be inhabited and bounded above. For a ratio q, the statement that $\eta(q)$ is an upper bound of S says that no member lies above $\eta(q)$. It is a negation, so its double negation implies it. Weak excluded middle therefore decides it: either $\eta(q)$ is an upper bound or it is not. Lemma 12.44 gives a located cut every point of which is a least upper bound of S, and Theorem 12.33, using countable choice at pairs of ratios, gives such a point. No regular sequences are needed: being an upper bound is a statement about the points themselves. □

Theorem 12.51 (Approached least upper bounds of sets cost exactly EM)**.** *Least upper bounds of sets approached by the members are equivalent to excluded middle, in the following sense.*

1. *If every inhabited set of points that is bounded above has a least upper bound approached by its members, then $P \vee \neg P$ for every proposition P. The proof uses no choice principle.*

2. *Assume excluded middle and* AC_ω*. Then every inhabited set of points that is bounded above has a least upper bound approached by its members. Countable choice is used once, at pairs of ratios, through Theorem 12.33.*

Proof. For the first statement, take the set T_P of the proof of Theorem 12.50 and a least upper bound L approached by its members. Cotransitivity at $\eta(0) < \eta(1/2)$ gives $\eta(0) < L$ or $L < \eta(1/2)$. If $L < \eta(1/2)$, then $\neg P$, as there. If $\eta(0) < L$, the ratio 0 is exceeded by some member s of T_P. The member $\eta(0)$ does not exceed $\eta(0)$, so s is a member of the second kind, and P holds.

For the second, let S be inhabited and bounded above. For every ratio q, excluded middle decides whether some member exceeds $\eta(q)$; if none does, every member s satisfies $s \leq \eta(q)$, since $s \leq \eta(q)$ means only that $\eta(q) < s$ fails. So Lemma 12.43 applies to S: its sets form a located cut, and every point with that cut is a least upper bound approached by the members. Theorem 12.33, using countable choice at pairs of ratios, gives such a point. □

Without countable choice the two assertions keep an exact price. Each of them makes every located cut the cut of a point, with no choice. Let $(\mathscr{L}, \mathscr{U})$ be a located cut. Every $q \in \mathscr{L}$ lies below every $r \in \mathscr{U}$, since $r \leq q$ would put r in $\mathscr{L}$. So the set of points $\eta(q)$ with $q \in \mathscr{L}$ is inhabited and bounded above by $\eta(r)$ for each $r \in \mathscr{U}$; let y be a least upper bound. If $q \in \mathscr{L}$, a larger $q' \in \mathscr{L}$ gives $\eta(q) < \eta(q') \leq y$. If $\eta(q) < y$, take a ratio q' with $\eta(q) < \eta(q') < y$; locatedness at $q < q'$ gives $q \in \mathscr{L}$ or $q' \in \mathscr{U}$, and $q' \in \mathscr{U}$ would make $\eta(q')$ an upper bound below y. So the lower set of y is $\mathscr{L}$, and in the same way its upper set is $\mathscr{U}$. Conversely, the proofs of the second statements use countable choice only through Theorem 12.33. Hence, with no choice principle, the assertion of Theorem 12.50 is equivalent to weak excluded middle together with the assertion that every located cut is the cut of a point, and the assertion of Theorem 12.51 is equivalent to excluded middle together with the same assertion. Theorem 12.63 shows that excluded middle, without unique choice, does not supply the second conjunct.

The passages back that produce a least upper bound or a limit share one pattern. The principle decides, for each ratio q, a question about the terms or members: whether some term exceeds $\eta(q)$, for LPO and excluded middle, or whether $\eta(q)$ is an upper bound, for WLPO and weak excluded middle. Those decisions make the candidate a located cut, by Lemma 12.43 or Lemma 12.44, and countable choice, applied once at pairs of ratios, turns the cut into a point; where the terms are given only as points, it also supplies regular sequences naming them. When the terms come with regular sequences and only the Cauchy condition is asked (Theorem 12.46), the cut is never turned into a point and no choice is used. The monotone subsequences of Theorem 12.47 follow a different pattern: the decisions concern peaks, and countable choice collects them into sequences. In the rows priced "none" that turn a cut into a point (the root of a strictly increasing f and the supremum), the cut is located with no omniscience principle and no choice: apart from decidable comparisons of ratios and finite searches, the only comparison used is the free one of cotransitivity. The root of a strictly increasing f, for example, is located by the signs of f at ratios, so only the passage from cut to point remains. The LLPO rows go back differently: they bisect. LLPO decides, at every dyadic ratio, a comparison that tells the bisection which half to keep, and countable choice tabulates these decisions in advance, one for every dyadic ratio, since a choice made along the path

would depend on the choices before it. The kept intervals then follow by recursion. For the maximum, the supremum of each dyadic interval comes from the supremum row, which uses countable choice at pairs of ratios.

12.9.10 Roots, maxima and expansions cost LLPO or nothing

The last seven rows of Table 12.3 concern functions on $[0,1]$ and digit expansions. Their proofs use a few facts about the order and about "within", collected first. None of them needs an omniscience principle or a choice principle.

Lemma 12.52 (Working with "within"). *Let x, y, z, u, v, w, L be points of $\mathbb{R}_\delta$ and k, m natural numbers.*

1. *If $x < z$, there are ratios $b < c$ with $x < \eta(b) < \eta(c) < z$.*
2. *If for every k some point $y \le z$ is within $1/(k+1)$ of L, then $L \le z$. If for every k some point $y \ge z$ is within $1/(k+1)$ of L, then $z \le L$.*
3. *If $x < z$, there is a K such that every point within $1/(K+1)$ of x lies below z; if $z < x$, there is a K such that every point within $1/(K+1)$ of x lies above z.*
4. *If a regular sequence s names x, then $\eta(s_n)$ and x are within $1/(n+1)$ for every n. For every x and m there are ratios $a < b$ with $\eta(a) < x < \eta(b)$ such that any two points between $\eta(a)$ and $\eta(b)$ are within $1/(m+1)$.*
5. *If x, x' are within $1/(k+1)$ and y, y' are within $1/(k+1)$, then so are $x+z$ and $x'+z$, $-x$ and $-x'$, $\max(x,y)$ and $\max(x',y')$, and $\min(x,y)$ and $\min(x',y')$. If x, y and y, z are within $1/(2k+2)$, then x, z are within $1/(k+1)$.*
6. *If $u < w$ and $v < w$, then $\max(u,v) < w$; if $w < u$ and $w < v$, then $w < \min(u,v)$. If $w < \max(u,v)$, then $w < u$ or $w < v$; if $\min(u,v) < w$, then $u < w$ or $v < w$.*

Proof. Two consequences of cotransitivity are used throughout: $u \le v < w$ gives $u < w$, and $u < v \le w$ gives $u < w$. In the first case cotransitivity applied to $v < w$ gives $v < u$ or $u < w$, and $v < u$ is excluded by $u \le v$; the second is the mirror image.

Item 1 is Lemma 12.30, used twice: first for a ratio b with $x < \eta(b) < z$, then for a ratio c with $\eta(b) < \eta(c) < z$; and $b < c$ because η reflects the order.

For the first assertion of item 2, suppose $z < L$. By item 1 there are ratios $r < q$ with $z < \eta(r) < \eta(q) < L$. Choose k with $1/(k+1) \le q - r$ and a point $y \le z$ within $1/(k+1)$ of L. Then

$$L \le y + \eta\big(1/(k+1)\big) \le z + \eta\big(1/(k+1)\big) < \eta\big(r + 1/(k+1)\big) \le \eta(q) < L,$$

which gives $L < L$, impossible. Hence $L \le z$. The second assertion is the mirror image.

For item 3, take ratios with $x < \eta(b) < \eta(c) < z$ by item 1, and K with $1/(K+1) \le c - b$. A point y within $1/(K+1)$ of x has $y \le x + \eta(1/(K+1)) < \eta(b + 1/(K+1)) \le \eta(c) < z$. The second assertion is the mirror image.

For item 4, regularity gives $|s_n - s_p| \le 1/(n+1) + 1/(p+1) \le 1/(n+1) + 2/(p+1)$ for every p; so, by Lemma 12.23 applied to the constant sequence of s_n and to s, $\eta(s_n)$ and x are within $1/(n+1)$. For the second assertion, which is an existence statement about one point, we may use one regular sequence s naming x. Take n with $n+1 \ge 4(m+1)$ and put $a = s_n - 2/(n+1)$ and $b = s_n + 2/(n+1)$. By the first assertion, $\eta(a) < \eta(s_n - 1/(n+1)) \le x \le \eta(s_n + 1/(n+1)) < \eta(b)$. Points u, v between $\eta(a)$ and $\eta(b)$ satisfy $u \le \eta(b) = \eta(a) + \eta(4/(n+1)) \le v + \eta(1/(m+1))$, and symmetrically.

Item 5 is read off the order form; write $e = 1/(k+1)$. From $x \le x' + \eta(e)$ and $y \le y' + \eta(e)$, both x and y lie below $\max(x', y') + \eta(e)$, so $\max(x, y)$ does; $\min(x, y)$ lies below $x' + \eta(e)$ and below $y' + \eta(e)$, hence below $\min(x' + \eta(e), y' + \eta(e))$, which is $\min(x', y') + \eta(e)$ because sums and minima are both computed stagewise. Translation and negation are immediate, and for the last assertion add the two order statements.

For item 6, let s, t, r name u, v, w; the maximum is named by the stagewise maximum. If $w < \max(u, v)$, a positive stage of $\max(u, v) - w$ is $\max(s_{2n+1}, t_{2n+1}) - r_{2n+1}$ for some n, which is the stage n of $u - w$ or of $v - w$; so $w < u$ or $w < v$. If $u < w$ and $v < w$, then by Lemma 12.16 the stages of $w - u$ and of $w - v$ exceed a fixed positive ratio δ from some index on. The stage n of $w - \max(u, v)$ is the smaller of the stages n of $w - u$ and $w - v$, so it exceeds $2/(n+1)$ once also $2/(n+1) < \delta$, and $\max(u, v) < w$. The two laws for the minimum are these applied to $-u$, $-v$ and $-w$, since $\min(u, v) = -\max(-u, -v)$. □

The test functions below move a given point into a fixed range without changing its sign.

Lemma 12.53 (A clamp keeps the sign)**.** *For a point a put $c(a) = \max\big(\eta(-\frac{1}{3}), \min(a, \eta(\frac{1}{3}))\big)$. Then $\eta(-\frac{1}{3}) \le c(a) \le \eta(\frac{1}{3})$; if $a > \eta(0)$ then $c(a) > \eta(0)$; and if $a < \eta(0)$ then $c(a) < \eta(0)$.*

Proof. The maximum lies above its first argument, and both arguments lie below $\eta(\frac{1}{3})$, so the maximum does. If $a > \eta(0)$, then also $\eta(\frac{1}{3}) > \eta(0)$, so $\min(a, \eta(\frac{1}{3})) > \eta(0)$ by Lemma 12.52, item 6, and $c(a)$, which lies above this minimum, is $> \eta(0)$. If $a < \eta(0)$, then $\min(a, \eta(\frac{1}{3})) \le a < \eta(0)$ and $\eta(-\frac{1}{3}) < \eta(0)$, so $c(a) < \eta(0)$ by item 6. □

Theorem 12.54 (The intermediate value theorem costs LLPO)**.** *Consider the assertion that every uniformly continuous f on $[0, 1]$ with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$ has a root in $[0, 1]$.*

1. *The assertion implies LLPO. The proof uses no choice principle.*
2. *Assuming AC_ω, LLPO implies the assertion. Countable choice is used once, to tabulate one bit for every dyadic ratio.*

Proof. Write $\frac{1}{3}$ and $\frac{2}{3}$ for $\eta(\frac{1}{3})$ and $\eta(\frac{2}{3})$, and let

$$g(x) = \max\big(\min(x - \tfrac{1}{3}, \eta(0)),\ x - \tfrac{2}{3}\big).$$

Then $g(\eta(0)) = -\frac{1}{3}$ and $g(\eta(1)) = \frac{1}{3}$. If $x \le \frac{2}{3}$, both arguments of the maximum are at most $\eta(0)$, so $g(x) \le \eta(0)$; if $x \ge \frac{1}{3}$, the first argument is $\eta(0)$, so $g(x) \ge \eta(0)$. By Lemma 12.52, item 5, points within $1/(k+1)$ have values of g within $1/(k+1)$.

For the first part, let a be a point, let $c = c(a)$ be its clamp (Lemma 12.53), and put $f(x) = g(x)+c$. Then $f(\eta(0)) = c-\frac{1}{3} \le \eta(0)$ and $f(\eta(1)) = \frac{1}{3}+c \ge \eta(0)$, and f is uniformly continuous on $[0,1]$: for each k take $j = k$. By the assertion f has a root x, so $c = -g(x)$. Since $\frac{1}{3} < \frac{2}{3}$, cotransitivity gives $\frac{1}{3} < x$ or $x < \frac{2}{3}$. In the first case $g(x) \ge \eta(0)$, so $c \le \eta(0)$; then $a > \eta(0)$ is impossible, because it would give $c > \eta(0)$, and so $a \le \eta(0)$. In the second case $g(x) \le \eta(0)$, so $c \ge \eta(0)$, and in the same way $a \ge \eta(0)$. Every point therefore satisfies $a \ge \eta(0)$ or $a \le \eta(0)$, and this is LLPO by Corollary 12.18. The function f is given outright, and the root was read with one use of cotransitivity, so no choice principle enters.

For the second part, assume LLPO and AC_ω, and let f satisfy the hypotheses. By Corollary 12.18 every point is $\ge \eta(0)$ or $\le \eta(0)$. So for every pair (n, j) of natural numbers there is a bit b such that $b = 1$ gives $f(\eta(j/2^n)) \le \eta(0)$ and $b = 0$ gives $f(\eta(j/2^n)) \ge \eta(0)$. Countable choice, applied to the pairs (n, j) listed as natural numbers, supplies one such bit $B(n, j)$ for every pair. Define natural numbers a_n by recursion, with no further choice: $a_0 = 0$, and $a_{n+1} = 2a_n + 1$ if $B(n+1, 2a_n+1) = 1$, otherwise $a_{n+1} = 2a_n$. The ratio $(2a_n+1)/2^{n+1}$ is the midpoint of $a_n/2^n$ and $(a_n+1)/2^n$, and induction on n gives

$$a_n + 1 \le 2^n, \qquad f\big(\eta(a_n/2^n)\big) \le \eta(0) \le f\big(\eta((a_n+1)/2^n)\big) \ :$$

if $B(n+1, 2a_n+1) = 1$, the value at the midpoint is at most $\eta(0)$ and the midpoint becomes the new left end, and otherwise it becomes the new right end. Put $l_n = a_n/2^n$ and $r_n = (a_n+1)/2^n$. The intervals are nested, so $l_m \le l_n < r_n \le r_m$ for $m \le n$, and $r_n - l_n = 2^{-n}$. Hence $|l_m - l_n| \le 2^{-\min(m,n)} \le 1/(\min(m,n)+1) \le 1/(m+1) + 1/(n+1)$: the ratios l_n form a regular sequence. Let L be its point. By Lemma 12.52, item 4, $\eta(l_n)$ is within $1/(n+1)$ of L. The points $\eta(r_{2n+1})$ and $\eta(l_{2n+1})$ are within $2^{-(2n+1)} \le 1/(2n+2)$, and $\eta(l_{2n+1})$ is within $1/(2n+2)$ of L, so $\eta(r_{2n+1})$ is within $1/(n+1)$ of L (item 5).

Every $\eta(l_n)$ lies in $[0,1]$, so item 2 puts L in $[0,1]$. Fix k and take j as in uniform continuity at k. The points $\eta(l_j)$ and L of $[0,1]$ are within $1/(j+1)$, so $f(\eta(l_j))$, which is at most $\eta(0)$, is within $1/(k+1)$ of $f(L)$. Since k was arbitrary, item 2 gives $f(L) \le \eta(0)$. In the same way $f(\eta(r_{2j+1})) \ge \eta(0)$ is within $1/(k+1)$ of $f(L)$, and so $f(L) \ge \eta(0)$. Hence $f(L) = \eta(0)$, by Proposition 12.19, item 2. □

Theorem 12.55 (An approximate root costs nothing)**.** *Let f be uniformly continuous on $[0,1]$ with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$. For every k some point x of $[0,1]$ has $f(x)$ within $1/(k+1)$ of $\eta(0)$. No omniscience principle and no choice principle is used.*

Proof. Fix k, and take j as in uniform continuity at the tolerance $1/(2k+2)$. Let $x_i = \eta(i/(j+1))$ for $0 \le i \le j+1$; neighbouring points x_{i-1} and x_i are within $1/(j+1)$. Since $-1/(k+1) < -1/(2k+2)$, cotransitivity gives, for each i,

$$(\mathrm{A}_i) \quad f(x_i) > \eta\big(-1/(k+1)\big) \qquad \text{or} \qquad (\mathrm{B}_i) \quad f(x_i) < \eta\big(-1/(2k+2)\big).$$

Going through $i = 0, 1, \dots, j+1$ in turn, induction on the number of steps gives either an $i \le j+1$ with (A_i) such that every earlier index satisfies (B), or (B_i) for every $i \le j+1$. The second alternative is impossible: (B_{j+1}) says $f(\eta(1)) < \eta(-1/(2k+2)) < \eta(0)$, against $\eta(0) \le f(\eta(1))$. So take the first i with (A_i), and put $x = x_i$. Then $f(x) \ge \eta(-1/(k+1))$. Moreover $f(x) \le \eta(0)$: for $i = 0$ this is the hypothesis $f(\eta(0)) \le \eta(0)$; for $i > 0$ the earlier index satisfies (B_{i-1}), and

$f(x_i)$, being within $1/(2k+2)$ of $f(x_{i-1})$, satisfies $f(x_i) \le f(x_{i-1}) + \eta(1/(2k+2)) < \eta(0)$. A point between $\eta(-1/(k+1))$ and $\eta(0)$ is within $1/(k+1)$ of $\eta(0)$. The number j was used for this one k, inside the proof, and every search was finite. □

Theorem 12.56 (The root of a strictly increasing function)**.** *Let f be uniformly continuous and strictly increasing on $[0,1]$, with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$. Let $\mathscr{L}$ be the set of ratios q such that $\eta(q) < \eta(0)$, or $\eta(q)$ lies in $[0,1]$ and $f(\eta(q)) < \eta(0)$; let $\mathscr{U}$ be the set of ratios r such that $\eta(1) < \eta(r)$, or $\eta(r)$ lies in $[0,1]$ and $f(\eta(r)) > \eta(0)$.*

1. *$(\mathscr{L}, \mathscr{U})$ is a located cut.*
2. *A point whose cut is $(\mathscr{L}, \mathscr{U})$ is a root of f in $[0,1]$, and f has at most one root in $[0,1]$.*
3. *Assuming countable choice at pairs of ratios, f has a root in $[0,1]$.*

The first two parts use no omniscience principle and no choice principle; the third uses countable choice once, to make the cut a point. So the assertion that every such f has a root in $[0,1]$ needs no omniscience principle, and it is proved from countable choice.

Proof. Comparisons between ratios are decided in integer arithmetic; besides cotransitivity they are the only case distinctions below.

The cut. The ratio -1 lies in $\mathscr{L}$ and 2 lies in $\mathscr{U}$. No ratio lies in both: each of the four combinations of clauses contradicts $\eta(0) < \eta(1)$, the definition of $[0,1]$, or $f(\eta(q)) < \eta(0) < f(\eta(q))$. Let $q < q'$ with $q' \in \mathscr{L}$. If $\eta(q') < \eta(0)$, then $\eta(q) < \eta(0)$. Otherwise $\eta(q')$ lies in $[0,1]$ with $f(\eta(q')) < \eta(0)$; then either $q < 0$, or $\eta(q)$ lies in $[0,1]$ and $f(\eta(q)) < f(\eta(q')) < \eta(0)$. In each case $q \in \mathscr{L}$, and the upper set is closed upward in the same way. To locate the cut, let $q < r$. If $q < 0$, then $q \in \mathscr{L}$; if $1 < r$, then $r \in \mathscr{U}$. Otherwise $\eta(q)$ and $\eta(r)$ lie in $[0,1]$, so $f(\eta(q)) < f(\eta(r))$, and cotransitivity at $\eta(0)$ gives $f(\eta(q)) < \eta(0)$, that is $q \in \mathscr{L}$, or $\eta(0) < f(\eta(r))$, that is $r \in \mathscr{U}$.

The lower set has no greatest member. If $\eta(q) < \eta(0)$, the ratio $q/2$ is a larger member. If $\eta(q)$ lies in $[0,1]$ and $f(\eta(q)) < \eta(0)$, take K as in Lemma 12.52, item 3, so that every point within $1/(K+1)$ of $f(\eta(q))$ is below $\eta(0)$; take j as in uniform continuity at K, and put $b = q + 1/(j+1)$. If $1 < b$, then $\eta(1)$ lies between $\eta(q)$ and $\eta(b)$, so it is within $1/(j+1)$ of $\eta(q)$, and $f(\eta(1)) < \eta(0)$, against the hypothesis. So $b \le 1$, $\eta(b)$ lies in $[0,1]$ within $1/(j+1)$ of $\eta(q)$, and $f(\eta(b)) < \eta(0)$: the ratio $b > q$ lies in $\mathscr{L}$. The mirror argument, with $f(\eta(0)) \le \eta(0)$, shows that $\mathscr{U}$ has no least member.

The root. Let x have the cut $(\mathscr{L}, \mathscr{U})$. If $x < \eta(0)$, a ratio r with $x < \eta(r) < \eta(0)$ would lie in $\mathscr{U}$, which contains no ratio below 0; so $\eta(0) \le x$, and in the same way $x \le \eta(1)$. Suppose $f(x) > \eta(0)$. Take K such that every point within $1/(K+1)$ of $f(x)$ is above $\eta(0)$, take j as in uniform continuity at K, and take ratios $a < b$ with $\eta(a) < x < \eta(b)$ such that any two points between $\eta(a)$ and $\eta(b)$ are within $1/(j+1)$ (Lemma 12.52, items 3 and 4). Then $a \in \mathscr{L}$. If $\eta(a) < \eta(0)$, then $\eta(0)$ lies between $\eta(a)$ and $\eta(b)$, so $f(\eta(0)) > \eta(0)$, against the hypothesis; otherwise $\eta(a)$ lies in $[0,1]$ and $f(\eta(a)) < \eta(0)$, against $f(\eta(a)) > \eta(0)$. So $f(x) \le \eta(0)$, and the mirror argument with $b \in \mathscr{U}$ gives $f(x) \ge \eta(0)$. Hence $f(x) = \eta(0)$. If x and y are roots in $[0,1]$ and $x < y$, then $\eta(0) = f(x) < f(y) = \eta(0)$; so neither lies below the other, and they are equal.

The point. With countable choice at pairs of ratios every located cut is the cut of a point (Theorem 12.33). Applied to $(\mathscr{L}, \mathscr{U})$, this gives a point, which by the second part is a root in $[0,1]$. □

A supremum is reached through an approximate maximum, which costs nothing.

Lemma 12.57 (An approximate maximum costs nothing)**.** *Let f be uniformly continuous on $[0,1]$. For every k some point x of $[0,1]$ satisfies $f(y) \le f(x) + \eta(1/(k+1))$ for every y in $[0,1]$. No omniscience principle and no choice principle is used.*

Proof. Fix k, take j as in uniform continuity at the tolerance $1/(2k+2)$, put $N = j+1$, and let $g_i = \eta(i/2^N)$ for $0 \le i \le 2^N$. Let M be the maximum of the finitely many values $f(g_0), \dots, f(g_{2^N})$. Since $M - \eta(1/(2k+2)) < M$, Lemma 12.52, item 6, applied along the finite maximum, gives an i with $M - \eta(1/(2k+2)) < f(g_i)$; so $M \le f(g_i) + \eta(1/(2k+2))$. Put $x = g_i$.

Let y be a point of $[0,1]$. Go through $i = 0, \dots, 2^N - 1$, using cotransitivity at $g_i < g_{i+1}$: $g_i < y$ or $y < g_{i+1}$. Either a first index has $y < g_{i+1}$, or $g_i < y$ for every $i < 2^N$. In every case there is a p with $p+1 \le 2^N$ such that y lies between g_p and $\eta((p+2)/2^N)$. These bounds are $2/2^N \le 1/(j+1)$ apart, so y and the grid point g_{p+1} are within $1/(j+1)$, and

$$f(y) \le f(g_{p+1}) + \eta\big(1/(2k+2)\big) \le M + \eta\big(1/(2k+2)\big) \le f(x) + \eta\big(1/(k+1)\big).$$

The searches are finite, and the one j is used inside the proof. □

Theorem 12.58 (A supremum needs only the passage from cut to point)**.** *Let f be uniformly continuous on $[0,1]$. Let $\mathscr{L}$ be the set of ratios q with $\eta(q) < f(y)$ for some y in $[0,1]$, and $\mathscr{U}$ the set of ratios r for which some ratio $r' < r$ has $f(y) \le \eta(r')$ for every y in $[0,1]$.*

1. *$(\mathscr{L}, \mathscr{U})$ is a located cut, and every point with this cut is a supremum of f. No omniscience principle and no choice principle is used.*
2. *Assuming countable choice at pairs of ratios, f has a supremum; the choice is used once, to make the cut a point.*

So the assertion that every uniformly continuous f on $[0,1]$ has a supremum needs no omniscience principle, and it is proved from countable choice.

Proof. A ratio below $f(\eta(0))$ lies in $\mathscr{L}$. By Lemma 12.57 at $k = 0$ some x has $f(y) \le f(x) + \eta(1)$ for all y in $[0,1]$; a ratio r' above $f(x) + \eta(1)$ (Proposition 12.19, item 4) gives $r' + 1 \in \mathscr{U}$. If $\eta(q) < f(y)$, every smaller ratio lies in $\mathscr{L}$, and a ratio q' with $\eta(q) < \eta(q') < f(y)$ is a larger member (Lemma 12.52, item 1). If $r' < r$ witnesses $r \in \mathscr{U}$, every larger ratio lies in $\mathscr{U}$ with the same witness, and every ratio strictly between r' and r is a smaller member. No ratio lies in both sets: $\eta(q) < f(y) \le \eta(r') < \eta(q)$ is impossible.

To locate the cut, let $q < r$, and choose k with $5/(k+1) < r - q$. Take x as in Lemma 12.57 at k. Since $q < q + 2/(k+1)$, cotransitivity gives $\eta(q) < f(x)$, so that $q \in \mathscr{L}$, or $f(x) < \eta(q + 2/(k+1))$. In the second case every y in $[0,1]$ has

$$f(y) \le f(x) + \eta\big(1/(k+1)\big) < \eta\big(q + 3/(k+1)\big) \le \eta\big(r - 2/(k+1)\big),$$

so $r' = r - 2/(k+1) < r$ witnesses $r \in \mathcal{U}$. The one k is used inside the proof of the disjunction.

Let s have the cut $(\mathcal{L}, \mathcal{U})$. If $f(y) > s$ for some y in $[0,1]$, a ratio q with $s < \eta(q) < f(y)$ would lie in $\mathcal{L}$ and in the upper set of the cut of s, which is $\mathcal{U}$; so s is an upper bound of the values. Given k, take x as in Lemma 12.57. Then $f(x) \le s$, and $s \le f(x) + \eta(1/(k+1))$: otherwise a ratio q with $f(x) + \eta(1/(k+1)) < \eta(q) < s$ lies in the lower set of the cut of s, which is $\mathcal{L}$, so $\eta(q) < f(y)$ for some y in $[0,1]$, while $f(y) \le f(x) + \eta(1/(k+1)) < \eta(q)$. So $f(x)$ is within $1/(k+1)$ of s, and s is a supremum. With countable choice at pairs of ratios every located cut is the cut of a point (Theorem 12.33), which gives the second part. □

The attained maximum is found by bisection on the suprema of dyadic intervals. For $j+1 \le 2^n$ write $I_{n,j}$ for the set of points between $\eta(j/2^n)$ and $\eta((j+1)/2^n)$; a *supremum of f on $I_{n,j}$* is an upper bound of the values of f on $I_{n,j}$ such that, for every k, some value at a point of $I_{n,j}$ lies within $1/(k+1)$ of it. The interval $I_{0,0}$ is $[0,1]$.

Lemma 12.59 (Suprema on dyadic intervals)**.** *Let f be uniformly continuous on $[0,1]$, let $j+1 \le 2^n$, and put*

$$\zeta(y) = \max\bigl(\eta(j/2^n),\ \min(\eta((j+1)/2^n),\ y)\bigr).$$

Then $f \circ \zeta$ is uniformly continuous on $[0,1]$, and a supremum of $f \circ \zeta$ is a supremum of f on $I_{n,j}$. Two suprema of f on $I_{n,j}$ are equal. Consequently, assuming countable choice at pairs of ratios, f has exactly one supremum on every $I_{n,j}$. No omniscience principle is used, and only the last sentence uses a choice principle.

Proof. Both arguments of the maximum lie below $\eta((j+1)/2^n)$, so $\zeta(y)$ lies in $I_{n,j}$ for every y; and if y lies in $I_{n,j}$, then $\min(\eta((j+1)/2^n), y) = y$ and $\zeta(y) = y$, by the lattice laws of Proposition 12.19, item 5. By Lemma 12.52, item 5, points within $1/(k+1)$ have images under ζ within $1/(k+1)$. Since $0 \le j/2^n$ and $(j+1)/2^n \le 1$, the interval $I_{n,j}$ lies in $[0,1]$, so $f \circ \zeta$ is uniformly continuous on $[0,1]$, with the same modulus as f: for each k, the number that uniform continuity of f supplies at k serves for $f \circ \zeta$. The values of $f \circ \zeta$ on $[0,1]$ are values of f on $I_{n,j}$, and every value $f(y)$ with y in $I_{n,j}$ is the value of $f \circ \zeta$ at the point y of $[0,1]$. So the upper bounds of the two sets of values are the same, and so are the values that approach a given point; a supremum of $f \circ \zeta$ is therefore a supremum of f on $I_{n,j}$.

If s and s' are suprema on $I_{n,j}$, then for every k some value, at most s', lies within $1/(k+1)$ of s; so $s \le s'$ by Lemma 12.52, item 2, and symmetrically $s' \le s$. The last sentence is Theorem 12.58 applied to $f \circ \zeta$. □

Theorem 12.60 (An attained maximum costs LLPO)**.** *Consider the assertion that every uniformly continuous f on $[0,1]$ attains a maximum.*

1. *The assertion implies LLPO. The proof uses no choice principle.*
2. *Assuming AC_ω, LLPO implies the assertion. Countable choice is used to tabulate one bit for every pair of adjacent dyadic intervals, and, through Lemma 12.59, at pairs of ratios for the suprema on dyadic intervals.*

Proof. For the first part, let a be a point with clamp $c = c(a)$ (Lemma 12.53), and let (with $\frac{1}{3}$ and $\frac{2}{3}$ again standing for $\eta(\frac{1}{3})$ and $\eta(\frac{2}{3})$)

$$h(x) = \max\big(\min(c,\ x - \tfrac{2}{3}),\ \min(-c,\ \tfrac{1}{3} - x)\big).$$

By Lemma 12.52, item 5, points within $1/(k+1)$ have values within $1/(k+1)$, so h is uniformly continuous on $[0,1]$. At $\eta(1)$ the first argument is $\min(c, \frac{1}{3}) = c$, so $h(\eta(1)) \geq c$; at $\eta(0)$ the second is $\min(-c, \frac{1}{3}) = -c$, so $h(\eta(0)) \geq -c$. If $c > \eta(0)$ and $x \leq \frac{2}{3}$, both arguments are at most $\eta(0)$, so $h(x) \leq \eta(0)$; the same holds if $c < \eta(0)$ and $x \geq \frac{1}{3}$. Let x be a maximum point of h. Cotransitivity gives $\frac{1}{3} < x$ or $x < \frac{2}{3}$. In the first case $a < \eta(0)$ is impossible: it would give $c < \eta(0)$ and then $h(\eta(0)) \geq -c > \eta(0) \geq h(x)$, against the maximum. So $a \geq \eta(0)$. In the second case $a > \eta(0)$ would give $h(\eta(1)) \geq c > \eta(0) \geq h(x)$, so $a \leq \eta(0)$. By Corollary 12.18 this is LLPO, and no choice entered.

For the second part, assume LLPO and AC_ω, and let f be uniformly continuous on $[0,1]$. Countable choice at pairs of ratios is a case of AC_ω, so by Lemma 12.59 f has exactly one supremum on each $I_{n,j}$. By Corollary 12.18, LLPO gives $v - u \geq \eta(0)$ or $v - u \leq \eta(0)$ for any two points u and v, with no choice principle; adding u (Lemma 12.40(b)), this is $u \leq v$ or $v \leq u$. So for every N and every q with $1 \leq q < 2^N$ there is a bit b with $s^- \leq s^+$ if $b = 1$ and $s^+ \leq s^-$ if $b = 0$, where s^- and s^+ are the suprema on $I_{N,q-1}$ and $I_{N,q}$; by uniqueness the bit does not depend on how the suprema are found, and at the other pairs any bit will do. Countable choice, applied to the pairs (N, q) listed as natural numbers, supplies such a bit $B(N, q)$ for all of them at once. A choice made only along the path of the bisection would depend on the earlier choices; listing every dyadic point in advance avoids that.

Define $a_0 = 0$, and $a_{n+1} = 2a_n + 1$ if $B(n+1, 2a_n + 1) = 1$, otherwise $a_{n+1} = 2a_n$. Let s be the supremum of f on $[0,1] = I_{0,0}$. We show by induction that s is the supremum on I_{n,a_n}. The two halves of I_{n,a_n} are $I^- = I_{n+1,2a_n}$ and $I^+ = I_{n+1,2a_n+1}$, meeting at $m = \eta((2a_n+1)/2^{n+1})$, with suprema s^- and s^+. Suppose $B(n+1, 2a_n+1) = 1$, so $s^- \leq s^+$. Every point y of I_{n,a_n} has $y \leq m$ or $m \leq y$, by LLPO as above, so it lies in I^- or in I^+, and $f(y) \leq s^+$ in both cases; values on I^+ approach s^+. So s^+ is a supremum on I_{n,a_n}, hence equal to s, and s is the supremum on $I^+ = I_{n+1,a_{n+1}}$. The case $B(n+1, 2a_n+1) = 0$ is symmetric.

As in the proof of Theorem 12.54, the ratios $a_n/2^n$ form a regular sequence; let L be its point, which lies in $[0,1]$. Fix k, take J as in uniform continuity at the tolerance $1/(2k+2)$, and let $n = 2J+2$. Some y in I_{n,a_n} has $f(y)$ within $1/(2k+2)$ of s. The width of I_{n,a_n} is $2^{-n} \leq 1/(2J+2)$, so y and $\eta(a_n/2^n)$ are within $1/(2J+2)$, and $\eta(a_n/2^n)$ is within $1/(n+1) \leq 1/(2J+2)$ of L; so y and L are within $1/(J+1)$, and $f(y)$ and $f(L)$ are within $1/(2k+2)$. Hence $f(L)$ is within $1/(k+1)$ of s; the number J was used for this one k, inside the proof. As k was arbitrary, $f(L) = s$ by Corollary 12.24, and $f(y) \leq s = f(L)$ for every y in $[0,1]$. Countable choice was used for the table of bits and, through Lemma 12.59, for the suprema of the dyadic intervals. □

Theorem 12.61 (Binary expansions cost LLPO)**.** *If every point of* $[0,1]$ *has a binary expansion, then LLPO holds, and the proof uses no choice principle. Conversely, assuming* AC_ω*, LLPO gives every point of* $[0,1]$ *a binary expansion; countable choice is used once, to tabulate one bit for every dyadic ratio.*

Proof. Suppose every point of $[0,1]$ has a binary expansion. By Corollary 12.18 it suffices to show that every point x satisfies $x \geq \eta(0)$ or $x \leq \eta(0)$; the passage from this dichotomy to LLPO uses no choice principle. Fix x, let $a = c(x)$ be its clamp (Lemma 12.53), and put $p = a + \eta(\frac{1}{2})$. Then $\eta(\frac{1}{6}) \leq p \leq \eta(\frac{5}{6})$, so p lies in $[0,1]$. Let (e_i) be a binary expansion of p. At $n = 1$ its bounds read $\eta(e_0/2) \leq p \leq \eta(e_0/2 + 1/2)$. If $e_0 = 0$, then $p \leq \eta(\frac{1}{2})$; subtracting $\eta(\frac{1}{2})$ gives $a \leq \eta(0)$, so $x > \eta(0)$ is impossible, and $x \leq \eta(0)$. If $e_0 = 1$, then $\eta(\frac{1}{2}) \leq p$, so $\eta(0) \leq a$, $x < \eta(0)$ is impossible, and $x \geq \eta(0)$. Only the first digit of one expansion of one point was used, inside the proof of a disjunction, so no choice principle enters.

Conversely, assume AC_ω and LLPO, and let x lie in $[0,1]$. By Corollary 12.18, applied to $x - \eta(j/2^n)$, and Lemma 12.40(b), LLPO gives $\eta(j/2^n) \leq x$ or $x \leq \eta(j/2^n)$ for every n and j, with no choice principle. So for every n and j there is a bit b such that $b = 1$ gives $\eta(j/2^n) \leq x$ and $b = 0$ gives $x \leq \eta(j/2^n)$. Countable choice, applied to the pairs (n, j) listed as natural numbers, supplies a table $B(n, j)$ of such bits, one for every dyadic ratio $j/2^n$. From here on nothing is selected. Put $a_0 = 0$, and let

$$e_n = B(n+1, 2a_n + 1), \qquad a_{n+1} = 2a_n + e_n,$$

so that e_n is the decision at the midpoint $(2a_n + 1)/2^{n+1}$ of $a_n/2^n$ and $(a_n + 1)/2^n$. By induction $a_n = \sum_{i<n} e_i 2^{n-1-i}$, that is, $a_n/2^n = c_n$. We show by induction that $\eta(a_n/2^n) \leq x \leq \eta((a_n+1)/2^n)$. At $n = 0$ this says that x lies in $[0,1]$. If $e_n = 1$, the midpoint lies at or below x; it is the new lower end $a_{n+1}/2^{n+1}$, and the new upper end $(2a_n + 2)/2^{n+1} = (a_n + 1)/2^n$ is the old one. If $e_n = 0$, then x lies at or below the midpoint, which is the new upper end $(2a_n + 1)/2^{n+1}$, and the new lower end $2a_n/2^{n+1}$ is the old one. So (e_n) is a binary expansion of x. □

Countable choice is used here to tabulate, in advance, a decision at every dyadic ratio; the bisection then reads its steps from the table. Choosing the decisions one step at a time along the bisection, where each midpoint depends on the decisions before it, would be a dependent choice instead. Allowing a digit -1 removes the decision altogether.

Proposition 12.62 (Signed digits cost nothing)**.** *Every point of* $[-1,1]$ *has a signed-digit expansion. The proof uses no omniscience principle and no choice principle: each digit is read off one stage of one regular sequence naming the point, together with the digits before it.*

Proof. Let $\eta(-1) \leq x \leq \eta(1)$. The assertion is an existence statement about the single point x, so we may use one regular sequence s naming it; nothing is selected. For each n let $r_n = s_{2m+1}$ with $m = 2^{n+3} - 1$. By regularity, $|s_i - r_n| \leq 1/(i+1) + 1/(2m+2) \leq 2^{-(n+3)} + 2/(i+1)$ for every i, so, by Lemma 12.23 with $1/(k+1) = 2^{-(n+3)}$, x and $\eta(r_n)$ are within $2^{-(n+3)}$. Write $h_n = 2^{-n}$, so that $2^{-(n+3)} = h_n/8$ and

$$\eta(r_n - h_n/8) \leq x \leq \eta(r_n + h_n/8).$$

Define integers t_n and digits d_n by $t_0 = 0$, $t_{n+1} = 2t_n + d_n$, where

$$d_n = \begin{cases} -1, & \text{if } r_n \le (t_n - \tfrac{1}{4})h_n, \\ 1, & \text{if not, and } r_n \ge (t_n + \tfrac{1}{4})h_n, \\ 0, & \text{otherwise.} \end{cases}$$

Each case is a comparison of two ratios, decided by integer arithmetic, so the recursion defines the digits outright. By induction $t_n = \sum_{i<n} d_i 2^{n-1-i}$, so $t_n h_n = c_n$. It remains to show

$$\eta\big((t_n - 1)h_n\big) \le x \le \eta\big((t_n + 1)h_n\big)$$

for every n, which is the signed-digit condition. At $n = 0$ it says that x lies in $[-1, 1]$. Suppose it holds at n, and write $t = t_n$, $h = h_n$. Since $h_{n+1} = h/2$, the condition at $n + 1$ reads $\eta\big((t + (d_n - 1)/2)h\big) \le x \le \eta\big((t + (d_n + 1)/2)h\big)$.

If $d_n = -1$, its lower bound $(t - 1)h$ is the hypothesis, and $x \le \eta(r_n + h/8) \le \eta((t - \tfrac{1}{8})h) \le \eta(th)$ is its upper bound.

If $d_n = 1$, its upper bound $(t + 1)h$ is the hypothesis, and $\eta(th) \le \eta((t + \tfrac{1}{8})h) \le \eta(r_n - h/8) \le x$ is its lower bound.

If $d_n = 0$, then $(t - \tfrac{1}{4})h < r_n < (t + \tfrac{1}{4})h$, so $\eta((t - \tfrac{1}{2})h) \le \eta(r_n - h/8) \le x \le \eta(r_n + h/8) \le \eta((t + \tfrac{1}{2})h)$, which are its two bounds.

So (d_n) is a signed-digit expansion of x. □

The three candidate intervals at each step overlap: the middle one, between $(t - \tfrac{1}{2})h$ and $(t + \tfrac{1}{2})h$, contains a neighbourhood of the point th where a binary digit would have to decide. So an approximation within $h/8$ always shows a safe digit, and no comparison of x itself with a dyadic ratio is ever decided.

12.9.11 Without unique choice, excluded middle does not replace countable choice

Theorem 12.63 (Without unique choice, excluded middle does not replace countable choice)**.** *Consider arithmetic with variables for sequences, induction for every formula, excluded middle for every formula, and countable choice for the relations whose witnesses a search can find: a decidable condition, or a decidable condition under one existential quantifier. Write each set of ratios, sequence of points and function on the points as a formula. Then none of the following is provable in that theory: every Cauchy sequence of points converges; every located cut is the cut of a point; every uniformly continuous, strictly increasing f on $[0, 1]$ with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$ has a root; every uniformly continuous f on $[0, 1]$ has a supremum. In the mathematics of this chapter, each of the four follows from countable choice at pairs of ratios. The theory does not contain the principle of unique choice; since excluded middle and unique choice together give countable choice for numbers, one of the two must be added. The proof reasons in a classical metatheory.*

Conditions and scope.

Base and premises

Arithmetic with variables for sequences, induction for every formula, excluded middle for every formula, and countable choice for numbers only at matrices that are decidable or a decidable condition under one existential quantifier; no unique choice. Sets of ratios, sequences of points and functions on the points are formulas. The metatheory is classical.

Conclusion

None of the four assertions is provable: Cauchy sequences of points converge; located cuts are cuts of points; a uniformly continuous, strictly increasing f on $[0,1]$ with $f(\eta(0)) \leq \eta(0) \leq f(\eta(1))$ has a root; a uniformly continuous f on $[0,1]$ has a supremum.

Proof. We describe the theory and a model of it in which the sequences are the computable ones. In that model there is a point that no computable sequence names, and each of the four assertions fails at data built from it. The model is described in ordinary classical mathematics.

The theory. Its language, logical rules and arithmetic axioms are those of the theory of Theorem 12.22, with induction for every formula. In place of the two choice schemas, its further axioms are excluded middle, $A \vee \neg A$ for every formula A, and countable choice for numbers, $\forall x \exists y\, A(x,y) \to \exists \alpha \forall x\, A(x, \alpha(x))$, for the formulas A that are quantifier-free, that is built from equations and $\bot$ by $\wedge$, $\vee$ and $\to$, or have the form $\exists z\, B$ with B quantifier-free. A quantifier-free formula is a condition decided by a finite computation from its number variables and finitely many values of its sequence variables, so these are the relations whose witnesses a search can find. Everything below applies to every theory with fewer axioms as well, for instance to the theory with no choice at all.

The four assertions as formulas. A sequence variable α codes the sequence of ratios whose stage n is $(\alpha(3n) - \alpha(3n+1))/(\alpha(3n+2)+1)$, and every sequence of ratios has a code. Regularity, naming the same point, the order relations $<$ and $\leq$ of points, being within $1/(k+1)$, and membership of a ratio in the lower or the upper set of the cut of a point are then formulas: each is the integer condition of the text with its denominators cleared, a ratio being three number variables. A set of ratios is a formula with a ratio variable. A sequence of points is a formula $P(n, \beta)$ such that for every n the β with $P(n,\beta)$ are exactly the regular sequences naming one point, and there is one. A function on the points is a formula $F(\beta, \beta')$ that relates every regular β to some regular β', to only one point, and to the same point for sequences naming the same point. These formulas may have parameters. Each of the four assertions thus becomes a schema with one instance for each formula of the relevant kind, closed by universal quantifiers over its parameters. To show that an assertion is not provable we exhibit one instance, with a single sequence parameter, that is not a theorem.

The model. Numbers range over the natural numbers and sequences over the total computable functions; truth is classical. Every rule of the theory preserves truth. Instantiating $\forall \alpha$ and introducing $\exists \alpha$ use sequence variables only, whose values lie in the model; induction holds over the natural numbers; and excluded middle holds because truth in the model is classical. If $\forall x \exists y\, A(x,y)$ is true with A quantifier-free and its sequence parameters computable, then $x \mapsto$ the least y with $A(x,y)$ is computable, since each candidate is tested by a finite computation; for $\exists z\, B$ the search runs over pairs (y,z) and keeps y. So the restricted choice schema is true as well, and every theorem of the theory is true in the model under every assignment of

computable functions to its sequence variables. Full countable choice is false there: with $\alpha(\langle x, n\rangle)$ the bit recording whether program x halts on input 0 within n steps, every x has a y with $y = 0 \wedge \forall n\, \alpha(\langle x, n\rangle) = 0$ or $y = 1 \wedge \exists n\, \alpha(\langle x, n\rangle) = 1$, but a computable choice of such y would decide halting. So the theory does not prove countable choice.

A point of the model is named by a computable regular sequence. Reasoning classically, every regular sequence s has a limit $\lim s$, a real number with $|s_n - \lim s| \le 1/(n+1)$ for every n. Two regular sequences name the same point exactly when their limits agree, and $<$, $\le$, being within $1/(k+1)$ and membership of a ratio q in the cut of a point are the familiar relations between the limits and q (Lemma F.7).

A point with no computable name. Let $b(e) = 1$ if program e halts on input 0 and $b(e) = 0$ otherwise, and let

$$c = \sum_{e \ge 0} b(e)\, 4^{-(e+1)}, \qquad x_n = \sum_{e < n} b(e)\, 4^{-(e+1)}.$$

The tail beyond n is at most $\sum_{e \ge n} 4^{-(e+1)} = 4^{-n}/3$, so $x_n \le c \le x_n + 4^{-n}/3$. No computable regular sequence s has limit c. Suppose one did. Fix e, put $n = 6 \cdot 4^{e+1} - 1$ and $D_e = 4^{e+1} x_{e+1} = \sum_{i \le e} b(i)\, 4^{e-i}$, an integer whose remainder on division by 4 is $b(e)$. From $|s_n - c| \le 1/(n+1)$ and $D_e \le 4^{e+1} c \le D_e + 1/3$ we get

$$D_e \le 4^{e+1} s_n + \frac{1}{6} \le D_e + \frac{2}{3},$$

so D_e is the integer part of the ratio $4^{e+1} s_n + 1/6$. A program would compute it from e, and its remainder modulo 4 would decide whether program e halts [21].

Approximations from below. Let $b_s(e) = 1$ if program e halts on input 0 within s steps and $b_s(e) = 0$ otherwise, and let $c_s = \sum_{e < s} b_s(e)\, 4^{-(e+1)}$. The ratio c_s is computed from s, and $c_s \le c$ because $b_s \le b$. The c_s approach c: given k, take e_0 with $4^{-e_0}/3 \le 1/(k+1)$; the finitely many programs $e < e_0$ that halt all do so within some number S of steps, and for $s \ge \max(S, e_0)$ we get $c_s \ge x_{e_0} \ge c - 1/(k+1)$. Let γ be a computable code of the sequence of ratios $s \mapsto c_s$; it is the parameter of the instances of the first two assertions below.

Located cuts. Let $\mathscr{L}(q)$ say that $q < c_s$ for some s, and $\mathscr{U}(r)$ that some ratio $r' < r$ satisfies $c_s \le r'$ for every s. In the model, with γ as above, $\mathscr{L}$ is the set of ratios below c and $\mathscr{U}$ the set of ratios above c. Indeed, a ratio $q < c$ lies below c_s once c_s is close enough to c, and $q < c_s$ gives $q < c$; a ratio $r' < r$ bounding every c_s satisfies $c \le r' < r$, and if $c < r$ any ratio strictly between c and r bounds every c_s. So in the model $(\mathscr{L}, \mathscr{U})$ is the cut of the real number c: both sets are inhabited, the lower set is closed downward with no greatest element, the upper set is closed upward with no least element, they are disjoint, and for $q < r$ either $q < c$ or $c < r$. The instance of "every located cut is the cut of a point" at these formulas would supply a computable regular β such that $q < \lim \beta$ exactly when $q < c$, for every ratio q; then $\lim \beta = c$, which is impossible. The instance is false in the model, so it is not a theorem.

Cauchy sequences of points. Let $P(n, \beta)$ say that β is regular and names the same point as the constant sequence c_n. In the model each section is the class of the rational point c_n, inhabited by a computable constant sequence, so P is a sequence of points. It is Cauchy: for each k some N has $|c_m - c_n| \le 1/(k+1)$ for all $m, n \ge N$, since the c_s approach c. A limit in the model would be a computable regular λ with c_n approaching $\lim \lambda$, so $\lim \lambda = c$, which is impossible. Here the representatives are listed by a program; the limit is what the model lacks.

Two functions on the points. We build an increasing map H of the real line onto itself with $H(0) = c$. For every s let

$$H(y) = x_s - 4^{-s} + \big(1 + \tfrac{b(s)}{3}\big)\big(y + 4^{-s}\big) \qquad \text{for } -4^{-s} \le y \le -4^{-(s+1)},$$
$$H(y) = x_{s+1} + 4^{-(s+1)} + \big(1 - \tfrac{b(s)}{3}\big)\big(y - 4^{-(s+1)}\big) \qquad \text{for } 4^{-(s+1)} \le y \le 4^{-s},$$

$H(y) = y$ for $|y| \ge 1$ and $H(0) = c$. Adjacent pieces agree at their common end, because $x_{s+1} = x_s + b(s)\,4^{-(s+1)}$; at $y = \mp 1$ the value is ∓ 1; and $x_s \mp 4^{-s}$ tends to c, so H is continuous at 0. Every slope lies between $2/3$ and $4/3$, so $\frac{2}{3}(y' - y) \le H(y') - H(y) \le \frac{4}{3}(y' - y)$ for $y < y'$, and H is a strictly increasing bijection of the real line. Its inverse G is strictly increasing, with $\frac{3}{4}(x' - x) \le G(x') - G(x) \le \frac{3}{2}(x' - x)$ for $x < x'$, $G(c) = 0$, $G(1) = 1$ and $G(0) \le G(c) = 0$, since $0 \le c \le 1/3$. Put $f(x) = H(-|G(x)|)$. Then f changes by at most twice the change of x, $f(x) \le H(0) = c$ for every x, and $f(x) = x$ when $x \le c$, because then $G(x) \le 0$.

Both functions send computable points to computable points. A computable point x differs from c, so $G(x) \ne 0$. Then $G(x)$ lies in a piece on which H is affine with rational coefficients, or $|G(x)| \ge 1$, and on that piece G is an affine map with rational coefficients, slope at most $3/2$. Applying it to the stages of a computable regular sequence naming x, read at stage $2n + 1$ in place of n, gives a computable regular sequence naming $G(x)$. The same holds for f.

To write the graphs as formulas, note that for a ratio $p \ne 0$ the value $H(p)$ is a ratio computed from the bits $b(0), \dots, b(s)$, where s is the index of the piece containing p. Computing it with b_t in place of b gives a ratio $H_t(p)$, computed from t and p, and equal to $H(p)$ for every large t. Let γ' be a computable code of $(t, p) \mapsto H_t(p)$; it is the parameter of the instances of the third and fourth assertions. Let $F_{15}(\beta, \beta')$ say that β and β' are regular and that for every ratio $p \ne 0$ and every ratio q equal to $H_t(p)$ for all large t, the ratio p lies below the point of β' exactly when q lies below the point of β, and above it exactly when q lies above. In the model, since H is increasing, $F_{15}(\beta, \beta')$ says that $\lim \beta' = G(\lim \beta)$. Let $F_{17}(\beta, \beta')$ say that β' is regular and that some δ, δ' satisfy $F_{15}(\beta, \delta)$, $F_{15}(\beta', \delta')$ and that δ and δ' name points u and $-|u|$ for some point u; in the model it says $\lim \beta' = f(\lim \beta)$. By the preceding paragraph both formulas are functions on the points of the model.

Strictly increasing functions. At F_{15} the premises of the third assertion hold in the model: G is uniformly continuous on $[0, 1]$ (for k, take j with $3/(2j + 2) \le 1/(k + 1)$), strictly increasing, and $G(0) \le 0 \le G(1)$. A root in the model would be a computable point x of $[0, 1]$ with $G(x) = 0$, that is $x = c$, which is impossible.

Suprema. At F_{17} the premise of the fourth assertion holds in the model: f is uniformly continuous. A supremum in the model would be a computable point w such that $f(x) \le \lim w$ for every computable x in $[0, 1]$, and such that for every k some computable x in $[0, 1]$ has $f(x)$ within $1/(k + 1)$ of $\lim w$. Every ratio x with $0 \le x < c$ has $f(x) = x$, so $\lim w \ge c$; and $\lim w \le f(x) + 1/(k + 1) \le c + 1/(k + 1)$ for every k, so $\lim w = c$, which is impossible.

In each case the failure comes from c. In the same model the four assertions hold at computable data: the cut of $1/2$ is the cut of the constant point $1/2$, the constant sequence of the point 0 converges, and the identity function has the root 0 and the supremum 1.

The last sentence. In the mathematics of this chapter, countable choice at pairs of ratios makes every located cut the cut of a point (Theorem 12.33). The other three assertions follow from that one with no further choice, because the limit, the root and the supremum are each

located as a cut first and only that cut is made a point (Corollary 12.35 and Theorems 12.56 and 12.58). □

In a classical theory, countable choice for numbers is the same as the principle of unique choice, that a relation with exactly one witness for each n defines a sequence: given witnesses, the least one is unique. So the theorem shows that one of the two must be added. Under the reading of maps of Appendix C, which contains unique choice, excluded middle therefore supplies countable choice for numbers, and with it the four assertions. Over an intuitionistic base that already contains unique choice, the second assertion still needs countable choice, and countable choice proves all four without excluded middle; we show both next.

12.9.12 A located cut that unique choice does not make a point

Let t be a classical real number, and let $\mathscr{L}_t$ and $\mathscr{U}_t$ be the sets of ratios below t and above t. For each t this is a located cut, and it moves continuously with t. A sequence of ratios that depends continuously on t cannot follow it. Each of its stages is a ratio, given by a triple of numbers, and a continuous function of t with values in a discrete set is constant on every interval of values of t. The ratio 0 lies in $\mathscr{L}_t$ for t slightly above 0 and not for t slightly below, while a sequence that is constant near $t = 0$ names one point on both sides. In the open sets of the real line this picture becomes a model of the system HAS of Chapter 7 in which unique choice holds and the assertion that every located cut is the cut of a point does not hold. That settles, for located cuts, the question left after Theorem 12.63. Two further results complete the account: in a theory without excluded middle, countable choice for numbers proves the four assertions of that theorem; and LLPO, with countable choice only for the relations whose witnesses a search can find, gives neither binary expansions, nor the directions of plane vectors, nor exact roots.

In the language of Definition 7.14, a triple $q = (a, b, d)$ of numbers stands for the ratio $(a - b)/(d + 1)$, and $\bar{q} = J(J(a, b), d)$ is its code. Comparisons, sums and differences of ratios are integer conditions with the denominators cleared, written with the order (7.9). A set S is read as a sequence of ratios: *stage n of S is q* means $J(n, \bar{q}) \in S$. By Lemma 7.17(h), distinct pairs have distinct codes.

Definition 12.64 (Located cuts and points in HAS)**.** Let S, L and U be sets.

1. A set S is a *point* when every stage of S is some triple, two triples at the same stage are equal as triples, and triples q at stage m and q' at stage n satisfy $|q - q'| \le 1/(m + 1) + 1/(n + 1)$.

2. A pair of sets (L, U) is a *located cut* when the sets of ratios $\{q : \bar{q} \in L\}$ and $\{q : \bar{q} \in U\}$ satisfy the conditions of Definition 12.27.

3. The *cut of the point S* consists of the set L_S of ratios q such that some n and some triple t at stage $2n + 1$ of S have $t - q > 2/(n + 1)$, and the set U_S of ratios q such that some n and t at stage $2n + 1$ have $q - t > 2/(n + 1)$.

4. LCP is the sentence: for all sets L and U, if (L, U) is a located cut, then some point S has $\bar{q} \in L \leftrightarrow q \in L_S$ and $\bar{q} \in U \leftrightarrow q \in U_S$ for every triple q.

5. Let $\varphi(n, q)$ be a formula with a number variable n, a triple q of number variables and any parameters. The instance UC_φ of *unique choice* says: if every n has a triple q with $\varphi(n, q)$, and any two triples q, q' with $\varphi(n, q)$ and $\varphi(n, q')$ are equal, then some set S, of which every stage is some triple and two triples at the same stage are equal, has stage n equal to q exactly when $\varphi(n, q)$, for all n and q.

Item 3 is the cut of Definition 12.27 for the point x that S names: the sequence $(s_{2n+1} - q)_n$ names $x - \eta(q)$, and $\eta(q) < x$ says that this sequence has a stage above $2/(n + 1)$.

Remark 12.65 (Unique choice is derivable in HAS)**.** Each instance UC_φ is derivable in HAS by comprehension. Comprehension, with the parameters of φ, gives a set S with $x \in S$ exactly when some n and some triple q have $x = J(n, \bar{q})$ and $\varphi(n, q)$. Stage n of S is then q exactly when $\varphi(n, q)$: from $J(n, \bar{q}) = J(n', \bar{q}')$, Lemma 7.17(h), applied three times, gives $n = n'$ and the three entries of q equal to those of q', and substitution of equals carries $\varphi(n', q')$ to $\varphi(n, q)$. So the two premises of UC_φ say that every stage of S is some triple and that two triples at the same stage are equal. Unique choice is therefore no axiom added to HAS, and part 1 of the next theorem also follows from the proof of Lemma 7.21, which gives every derivable formula the value $\top$ under every assignment.

Theorem 12.66 (A located cut need not be a point, although unique choice holds)**.** *Let* LCP *and the instances* UC_φ *be as in Definition 12.64.*

1. *In every system of truth values, every instance* UC_φ *of unique choice has the value* $\top$ *under every assignment.*
2. *In the open sets of the classical real line,* LCP *does not have the value* $\top$*.*
3. *In the two-valued system* $\{\bot, \top\}$*,* LCP *has the value* $\top$*.*

Consequently neither LCP *nor* $\neg$LCP *is derivable in HAS, alone or from any finite list of instances of unique choice: over HAS with unique choice, the assertion that every located cut is the cut of a point is independent. The proof reasons in a classical metatheory.*

Proof. Values are written $[\![\varphi]\!]$ as in Section 7.10, with the assignments dropped when they are fixed. A formula without set variables has the value $\top$ when it is true in $\mathbb{N}$ and $\bot$ when it is false, in every system of truth values: by induction on the formula, since meets, joins and implications of the elements $\bot$ and $\top$ are computed as in the two-valued system. This applies to every comparison of ratios.

Unique choice. Fix a system H, an assignment and a formula φ. Let $A : \mathbb{N} \to H$ send $J(n, \bar{q})$ to $[\![\varphi(n, q)]\!]$, for every number n and triple q, and every other number to $\bot$; this is well defined because distinct pairs and distinct triples have distinct codes. Assign A to S. Then "stage n of S is q" has the value $[\![\varphi(n, q)]\!]$. So the two conditions on S have the values a and b of the two premises of UC_φ, and the final equivalence has the value $\top$. The conclusion of UC_φ, a join over all assignments to S, therefore lies above $a \wedge b$, and UC_φ has the value $(a \wedge b) \Rightarrow [\![\text{conclusion}]\!] = \top$.

A located cut of the real line. Let the truth values be the open subsets of the classical real line $\mathbb{R}$. Assign to L the map sending $\bar{q}$ to the open set $\{y \in \mathbb{R} : q < y\}$, and to U the map sending

$\bar{q}$ to $\{y : y < q\}$, with $\emptyset$ at every number that is not the code of a triple. Each condition of a located cut then has the value $\mathbb{R}$. A universal quantifier over ratios has as its value the interior of an intersection, which is $\mathbb{R}$ when every member is $\mathbb{R}$, so it suffices to check each instance. Both sets are inhabited: the sets $\{y : q < y\}$, and also the sets $\{y : y < q\}$, cover $\mathbb{R}$. Downward closure at $q' < q$ asks for $\{y : q < y\} \Rightarrow \{y : q' < y\}$, which is $\mathbb{R}$ because the first set lies in the second; when $q' < q$ is false its value is $\emptyset$ and the implication is $\mathbb{R}$. The absence of a greatest element asks for $\{y : q < y\} \Rightarrow \bigcup_{q'>q}\{y : q' < y\}$, and the two sets are equal because the ratios are dense in $\mathbb{R}$. The upper set is treated in the same way. Disjointness asks for the negation of $\{y : q < y\} \cap \{y : y < q\}$; this intersection is empty, so its negation is $\mathbb{R}$. Locatedness at $q < r$ asks for $\{y : q < y\} \cup \{y : y < r\}$, which is $\mathbb{R}$.

No point has this cut. Suppose that LCP had the value $\mathbb{R}$. Its value lies below that of its instance at the assignment above, whose premise has the value $\mathbb{R}$. So the open sets $[\![S \text{ is a point}]\!] \cap [\![(L,U) \text{ is the cut of } S]\!]$, one for each assignment A to S, cover $\mathbb{R}$. The point 0 lies in one of them, and with it an interval $B = (-\varepsilon, \varepsilon)$, where $\varepsilon > 0$. Two facts about open sets are used: a point of $V \Rightarrow W$ that lies in V lies in W, and the interior of an intersection lies in each member.

First, every stage of S is constant on B. Fix n. Totality puts B inside the union of the open sets $A(J(n,\bar{q}))$ over all triples q. Single-valuedness puts B inside $A(J(n,\bar{q})) \Rightarrow \big(A(J(n,\bar{q}')) \Rightarrow \emptyset\big)$ for distinct triples q, q', so no point of B lies in both sets. Thus the sets $B \cap A(J(n,\bar{q}))$ are open, pairwise disjoint and cover B. An interval is connected, so one of them is B: some triple t_n has $B \subseteq A(J(n,\bar{t}_n))$.

Second, look at the ratio 0. The point $y = \varepsilon/2$ of B lies in $\{y : 0 < y\}$, the value of $\bar{0} \in L$, so it lies in the value of $0 \in L_S$. That value is the union of the sets $A(J(2n+1,\bar{t}))$ over the n and the triples t with $t > 2/(n+1)$, so y lies in one of them. Since $y \in B$, the triple is t_{2n+1}, and all of B lies in that set. Hence $-y$ lies in the value of $0 \in L_S$ as well, and by the equivalence read from right to left it lies in $\{y' : 0 < y'\}$, the value of $\bar{0} \in L$. That says $0 < -\varepsilon/2$, which is false. So LCP does not have the value $\mathbb{R}$.

The two-valued system. Here a set is a set of numbers and every formula has its ordinary meaning. Let (L,U) be a located cut, and let x be the supremum of its lower set of ratios, a real number. The lower set consists of the ratios below x: its members lie below x because it has no greatest member, and a ratio below x lies below a member. The upper set consists of the ratios above x: a member lies above some smaller member, which bounds the lower set, and if $x < r$, a ratio q with $x < q < r$ is not in the lower set, so locatedness puts r in the upper set. Let S consist of the codes $J(m,\bar{t}_m)$, where, with $z = \lfloor x(m+1) \rfloor$, $t_m = (\max(z,0), \max(-z,0), m)$ is a triple of the ratio $z/(m+1)$. Then $x - 1/(m+1) < t_m \leq x$, so S is a point. If $q < x$, take n with $2/(n+1) + 1/(2n+2) < x - q$; then $t_{2n+1} - q > x - q - 1/(2n+2) > 2/(n+1)$. Conversely, $t_{2n+1} - q > 2/(n+1)$ gives $q < t_{2n+1} \leq x$. So L_S is the lower set, and in the same way U_S is the upper set. Hence LCP is true: its value is $\top$.

Derivations. The proof of Lemma 7.21 shows that a derivation of $\Gamma \vdash \varphi$ gives $[\![\Gamma]\!]_{\rho,\sigma} \leq [\![\varphi]\!]_{\rho,\sigma}$ for every assignment. When Γ is a list of instances of unique choice, its value is $\top$ in every system, by the first part. A derivation of LCP from Γ would give LCP the value $\top$ in the open sets of $\mathbb{R}$, against the second part. A derivation of $\neg$LCP would give $\neg$LCP the value $\top$ in the two-valued system, where LCP has the value $\top$ and its negation the value $\bot$. $\square$

Models of truth values on the open sets of the real line are developed for analysis by Fourman

and Hyland [59]; see also [5]. Unique choice holds in every such model because a set of HAS is any assignment of truth values to numbers, so the set that an instance asks for is the relation itself, read through the codes. The theorem therefore answers, for the second assertion of Theorem 12.63, the question that theorem leaves: over an intuitionistic base with unique choice, countable choice cannot be dropped from the passage from a located cut to a point, where Theorem 12.33 uses it once. For the other three assertions of Theorem 12.63, that every Cauchy sequence of points converges, that every uniformly continuous, strictly increasing f on $[0,1]$ with $f(\eta(0)) \le \eta(0) \le f(\eta(1))$ has a root, and that every uniformly continuous f on $[0,1]$ has a supremum, the same question over HAS with unique choice is not settled here: the argument above shows only that the cut assertion is not derivable.

12.9.13 Countable choice proves the four assertions without excluded middle

Countable choice, on the other hand, proves all four assertions with no excluded middle at all.

Theorem 12.67 (Countable choice proves the four assertions intuitionistically)**.** *Let* $\mathrm{HA}_1 + \mathrm{AC}_{00}$ *be the theory with the language, logical rules, arithmetic axioms and induction of Theorem 12.22 whose only further axioms are the instances*

$$\forall x \exists y\, A(x,y) \to \exists \alpha \forall x\, A(x, \alpha(x))$$

of countable choice for numbers, for every formula A. Each of the four assertions of Theorem 12.63, written as a schema as in its proof, has every instance provable in $\mathrm{HA}_1 + \mathrm{AC}_{00}$*. Hence every instance is provable in the theory of Theorem 12.22, and in the theory of Theorem 12.63 with countable choice for numbers extended to every formula.*

Proof. We follow the proofs of the chapter and check that they are derivations in this theory. Two facts about the theory are used throughout. Every quantifier-free formula B satisfies $B \vee \neg B$: an equation between two terms is decided by induction, as in Lemma 7.17(a), and the connectives preserve decided formulas. The order of two terms, written with an existential quantifier as in (7.9), is decided by induction as in Lemma 7.17(b). So every comparison of ratios, and every condition on finitely many stages of given sequences, is decided, as the chapter's proofs assume. And a relation with exactly one witness for each number is a sequence, by countable choice for numbers.

Located cuts. Let $\mathscr{L}$ and $\mathscr{U}$ be formulas with a ratio variable, and assume that they form a located cut. By existential elimination take $a \in \mathscr{L}$ and $b \in \mathscr{U}$. For each n let G_n be the product of the denominators of a and b with $4(n+1)$, and put $p_{n,i} = a + i/G_n$. With $a = (a_1, a_2, a_3)$ and $g_n = G_n/(a_3+1)$, the triple $(a_1 g_n + i,\ a_2 g_n,\ G_n - 1)$ stands for $p_{n,i}$; its entries are terms in n, i and the entries of a and b. The induction in the proof of Lemma 12.32, made inside the theory for each n, proves

$$\forall n \exists i \left(p_{n,i} \in \mathscr{L} \wedge p_{n,i+2} \in \mathscr{U} \right),$$

and it selects nothing. One instance of countable choice for numbers, at a matrix that asks at the place $3n$ for the first entry of the triple of such a $p_{n,i}$ and at the places $3n+1$ and $3n+2$ for its other two entries, which do not depend on i, gives one sequence β whose stage n,

read as in the proof of Theorem 12.63, is a ratio q_n with $q_n \in \mathscr{L}$ and $q_n + 2/G_n \in \mathscr{U}$. Since $2/G_n < 1/(n+1)$, the pairs $(q_n, q_n + 2/G_n)$ form an approximation sequence, and the converse half of the proof of Theorem 12.33, from an approximation sequence to a point, an integer computation followed by Lemma 12.28, shows that β is regular and that its cut is $(\mathscr{L}, \mathscr{U})$.

The other three assertions. Corollary 12.35 and Theorems 12.56 and 12.58 reduce them to the cut assertion. Each writes down a pair of sets of ratios, the cut of the limit (by Theorem 12.29), of the root or of the supremum, proves that it is a located cut, and proves that a point with this cut is the limit, the root or the supremum. These proofs use no choice principle beyond collecting uniquely determined values into sequences, which the second fact supplies, and no excluded middle beyond decided comparisons of ratios, and the sets, sequences of points and functions they mention are formulas of the kinds fixed in the proof of Theorem 12.63. Together with the instance of the cut assertion at the formulas of that cut, they are derivations in $\mathrm{HA}_1 + \mathrm{AC}_{00}$.

The two other theories contain every axiom of $\mathrm{HA}_1 + \mathrm{AC}_{00}$, so they prove every instance as well. □

With Theorem 12.22, the four assertions are theorems of a theory that proves none of LPO, WLPO, LLPO and $\mathrm{MP}_{\mathrm{bin}}$. With Theorem 12.63, excluded middle with countable choice for the relations whose witnesses a search can find, *search-choice* for short, does not prove them. With Theorem 12.66, HAS does not prove the second, even with unique choice added. In these four forms, completeness of the line follows from countable choice, which decides nothing; excluded middle with search-choice does not replace it, and for the second form neither does unique choice.

12.9.14 LLPO does not replace countable choice

The rows of Table 12.3 for exact roots and binary expansions cost LLPO, and in Theorems 12.54 and 12.61 the passage back from LLPO uses countable choice once, to tabulate a bit for every dyadic ratio. That use cannot be dropped either. For exact roots the model of Theorem 12.63 shows it: excluded middle holds there, and so LLPO, while the function G of that proof is uniformly continuous with $G(\eta(0)) \le \eta(0) \le G(\eta(1))$ and has no root. For binary expansions that model is of no use. In it every point of $[0,1]$ has a binary expansion: a computable point that is not a dyadic ratio has digits computed by bisection, each comparison with a dyadic ratio being strict and found by a search, a dyadic ratio below 1 has an expansion ending in zeros, and 1 the expansion whose digits are all 1. The same holds for the directions defined below: $(1,0)$ at the origin, and otherwise the vector divided by its length, computed from programs for its coordinates. A realizability of another kind separates them, one whose realizers may leave a choice among finitely many candidates open and strike the wrong candidates later [57, 58].

A *direction* of a vector (a,b) of points is a pair of points (p,q) with $p^2 + q^2 = \eta(1)$, $aq = bp$ and $ap + bq \ge \eta(0)$. When $a^2 + b^2 > \eta(0)$ the direction is (a,b) divided by its length, and every unit vector is a direction of $(0,0)$; in each case $(a,b) = \ell(p,q)$ with $\ell = ap + bq$, the polar form of the vector.

We write three statements in the language of Theorem 12.22, with points given by codes of regular sequences and functions on the points by formulas, as in the proof of Theorem 12.63.

- *Binary expansions*: every point x of $[0,1]$ has a binary sequence β with $\eta(c_n) \le x \le \eta(c_n + 2^{-n})$ for every n, where $c_n = \sum_{i<n} \beta(i) 2^{-(i+1)}$. The theory has no symbol for 2^n, so the statement asks for the bounds $\neg(x < \eta(\nu(n)/(\pi(n)+1)))$ and $\neg(\eta((\nu(n)+1)/(\pi(n)+1)) < x)$ for all sequences π, ν with $\pi(0) = \nu(0) = 0$, $\pi(n+1) = 2\pi(n) + 1$ and $\nu(n+1) = 2\nu(n) + \beta(n)$; these force $\pi(n) = 2^n - 1$ and $\nu(n) = 2^n c_n$.

- *Directions*: for all points a, b in $[-1,1]$ there are points p, q whose stages satisfy

$$|p_k^2 + q_k^2 - 1| \le \tfrac{6}{k+1}, \qquad |a_k q_k - b_k p_k| \le \tfrac{6}{k+1}, \qquad a_k p_k + b_k q_k \ge -\tfrac{6}{k+1}$$

  for every k. A product of stages of two points of $[-1,1]$ lies within $3/(k+1)$ of the product of the points, so a direction satisfies these conditions; conversely, the conditions give $p^2 + q^2 = \eta(1)$, $aq = bp$ and $ap + bq \ge 0$, since the tolerances tend to 0.

- *Exact roots*: the third assertion of Theorem 12.63 without the hypothesis that f is strictly increasing. Its instance at the function G is the instance at the formula F_{15} of that proof.

Definition 12.68 (Lifschitz realizability)**.** We use the programs, the pairing π and the valuations of the proof of Theorem 12.22. The *candidates* of a number r are the numbers $k \le (r)_1$ at which the run of program $(r)_0$ on input k does not halt; a number $k \le (r)_1$ is *struck* when that run halts. Under a valuation, $r \Vdash_1 A$, read *r realizes A*, is defined by recursion on A. For equations, $\bot$, $\wedge$, $\to$, $\forall x$ and $\forall \alpha$ the clauses are those of Kleene realizability $\Vdash_{\mathrm{k}}$ in that proof. The other three clauses are:

- $r \Vdash_1 A \vee B$ when r has a candidate, and every candidate k has $(k)_0 = 0$ and $(k)_1 \Vdash_1 A$, or $(k)_0 \neq 0$ and $(k)_1 \Vdash_1 B$;

- $r \Vdash_1 \exists x\, A(x)$ when r has a candidate, and every candidate k has $(k)_1 \Vdash_1 A((k)_0)$;

- $r \Vdash_1 \exists \alpha\, A(\alpha)$ when r has a candidate, and every candidate k has $(k)_0$ total and $(k)_1 \Vdash_1 A((k)_0)$.

A realizer of a disjunction or of an existential statement names a nonempty finite set of answers, each of them correct, without saying which; its program may strike candidates over time, but never all of them. For every k_0 a program, computed from k_0, halts on every input except k_0; paired with the bound k_0 it has the single candidate k_0. We call this number the *singleton* of k_0.

Lemma 12.69 (Derivations have Lifschitz realizers)**.** *Consider a theory with the language, logical rules, arithmetic axioms and induction of Theorem 12.22, whose further axioms each have a realizer computed by one program from the values of the free variables of the axiom. For every derivation of A from hypotheses $B_1, \dots, B_m$ there is a program that, given the values of the free variables and realizers of $B_1, \dots, B_m$, halts with a realizer of A. In particular every sentence that the theory proves has a realizer. The proof reasons in a classical metatheory.*

Proof. The program is built by induction on the derivation, as for Kleene realizability in the proof of Theorem 12.22 and Appendix F.1. The clauses for equations, $\bot$, $\wedge$, $\to$, $\forall x$ and $\forall \alpha$ are Kleene's, so the programs given there for hypotheses, $\bot$, $\wedge$, $\to$, the universal quantifiers, equality, the arithmetic axioms and induction serve unchanged; an axiom returns its given realizer. Only the rules for $\vee$, $\exists x$ and $\exists \alpha$ change. An introduction returns the singleton of $\pi(0, w)$ or $\pi(1, w)$, of $\pi(v, w)$ with v the value of the term, or of $\pi(i_\beta, w)$ with i_β the program assigned to β, where w is the value of the premise program.

The eliminations rest on *mixing*: for every formula C there is a program M_C such that, whenever a number r has a candidate and a program f halts with a realizer of C at every candidate of r, the run $M_C(r, f)$ halts with a realizer of C. Given this, to infer C from $A \vee B$ and the two branches, run the first premise program to obtain r and return $M_C(r, f)$, where f at k runs the second premise program with $(k)_1$ as the realizer of A if $(k)_0 = 0$, and the third with $(k)_1$ as the realizer of B otherwise. For $\exists x\, A(x)$, the program f runs the branch with x given the value $(k)_0$ and with $(k)_1$ as the realizer of $A(x)$; for $\exists \alpha\, A(\alpha)$, with α assigned $(k)_0$, which is total when k is a candidate. At a candidate the answer of f realizes C; elsewhere f may run forever, and M_C never needs those answers.

Mixing is built by induction on C. For an equation return 0: some candidate carries a realizer, so the equation is true. No candidate carries a realizer of $\bot$, so for $\bot$ the hypothesis never holds. For $A \wedge B$ return $\pi(M_A(r, f_0), M_B(r, f_1))$, where f_j returns the component j of the answer of f. For $A \to B$ return a program that on input s returns $M_B(r, f_s)$, where f_s at k applies the answer of f at k to s; when s realizes A, every candidate gives a realizer of B. For $\forall x\, A$ and $\forall \alpha\, A$ apply the answers to the input n or i in the same way.

In the remaining cases C is $A \vee B$, $\exists x\, A$ or $\exists \alpha\, A$, and the answers v_k of f at candidates k have candidates of their own. Write $e = (r)_0$ and $b = (r)_1$. Search for a time t at which every $k \le b$ is *settled*: the run of e on k halts within t steps, or f halts on k within t steps with an answer v_k. Such a time exists, since a $k \le b$ that is not a candidate is struck at some time and a candidate is answered at some time. Let b' be the largest $(v_k)_1$ over the k answered by time t, and let e' be the program that on input j searches for a time $t' \ge t$ at which every $k \le b$ is struck within t' steps, or was answered by time t with $j > (v_k)_1$ or with the run of $(v_k)_0$ on j halting within t' steps. Return $\pi(e', b')$. The search of e' on j fails exactly when some k fails at every time t', since there are finitely many k and the condition on each persists once it holds. Such a k is never struck, so it is a candidate of r, and j is a candidate of v_k. So the candidates of $\pi(e', b')$ are exactly the candidates of the v_k with k a candidate of r; every candidate of r was answered by time t, so its v_k has bound at most b'. There is at least one, and each carries what the clause of C asks, because it does so as a candidate of a realizer v_k of C. So $\pi(e', b')$ realizes C. □

Theorem 12.70 (LLPO does not replace countable choice)**.** *Let* $\mathrm{T}_{\mathrm{LLPO}}$ *be the theory of Theorem 12.63 with excluded middle replaced by LLPO: the language, logical rules, arithmetic axioms and induction of Theorem 12.22, the sentence LLPO stated in its proof, and countable choice for numbers at the formulas that are quantifier-free or of the form* $\exists z\, B$ *with* B *quantifier-free. Let* $\mathrm{T}^{+}_{\mathrm{LLPO}}$ *have instead LLPO and countable choice for numbers at every formula.*

1. *In* $\mathrm{T}_{\mathrm{LLPO}}$*, binary expansions and directions are each neither provable nor refutable, and so is the instance of exact roots at the function G of Theorem 12.63, also when its hypothesis of uniform continuity is strengthened to the existence of a modulus sequence.*

2. *Binary expansions, directions and every instance of exact roots are provable in* $\mathrm{T}^{+}_{\mathrm{LLPO}}$.

The proof of the first part reasons in a classical metatheory.

Proof. Reading realizers. Call a formula *plain* when it is built from equations by $\wedge$, $\vee$ and $\exists x$, or from such formulas and their negations by $\wedge$ and $\forall x$. Under a valuation, a plain formula is true exactly when it has a realizer, and when it is true a realizer is computed from the values of its free variables by a fixed program. This is an induction on the formula: a true equation is realized by 0; a true disjunction or existential statement is realized by the singleton of a true side or of a witness, found by a search through all tuples of numbers, and a realizer has a candidate whose side or witness is correct; a negation $\neg A$ of a formula A of the first kind is realized by every number when A is false and by none when A is true. The same holds for quantifier-free formulas, in which a true implication $A \to B$ is realized by the program returning the computed realizer of B. Regularity of a sequence, membership of a point in $[0,1]$ or $[-1,1]$, being a binary sequence and the stage conditions of a direction are plain. In the formula for binary expansions, a realizer applied to programs for the two sequences π, ν that the recursion determines, and to the computed realizer of the recursion, gives a realizer of the plain bounds; so a realizer shows that the expansion is one.

The axioms of $\mathrm{T}_{\mathrm{LLPO}}$ *are realized.* LLPO is realized by a program that ignores the realizers of its two premises and, at a binary sequence α given by a total program, returns the number with bound $\pi(1,0)$ whose program, at input $\pi(0,0)$, searches the even places of α for an entry 1, at input $\pi(1,0)$ searches the odd places, and halts at once at every other input. Recall that $\pi(0,0) = 0 < \pi(1,0)$. The premises are realized, hence true; for the second, apply its realizer at m and n, and then to 0 and 0, when $\alpha(m) = \alpha(n) = 1$. So α has at most one entry 1, at most one search succeeds, and a candidate remains. A remaining $\pi(0,0)$ carries the tag 0 and the realizer 0 of $\forall k\, \alpha(2k) = 0$, which is true because α is binary and the search fails; a remaining $\pi(1,0)$ carries the tag 1 and the realizer 0 of the other side. An instance of countable choice at a matrix $\exists z\, B(x,y,z)$ with B quantifier-free is realized by the program that ignores the realizer s of the premise and returns the singleton of $\pi(i,w)$, where i computes $\alpha(x)$ as the y of the first pair (y,z) that satisfies B, and w computes realizers of the true formulas $\exists z\, B(x,\alpha(x),z)$. The premise is realized, hence true, so every search halts and i is total. A quantifier-free matrix is the case without z. The arithmetic axioms are realized as in Appendix F.1. By Lemma 12.69, every theorem of $\mathrm{T}_{\mathrm{LLPO}}$ has a realizer.

Binary expansions have no realizer. Suppose R realized them. For a total program c whose sequence is regular with its point in $[0,1]$, apply R to c, the result to the computed realizer $g(c)$ of regularity, and that result to 0, which realizes membership in $[0,1]$. The value r realizes the existence of a binary expansion, so every candidate k of r has a total program $(k)_0$ computing a binary expansion of the point. By Kleene's recursion theorem [19, Chapter XII] there is a program c computing the following sequence of ratios. It keeps a target $m/2^N$, first $1/2$, and its stage n is the target before step n. At step n it runs the three applications above, each for at most n steps. If they halt with a value r, it takes the least $k \le (r)_1$ that is not struck within n steps and whose program $(k)_0$ computes its first N entries within n steps, if there is one, and lets ν be the numerator $\sum_{i<N} \beta(i) 2^{N-1-i}$ of those entries $\beta(i)$. If $\nu = m$ it moves the target to $m/2^N - 4^{-(n+2)}$, and if $\nu + 1 = m$ to $m/2^N + 4^{-(n+2)}$. In every other case the target stays. A moved target is again of the form $m/2^N$, now with $N = 2n + 4$.

The moves from step n on total at most $\sum_{j\ge n} 4^{-(j+2)} = \frac{1}{3}4^{-(n+1)}$, so the stages form a regular sequence whose point x lies within $1/12$ of $1/2$, in $[0,1]$. So R produces r. Suppose a step n moved the target on account of a candidate k. Its expansion of x has $v/2^N \le x \le (v+1)/2^N$. If $v = m$, the target moved to $m/2^N - 4^{-(n+2)}$ and the later moves total at most $\frac{1}{3}4^{-(n+2)}$, so $x < m/2^N = v/2^N$; if $v+1 = m$, symmetrically $x > (v+1)/2^N$. Both are impossible, so the program never moves on account of a candidate. Now take a time T_1 beyond the steps the three applications need, at which every $k \le (r)_1$ that is not a candidate is struck. From step T_1 on, every k that the program examines is a candidate, so the target never moves again: it is a fixed $m/2^N$, and $x = m/2^N$. The number r has a candidate k_0, whose program is total and computes its first N entries within some T_2 steps. At step $\max(T_1, T_2)$ the program finds a candidate k, whose expansion has $v/2^N \le m/2^N \le (v+1)/2^N$, so $v = m$ or $v+1 = m$, and it moves the target, on account of a candidate. This contradiction shows that no realizer exists.

Directions have no realizer. Suppose R realized them. For total programs a, b whose sequences are regular with points in $[-1,1]$, six applications of R, to a, the computed realizer of its regularity, 0, then b, its regularity and 0, give a number r whose candidates k carry total programs $(k)_0$ computing regular sequences p such that some q makes (p,q) a direction of (a,b). By the recursion theorem there is a program c computing a pair of sequences a, b, with programs for them computed from c. Both are 0 until the first step s_0 at which the six applications have produced r within s_0 steps each and, with $M = (r)_1 + 2$ and $K = 4M^2$, every $k \le (r)_1$ is struck within s_0 steps or its program has computed stage K of its sequence p within s_0 steps. At step s_0 the program takes the least $j < M$, which exists as shown below, such that every $k \le (r)_1$ that is not struck within s_0 steps has its stage K at distance at least $1/(4M^2)$ from

$$x_j = \frac{M^2 - j^2}{M^2 + j^2}, \qquad \text{and puts} \qquad y_j = \frac{2jM}{M^2 + j^2},$$

and from step s_0 on the two sequences are the constant ratios εx_j and εy_j, with $\varepsilon = 2^{-(s_0+2)}$.

Such sequences are regular, since they change once, by at most $\varepsilon < 1/(s_0+1)$, and their points lie in $[-1,1]$. So R produces r, and the step s_0 exists: a non-candidate is struck at some time, and the program of a candidate is total. A suitable j exists. For $j < j' < M$,

$$x_j - x_{j'} = \frac{2M^2(j'^2 - j^2)}{(M^2 + j^2)(M^2 + j'^2)} \ge \frac{2M^2}{4M^4} = \frac{1}{2M^2},$$

so a ratio within less than $1/(4M^2)$ of one x_j is not that close to another; the at most $(r)_1 + 1 = M - 1$ unstruck stages exclude at most $M - 1$ of the M indices. Let J be the index taken. Then $(a,b) = \varepsilon(x_J, y_J)$ with $x_J^2 + y_J^2 = 1$ and $\varepsilon > 0$. Let k_0 be a candidate of r and (p,q) its direction. From $p^2 + q^2 = 1$, $x_J q = y_J p$ and $x_J p + y_J q \ge 0$,

$$(x_J p + y_J q)^2 = (x_J^2 + y_J^2)(p^2 + q^2) - (x_J q - y_J p)^2 = 1,$$

so $x_J p + y_J q = 1$ and $(p - x_J)^2 + (q - y_J)^2 = 2 - 2(x_J p + y_J q) = 0$: $p = x_J$. The candidate k_0 is not struck within s_0 steps, so its stage K lies at distance at least $1/(4M^2)$ from $x_J = p$, while a regular sequence has $|p_K - p| \le 1/(K+1) < 1/(4M^2)$. This contradiction shows that no realizer exists.

Exact roots, and the models. The model of Theorem 12.63, whose sequences are the computable ones, satisfies $\mathrm{T}_{\mathrm{LLPO}}$: excluded middle holds in it, and LLPO follows from excluded middle, since if not every even entry is 0 the binary sequence has its entry 1 at an even place and every odd entry is 0. The function G is uniformly continuous, with the computable modulus $k \mapsto 2k+1$ because G changes by at most twice the change of its argument, and $G(\eta(0)) \leq \eta(0) \leq G(\eta(1))$, but it has no root in the model. So the instance at F_{15}, with either form of uniform continuity, is not provable. In the classical model of the proof of Theorem 12.22, whose sequences are all functions, every axiom of $\mathrm{T}^{+}_{\mathrm{LLPO}}$ holds, LLPO by excluded middle in the metatheory. Every point of $[0,1]$ has a binary expansion there, with digits $\lfloor 2^{n+1}x \rfloor - 2\lfloor 2^{n}x \rfloor$, and all digits 1 at $x = 1$; every vector of $[-1,1]^2$ has a direction, (a,b) divided by its length or $(1,0)$ at the origin, named by the sequences $\lfloor u(k+1) \rfloor/(k+1)$ of the two coordinates u; and the classical intermediate value theorem gives every uniformly continuous function with a change of sign a root, named in the same way. So the three statements are true there, and none of their negations is provable, in $\mathrm{T}^{+}_{\mathrm{LLPO}}$ or in $\mathrm{T}_{\mathrm{LLPO}}$. With the realizers above this proves the first part.

The second part. Read in the language of the theory, the proofs of the second parts of Theorems 12.54 and 12.61, and the proof of directions below, use, besides intuitionistic reasoning with decided comparisons of ratios, LLPO and countable choice for numbers in three ways: to tabulate a bit for every dyadic ratio; to form, for a point x and a ratio u, the binary sequence of first detections from which LLPO gives $x \leq \eta(u)$ or $\eta(u) \leq x$ (Corollary 12.18); and to define sequences by recursion, such as $a_{n+1} = 2a_n + B(n+1, 2a_n + 1)$. The last two collect uniquely determined values, which this theory obtains only through countable choice. For a recursion, every n has a sequence that follows it up to n, by induction on n, where one instance of countable choice extends such a sequence by one step; two such sequences agree up to n, by induction; and one more instance collects their values at n into one sequence. So these proofs are derivations in $\mathrm{T}^{+}_{\mathrm{LLPO}}$.

For directions, let a, b lie in $[-1,1]$. LLPO gives every point u with $u \geq \eta(0)$ or $u \leq \eta(0)$ (Corollary 12.18). Applied to a, to b, and then to the difference of the two resulting coordinates, it lets us replace (a,b) by $(-a,b)$, $(a,-b)$ or (b,a) where needed until $0 \leq b \leq a \leq 1$. Each replacement carries a direction (p,q) of the new vector to a direction of the old one, by the same replacement: it keeps p^2+q^2 and $ap+bq$, and it keeps $aq-bp$ or changes its sign. So let $0 \leq b \leq a \leq 1$, and put $h(s) = as - b + bs^2/4$. Then $h(\eta(0)) = -b \leq \eta(0)$, $h(\eta(1)) = a - \frac{3}{4}b \geq \eta(0)$, and $|h(s) - h(s')| \leq \frac{3}{2}|s - s'|$ on $[0,1]$, so h is uniformly continuous. The exact intermediate value theorem gives s in $[0,1]$ with $h(s) = \eta(0)$. With $t = s/2$ put $p = (1-t^2)/(1+t^2)$ and $q = 2t/(1+t^2)$. Then $p^2+q^2 = \eta(1)$, $aq - bp = h(s)/(1+t^2) = \eta(0)$, and $ap+bq \geq \eta(0)$ because a, b, p and q are at least $\eta(0)$. □

The first parts of Theorems 12.54 and 12.61 derive LLPO from exact roots and from binary expansions with no choice. So in both rows of Table 12.3 LLPO is the price, and the way back from LLPO needs countable choice: LLPO with search-choice does not give the statement, and LLPO with countable choice does. Whether binary expansions or directions follow from excluded middle with search-choice is not settled here; the model of computable sequences, which settles the case of exact roots, satisfies both statements.

12.9.15 The same prices away from the line

The same prices appear for statements about binary sequences and colourings. Weak König's lemma [15] for decidable binary trees is equivalent to LLPO, and the infinite pigeonhole principle, for colourings with any finite number of colours, and Ramsey's theorem for pairs with two colours [16] are each equivalent to LPO. In each case the passage to the principle uses no choice, and countable choice is used only on the way back. The omniscience principles are the usual yardstick of constructive analysis [14, 4]; we prove the three equivalences here, because where choice enters is part of what the table records.

Definition 12.71 (Decidable binary trees)**.** A *binary string* is a finite sequence $s = (s_0, \dots, s_{n-1})$ of digits in $\{0, 1\}$; $n = |s|$ is its *length*, and sb is s followed by the digit b. For a binary sequence p write $\bar{p}(n) = (p(0), \dots, p(n-1))$. A *decidable binary tree* is a set T of binary strings, given by its characteristic function, a map from binary strings to $\{0, 1\}$, so that membership is decidable, which contains the empty string and contains s whenever it contains sb; so it contains every initial segment of each of its members. It is *infinite* when it has a member of every length. A *path* through T is a binary sequence p with $\bar{p}(n) \in T$ for every n. *Weak König's lemma* states that every infinite decidable binary tree has a path.

For such a tree the usual readings of "infinite" agree: a member of every length, members of arbitrarily large length, and infinitely many members. Whether T has a member of length n is decided by inspecting the 2^n strings of that length, and a tree with no member of length n has all its members among the $2^n - 1$ shorter strings.

Theorem 12.72 (Weak König's lemma is LLPO)**.** *If weak König's lemma holds, then LLPO holds; the proof uses no choice principle. Conversely, LLPO and* AC_ω *give weak König's lemma; countable choice is used once, to collect for every depth a finite table of extendable children.*

Proof. Assume weak König's lemma, and let α have at most one entry equal to 1. Let T_α consist of the strings s such that either every digit of s is 0 and $\alpha(m) = 0$ for every even $m < |s|$, or every digit of s is 1 and $\alpha(m) = 0$ for every odd $m < |s|$. Membership is decided by inspecting s and $\alpha(0), \dots, \alpha(|s| - 1)$. The empty string belongs to T_α, and deleting the last digit of a member preserves both conditions, so T_α is a decidable binary tree. It is infinite. Given n, inspect the even indices $m < n$. If $\alpha(m) = 0$ at each of them, the string of n zeros belongs to T_α. If $\alpha(m) = 1$ at one of them, that is the only entry 1 of α, so α vanishes at every odd index and the string of n ones belongs to T_α.

Let p be a path through T_α, and decide its first digit. Suppose $p(0) = 0$, and fix k. The member $\bar{p}(2k + 1)$ of T_α begins with 0, so it is not a string of ones. Hence it is a string of zeros, α vanishes at every even index below $2k + 1$, and in particular $\alpha(2k) = 0$. If instead $p(0) = 1$, the member $\bar{p}(2k + 2)$ is not a string of zeros, so $\alpha(2k + 1) = 0$, for every k. These are the two alternatives of LLPO. Every step is a bounded inspection of data already given; no choice principle is used.

For the converse, assume LLPO and AC_ω, and let T be an infinite decidable binary tree. Say that a string s *reaches depth* n when $se \in T$ for some string e of length n. This is decided by inspecting the 2^n strings e, and since T is closed under initial segments, a string that reaches depth n reaches every smaller depth. Call s *extendable* when it reaches every depth. The empty string is extendable, because T is infinite.

A child for each string, from LLPO. Fix s, and let $b_0(n)$ and $b_1(n)$ be the decidable statements that $s0$, respectively $s1$, reaches depth n. Define a binary sequence γ: $\gamma(2n) = 1$ when n is the first index at which b_0 or b_1 fails and b_0 fails there; $\gamma(2n+1) = 1$ when n is that first index, b_0 holds there and b_1 fails; γ is 0 at all other positions. Each value is a bounded search. The first index of a failure is unique, so γ has at most one entry equal to 1, and LLPO applies to it. If every even entry is 0, put $c_s = 0$; if every odd entry is 0, put $c_s = 1$. We show that sc_s is extendable whenever s is.

Let $c_s = 0$, assume that s is extendable, and fix n. The statement $b_0(n)$ is decidable; suppose it fails. Since s reaches depth $n+1$, one of $s0$ and $s1$ reaches depth n, so $b_1(n)$ holds. A bounded search finds the first index $j \leq n$ at which b_0 or b_1 fails. Since $\gamma(2j) = 0$, b_0 holds at j, so b_1 fails at j; but $b_1(n)$ holds and $j \leq n$, so $b_1(j)$ holds. This contradiction proves $b_0(n)$. The case $c_s = 1$ is symmetric: a failure of $b_1(n)$ forces $b_0(n)$, hence b_0 holds at the first failure $j \leq n$ and b_1 fails there, so $\gamma(2j+1) = 1$, contrary to the case. The child is named without deciding whether s is extendable, which is a universal statement.

Finitely many strings at once, with no choice principle. For each d there is a function f on the strings of length d such that $sf(s)$ is extendable for every extendable s of length d. By induction on d one proves, for every string t, that there is such a function on the strings te with $|e| = d$: for $d = 0$ take the child named for t, and for $d+1$ combine the functions given for $t0$ and for $t1$. The case of the empty string t is the claim.

Countable choice, once. AC_ω, applied to the relation "f is such a function for the strings of length d", gives a sequence $F_0, F_1, \ldots$ of these functions. Each is a finite table of digits, so the choice can be read as a choice of numbers.

The path. Let s_0 be the empty string, $s_{d+1} = s_d F_d(s_d)$, and $p(d) = F_d(s_d)$, so that $\bar{p}(d) = s_d$. By induction on d every s_d is extendable. An extendable string reaches depth 0, that is, it belongs to T. So every initial segment of p belongs to T, and p is a path. □

The step that names a child, taken alone, is equivalent to LLPO with no choice principle in either direction: the root of T_α is extendable, and its extendable child is the decision. Countable choice enters only to collect these decisions along all depths. Without countable choice weak König's lemma still has an exact price: it is equivalent to LLPO for a whole sequence of questions at once, with no choice principle in either direction (Proposition 13.9).

Definition 12.73 (Colourings and the infinite pigeonhole principle)**.** For a natural number k, a *colouring of* $\mathbb{N}$ *with* $k+1$ *colours* is a sequence c with values in $\{0, 1, \ldots, k\}$. A strictly increasing sequence σ of natural numbers is *homogeneous* for c when $c(\sigma(n))$ is the same colour for every n. The *infinite pigeonhole principle* states that, for every k, every colouring of $\mathbb{N}$ with $k+1$ colours has a homogeneous sequence.

A strictly increasing sequence of natural numbers satisfies $\sigma(n) \geq n$, by induction on n. Both converses below use one consequence of LPO and countable choice.

Lemma 12.74 (Splitting a double sequence)**.** *Assume LPO and* AC_ω*, and let* $f(N,m) \in \{0,1\}$ *for all* N, m*. Either every row has an entry* 1*, that is, for every* N *some* m *has* $f(N,m) = 1$*, or some row is entirely* 0*.*

Proof. For each N, LPO applied to the row $m \mapsto f(N,m)$ decides whether it has an entry 1. Countable choice collects these decisions into a binary sequence e, with $e(N) = 1$ exactly when row N has an entry 1. LPO applied to $1 - e$ gives either $e(N) = 1$ for every N, which is the first case, or an N with $e(N) = 0$, whose row is entirely 0. □

Theorem 12.75 (The infinite pigeonhole principle is LPO)**.** *If every colouring of* $\mathbb{N}$ *with two colours has a homogeneous sequence, then LPO holds; the proof uses no choice principle. Conversely, LPO and* AC_ω *give the infinite pigeonhole principle, and the passage from two colours to any finite number of colours uses no choice principle. So, under* AC_ω*, the infinite pigeonhole principle, for colourings with any finite number of colours, is equivalent to LPO, and the passage to LPO uses no choice. Countable choice is used in Lemma 12.74 and once more to pick later indices of colour* 1*.*

Proof. Assume the principle for two colours, and let α be a binary sequence. Colour n by $a(n) = 1$ if $\alpha(m) = 1$ for some $m \le n$, and by $a(n) = 0$ otherwise; each value is a bounded search. Let σ be homogeneous for a, with colour b. If $b = 1$, then $a(\sigma(0)) = 1$, and the search behind this value supplies an index $m \le \sigma(0)$ with $\alpha(m) = 1$: the second alternative of LPO. If $b = 0$, fix n. Since $\sigma(n) \ge n$ and $a(\sigma(n)) = 0$, the sequence α vanishes at every index up to $\sigma(n)$, and in particular $\alpha(n) = 0$: the first alternative. Nothing is selected. Two colours are the case $k = 1$ of the infinite pigeonhole principle, so the principle gives LPO with no choice.

Conversely, assume LPO and AC_ω, and let c be a colouring with two colours. Apply Lemma 12.74 to $f(N,m) = c(N+m)$, whose rows are the tails of c. If some tail, from N on, is entirely 0, then $\sigma(n) = N + n$ is homogeneous with colour 0. Otherwise every tail has an entry 1. Countable choice gives a sequence g with $g(n) > n$ and $c(g(n)) = 1$ for every n. Take an index a with $c(a) = 1$, and put $\sigma(0) = a$ and $\sigma(n+1) = g(\sigma(n))$. This sequence is strictly increasing and homogeneous with colour 1.

Finally, we show by induction on k that every colouring with values at most k has a homogeneous sequence, using only the principle for two colours. For $k = 0$ the colouring is constant, and $\sigma(n) = n$ serves. Let c have values at most $k+1$. Colour n by 1 if $c(n) = k+1$ and by 0 otherwise, and let σ be homogeneous for this colouring. If its colour is 1, then σ is homogeneous for c, with colour $k+1$. If its colour is 0, the colouring $n \mapsto c(\sigma(n))$ has values at most k; by the induction hypothesis it has a homogeneous sequence τ, with some colour i. Then $n \mapsto \sigma(\tau(n))$ is strictly increasing, since σ and τ are, and $c(\sigma(\tau(n))) = i$ for every n. This step selects nothing. □

Both uses of countable choice in the converse select uniquely determined data: each decision $e(N)$ in Lemma 12.74 is the only correct bit, and $g(n)$ can be taken to be the least index above n of colour 1. So the converse needs only the principle of unique choice, that a relation with exactly one witness for each n defines a sequence.

Definition 12.76 (Ramsey's theorem for pairs)**.** A *colouring of pairs with two colours* assigns a colour $c(x, y) \in \{0, 1\}$ to each pair of natural numbers $x < y$. A strictly increasing sequence σ is *homogeneous* for c when $c(\sigma(i), \sigma(j))$ is the same colour for all $i < j$. *Ramsey's theorem for pairs with two colours* states that every colouring of pairs with two colours has a homogeneous sequence.

Theorem 12.77 (Ramsey's theorem for pairs is LPO)**.** *Ramsey's theorem for pairs with two colours gives LPO; the proof uses no choice principle. Conversely, LPO and* AC_ω *give Ramsey's theorem for pairs with two colours; countable choice is used through Lemma 12.74, once to pick a successor for every node, and through Theorem 12.75.*

Proof. Assume Ramsey's theorem for pairs, and let a be a colouring of $\mathbb{N}$ with two colours. Colour each pair $x < y$ by $a(x)$, and let σ be homogeneous for this colouring of pairs, with colour b. For every n, $a(\sigma(n))$ is the colour of the pair $\sigma(n) < \sigma(n + 1)$, which is b; so σ is homogeneous for a. Theorem 12.75 turns this into LPO, and neither step uses a choice principle.

For the converse assume LPO and AC_ω, and fix a colouring c of pairs with two colours.

The tree of the colouring. The tree is that of Erdős and Rado [17]. By recursion on x, call x an *ancestor* of y, written $x \prec y$, when $x < y$ and $c(w, x) = c(w, y)$ for every ancestor w of x. Every ancestor of x is smaller than x, so each instance is decided by a finite computation. Four properties follow, each by induction on the smallest node involved.

(i) $0 \prec y$ for every $y > 0$, since 0 has no ancestor.

(ii) If $w \prec x$ and $x \prec y$, then $w \prec y$. Clearly $w < y$. For an ancestor v of w, induction gives $v \prec x$, and then $c(v, w) = c(v, x) = c(v, y)$.

(iii) If $w < x$, $w \prec y$ and $x \prec y$, then $w \prec x$. For an ancestor v of w, (ii) gives $v \prec y$, induction gives $v \prec x$, and so $c(v, w) = c(v, y) = c(v, x)$.

(iv) Let $z \prec x'$ and $b = c(z, x')$, and suppose that no $v < x'$ with $z \prec v$ has $c(z, v) = b$. Then $x' \prec y$ for every $y > x'$ with $z \prec y$ and $c(z, y) = b$. Indeed, let $w \prec x'$. If $w < z$, then $w \prec z$ by (iii), and $c(w, x') = c(w, z) = c(w, y)$. If $w = z$, both colours are b. If $z < w$, then $z \prec w$ by (iii) and $c(z, w) = c(z, x') = b$, which is impossible because $w < x'$.

Nodes with many descendants. Say that z has *many descendants* when for every N some $y \geq N$ has $z \prec y$. By (i) the root 0 has many descendants. Fix a node z, and apply Lemma 12.74 twice: to the double sequence that records whether $N + m$ is a descendant of z with $c(z, N + m) = 1$, and to the one with colour 0. Suppose that for one colour b every row has an entry 1, so that z has descendants y with $c(z, y) = b$ beyond every bound. Take one of them, y_0, and let x' be the least $v \leq y_0$ with $z \prec v$ and $c(z, v) = b$, found by a bounded search. Then $z \prec x'$, and by (iv) every later descendant y of z with $c(z, y) = b$ satisfies $x' \prec y$; there are such y beyond every bound, so x' has many descendants. If instead both applications give an all-zero row, at N_1 for colour 1 and at N_2 for colour 0, then z has no descendant $y \geq N_1 + N_2$, so z does not have many descendants; put $x' = 0$. In every case we have found x' such that, if z has many descendants, then $z \prec x'$ and x' has many descendants.

The path. Countable choice gives a sequence g such that, for every z with many descendants, $z \prec g(z)$ and $g(z)$ has many descendants. Put $x_0 = 0$ and $x_{k+1} = g(x_k)$. By induction on k, every x_k has many descendants and $x_k \prec x_{k+1}$, so in particular $x_k < x_{k+1}$. By (ii), $x_i \prec x_j$ whenever $i < j$. Hence $c(x_i, x_j) = c(x_i, x_{i+1})$ for $i < j$: for $j = i+1$ there is nothing to prove, and for $j > i+1$ it is the definition of $x_{i+1} \prec x_j$ at the ancestor x_i of x_{i+1}.

Homogeneity. Colour $\mathbb{N}$ by $d(i) = c(x_i, x_{i+1})$. By Theorem 12.75, LPO and AC_ω give a homogeneous sequence τ for d, with some colour b. Put $\sigma(n) = x_{\tau(n)}$. It is strictly increasing, and for $i < j$ we have $\tau(i) < \tau(j)$, so

$$c(\sigma(i), \sigma(j)) = c(x_{\tau(i)}, x_{\tau(i)+1}) = d(\tau(i)) = b. \qquad \square$$

What is particular here is the carrier: every row of Table 12.3 is proved on the line built from the ratios of Chapter 4, and every passage from a theorem to its principle, in the table and in the three theorems above, is made without choice.

12.9.16 Monotone convergence splits as LPO does

Table 12.3 repeats the split of LPO.

Proposition 12.78 (A nondecreasing limit is the least upper bound)**.** *If a nondecreasing sequence (x_n) converges to L, then L is a least upper bound of the sequence. No omniscience principle and no choice principle is used. (Limits are unique for every sequence, Theorem 12.26; here this also follows from the uniqueness of least upper bounds.)*

Proof. Suppose $L < x_n$ for some n. By Lemma 12.30, used twice, there are ratios $c < a$ with $L < \eta(c) < \eta(a) < x_n$; take k with $1/(k+1) \le a - c$. Some N has x_m within $1/(k+1)$ of L for every $m \ge N$. For $m = N + n$ we have $x_n \le x_m$, so $\eta(a) < x_m$ by Lemma 12.40(a), while $L < \eta(c)$; Lemma 12.41(b) says that x_m and L are not within $1/(k+1)$, a contradiction. So $x_n \le L$ for every n.

Let b be an upper bound, and suppose $b < L$. Choose ratios $c < a$ with $b < \eta(c) < \eta(a) < L$ and k with $1/(k+1) \le a - c$, and take N as before. Then $x_N \le b < \eta(c)$ gives $x_N < \eta(c)$, while $\eta(a) < L$, and Lemma 12.41(b) again contradicts the choice of N. So $L \le b$.

Two limits of the sequence are therefore two least upper bounds, each below the other, and they are equal by item 2 of Proposition 12.19. $\square$

Proposition 12.79 (Approaching a least upper bound costs exactly $\mathrm{MP}_{\mathrm{bin}}$)**.** *That least upper bounds of sequences are approached by the terms is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$*, in the following sense.*

1. *If every least upper bound of every sequence of points is approached by its terms, then* $\mathrm{MP}_{\mathrm{bin}}$ *holds. The proof uses no choice principle.*

2. *Assume* $\mathrm{MP}_{\mathrm{bin}}$ *and* AC_ω*. Then every least upper bound of a sequence of points is approached by its terms. Countable choice is used only to fix regular sequences naming the terms; for a sequence given by regular sequences no choice is used.*

Proof. For the first statement, let α be a binary sequence that is not all zero, and let $b_n = \eta(\alpha(n))$. The point $\eta(1)$ is an upper bound. It is the least: if an upper bound y had $y < \eta(1)$, every entry of α would be 0, as in the proof of Theorem 12.48, which is excluded; so $\eta(1) \leq y$ for every upper bound y. By hypothesis the ratio 0, which has $\eta(0) < \eta(1)$, is exceeded by some term b_n. Then $b_n \neq \eta(0)$, so $\alpha(n) = 1$.

For the second, let L be a least upper bound of (x_n) and $\eta(q) < L$. Then $\eta(q)$ is not an upper bound, since leastness would give $L \leq \eta(q)$. Fix regular sequences naming the terms, by countable choice unless they are given. Then $\mathrm{MP}_{\mathrm{bin}}$, through Lemma 12.42(c), gives a term with $\eta(q) < x_n$. □

So, with countable choice, monotone convergence is the least-upper-bound principle together with $\mathrm{MP}_{\mathrm{bin}}$, just as LPO is WLPO together with $\mathrm{MP}_{\mathrm{bin}}$: by Theorem 12.45 the first is LPO, by Theorem 12.48 the second is WLPO, and Proposition 12.9 joins them. Proposition 12.79 locates the difference: what monotone convergence adds to a least upper bound is that the terms approach it, and that costs exactly $\mathrm{MP}_{\mathrm{bin}}$.

12.10 A price table for the calculus on the line

Rolle's theorem promises a point where the derivative vanishes. Here is a function for which we can watch that point move. For a point a put

$$f_a(x) = \max(a, 0)\, x(1 - x)(2 - x) + \min(a, 0)\, x(1 - x)(1 + x).$$

Then $f_a(0) = f_a(1) = 0$. If $a > 0$ the derivative $a(2 - 6x + 3x^2)$ vanishes in $[0, 1]$ only at $1 - 1/\sqrt{3} \approx 0.42$; if $a < 0$ the derivative $a(1 - 3x^2)$ vanishes only at $1/\sqrt{3} \approx 0.58$; if $a = 0$ every point is critical. A procedure that returns a critical point c of every f_a would decide a side of every point: one free comparison places c above $9/20$, which excludes $a > 0$, or below $11/20$, which excludes $a < 0$. That is LLPO. Yet a point where the derivative is within a given tolerance of 0 is found by a finite search.

This section prices the calculus of the line; the rows are collected in Table 12.4. Throughout, a ratio q also denotes the point $\eta(q)$, and $|x| = \max(x, -x)$. Points x, y are within $1/(k + 1)$ exactly when $|x - y| \leq 1/(k + 1)$, since a maximum lies at or below a point exactly when both arguments do (Proposition 12.19, item 5). The rules $|u + v| \leq |u| + |v|$, $|uv| = |u|\,|v|$ and "$|u| \leq b$ exactly when $-b \leq u \leq b$" are equations or $\leq$-inequalities proved by cases on the order, so they hold with no principle (Remark 12.20).

Derivatives with a modulus

Definition 12.80 (Derivatives on the line)**.** Let f, g be functions on the points of $\mathbb{R}_\delta$.

1. g is a *uniform derivative* of f on $[0, 1]$ when for every k there is a j such that $|f(y) - f(x) - g(x)(y - x)| \leq |y - x|/(k + 1)$ for all x, y in $[0, 1]$ within $1/(j + 1)$.
2. f has *derivative* d at the point x when for every k there is a j such that $|f(y) - f(x) - d(y - x)| \leq |y - x|/(k + 1)$ for every y within $1/(j + 1)$ of x.

The first notion is Bishop's [38, 14]: one j serves every pair of points. Continuity of g follows.

Lemma 12.81 (A uniform derivative is uniformly continuous)**.** *A uniform derivative g of f on $[0,1]$ is uniformly continuous on $[0,1]$. No omniscience principle and no choice principle is used.*

Proof. For points x, y, w expanding the products gives

$$\big(g(y)-g(x)\big)(w-y) = \big[f(w)-f(x)-g(x)(w-x)\big] - \big[f(w)-f(y)-g(y)(w-y)\big] \\ - \big[f(y)-f(x)-g(x)(y-x)\big].$$

Fix k, let J be the number that the derivative condition supplies at $4k+3$, put $\varepsilon = 1/(4k+4)$ and $t = 1/(4J+4)$, and let x, y in $[0,1]$ be within t. Cotransitivity at $3/8 < 1/2$ gives $y < 1/2$ or $3/8 < y$; put $w = y + t$ in the first case and $w = y - t$ in the second. Since $t \le 1/4$, w lies in $[0,1]$, $|w-y| = t$ and $|w-x| \le 2t \le 1/(J+1)$, so each bracket is at most ε times the distance of its pair: $|g(y)-g(x)|\,t \le \varepsilon(2t+t+t)$. Multiplying by the ratio $1/t$ gives $|g(y)-g(x)| \le 4\varepsilon = 1/(k+1)$. □

Proposition 12.82 (Calculus without principles)**.** *Let g be a uniform derivative of f on $[0,1]$, and let x, y lie in $[0,1]$.*

1. *(The mean value inequality.) If $|g(z)| \le C$ for every z in $[0,1]$, then $|f(y)-f(x)| \le C|y-x|$.*
2. *If $g(z) \ge 0$ for every z in $[0,1]$ and $x \le y$, then $f(x) \le f(y)$. If $g(z) = 0$ for every z in $[0,1]$, then $f(x) = f(y)$.*
3. *If $g(z) > 0$ for every z in $[0,1]$ and $x < y$, then $f(x) < f(y)$.*

No omniscience principle and no choice principle is used.

Proof. For parts 1 and 2 fix k, take j from the derivative condition at k, and put $z_i = x + i(y-x)/(j+1)$ for $i \le j+1$; neighbours are within $1/(j+1)$. Adding the $j+1$ step estimates gives

$$\Big|f(y)-f(x)-\frac{y-x}{j+1}\sum_{i\le j} g(z_i)\Big| \le \frac{|y-x|}{k+1}.$$

In part 1 the sum has absolute value at most $C|y-x|$, so $|f(y)-f(x)| \le C|y-x| + 1/(k+1)$ for every k, and a point at most $1/(k+1)$ above b for every k lies at or below b (a ratio strictly between them is overtaken for large k, as in Lemma 12.52, item 2). In part 2 the sum and $y-x$ are nonnegative, so $f(x)-f(y) \le 1/(k+1)$ for every k; the second assertion is part 1 with $C = 0$. The estimate uses g only between x and y, so part 2 holds on every subinterval on which its hypothesis holds.

For part 3 let z be the midpoint of $x < y$, and take a ratio μ with $0 < \mu < g(z)$ (Lemma 12.52, item 1). By item 3 of that lemma and Lemma 12.81, some j makes $g > \mu$ at the points of $[0,1]$ within $1/(j+1)$ of z. Take a positive ratio $w \le 1/(j+1)$ below half of a ratio lying between 0 and $y-x$; the window $[z-w, z+w]$ lies in $[x,y]$. Part 2 on the window, applied to $f(u) - \mu u$ with derivative $g - \mu \ge 0$, gives $f(z+w) - f(z-w) \ge 2\mu w$, and part 2 on $[x, z-w]$ and $[z+w, y]$ gives $f(x) \le f(z-w)$ and $f(z+w) \le f(y)$. So $f(y) - f(x) \ge 2\mu w > 0$. □

The proof of part 3 seeks a positive lower bound of g only near one point. A bound on all of $[0,1]$ is a compactness statement: Julian and Richman [37] constructed, in Bishop's constructive mathematics with a consequence of Church's thesis, a uniformly continuous function on $[0,1]$ that is positive at every point and has infimum 0.

The fundamental theorem and integrals

Definition 12.83 (Riemann sums and integrals)**.** The *Riemann sum* of a function g on the points at depth m is $R_m(g) = \sum_{i<2^m} g\big(i/2^m\big)\,2^{-m}$. A point I is an *integral of g on* $[0,1]$ when the sums $R_m(g)$ converge to I.

Limits are unique (Theorem 12.26), so g has at most one integral on $[0,1]$. When an antiderivative is known, the integral is not found by a limit at all.

Theorem 12.84 (The fundamental theorem of calculus is free)**.** *Let g be a uniform derivative of f on $[0,1]$.*

1. *$f(1) - f(0)$ is an integral of g on $[0,1]$.*
2. *For every natural number n, $1/(n+1)$ is an integral of $x \mapsto x^n$ on $[0,1]$.*
3. *(Integration by parts.) If u', v' are uniform derivatives of u, v on $[0,1]$ and J is an integral of $u'v$ on $[0,1]$, then $u(1)v(1) - u(0)v(0) - J$ is an integral of uv' on $[0,1]$.*
4. *(Substitution.) If f is a uniform derivative of F and h' one of h on $[0,1]$, and h maps $[0,1]$ into $[0,1]$, then $F(h(1)) - F(h(0))$ is an integral of $(f \circ h)\,h'$ on $[0,1]$.*

No omniscience principle and no choice principle is used.

Proof. 1. Fix k, take j from the derivative condition at k, and let $m \geq j+1$ and $x_i = i/2^m$. Since $2^m > j+1$, neighbours are within $1/(j+1)$, and telescoping gives

$$\big(f(1) - f(0)\big) - R_m(g) = \sum_{i<2^m} \Big[f(x_{i+1}) - f(x_i) - g(x_i)\,2^{-m} \Big],$$

a sum of 2^m brackets each at most $2^{-m}/(k+1)$ in absolute value. So the sums reach the tolerance $1/(k+1)$ at the stated depth $j+1$.

2. The function $x^{n+1}/(n+1)$ has the uniform derivative x^n, since $y^{n+1} - x^{n+1} - (n+1)x^n(y-x) = (y-x)^2 \sum_{i\leq n} \sum_{l<i} x^{n-1-l}y^l$, a double sum of $n(n+1)/2$ terms in $[0,1]$. Part 1 applies.

3 and 4. A function uniformly continuous on $[0,1]$ is bounded there (Lemma 12.57 and Proposition 12.19, item 4); with Lemma 12.81 and part 1 of Proposition 12.82, the functions u, v, u', v', h', f are bounded and u, v, h have Lipschitz bounds. The product rule follows from the splitting $(uv)(y) - (uv)(x) - (u'v + uv')(x)(y-x) = u(y)\Delta_v + v(x)\Delta_u + (u(y) - u(x))v'(x)(y-x)$, where $\Delta_u = u(y) - u(x) - u'(x)(y-x)$ and Δ_v likewise, and the chain rule from $F(h(y)) - F(h(x)) - f(h(x))h'(x)(y-x) = \Delta_F + f(h(x))\Delta_h$, with Δ_F taken between the points $h(x), h(y)$ of $[0,1]$. So $u'v + uv'$ is a uniform derivative of uv and $(f \circ h)h'$ one of $F \circ h$. Part 1 applies to both; for parts, Riemann sums are additive and limits subtract. $\square$

Without an antiderivative an integral is a limit, and our proof takes it with countable choice. One dyadic grid serves every interval. For points a, b and a natural number A with $|a|, |b| \le A$, let $\kappa_i(x) = \max\big(i/2^n, \min((i+1)/2^n, x)\big)$ be the clamp to the cell $[i/2^n, (i+1)/2^n]$ and

$$S_n^A(f; a, b) = \sum_{i < 2A \cdot 2^n} f\big(i/2^n - A\big)\,\big(\kappa_i(b + A) - \kappa_i(a + A)\big).$$

The weight of a cell is the oriented length of its part of the shifted interval, so a and b need not be compared. A point I is an *integral of f from a to b* when the sums $S_n^A(f; a, b)$ converge to I for every natural number A with $|a|, |b| \le A$; for $a = 0$ and $b = 1$ they are the sums $R_n(f)$. A function is *uniformly continuous on the line* when for every k some j makes points within $1/(j+1)$ have values within $1/(k+1)$. It is *continuous at* a point b when for every k some j makes the points within $1/(j+1)$ of b have values within $1/(k+1)$ of $f(b)$.

Proposition 12.85 (Integrals over intervals)**.** *Let f be a function on the points of $\mathbb{R}_\delta$.*

1. *Assume AC_ω. If f is uniformly continuous on the line, it has an integral from a to b for all points a, b. Countable choice is used once, for the limit, at pairs of ratios (Corollary 12.35); no modulus is selected, and no omniscience principle is used.*
2. *If I_1, I_2, I_3 are integrals of f from a to b, from b to c and from a to c, then $I_1 + I_2 = I_3$.*
3. *If $F(x)$ is an integral of f from a to x for every point x, and f is continuous at b, then F has derivative $f(b)$ at b.*

Parts 2 and 3 use no omniscience principle and no choice principle.

Proof. 2. With A bounding $|a|, |b|, |c|$ the weights of each cell add, so $S_n^A(f; a, b) + S_n^A(f; b, c) = S_n^A(f; a, c)$ at every depth; limits add.

3. Given $\varepsilon = 1/(k+1)$, take j with $|f(y) - f(b)| \le \varepsilon$ for y within $1/(j+1)$ of b, let x be within $1/(2j+2)$ of b, and let $2^{-n} \le 1/(2j+2)$. By part 2, $S_n^A(f; a, x) - S_n^A(f; a, b) = S_n^A(f; b, x)$, whose weights add up to $x - b$ and have absolute values adding up to $|x - b|$; a cell of nonzero weight has its left end within $1/(j+1)$ of b. These are equations and inequalities proved by cases on the order of $b + A$, $x + A$ and the ends of the cells (Remark 12.20). So $|S_n^A(f; b, x) - f(b)(x - b)| \le \varepsilon |x - b|$, and in the limit $|F(x) - F(b) - f(b)(x - b)| \le \varepsilon |x - b|$.

1. From depth n to $n + e$ each cell splits into cells whose weights add up to its weight, and left ends move by at most 2^{-n}; so $|S_n^A - S_{n+e}^A| \le \varepsilon |b - a|$ when f varies by at most ε over 2^{-n}. Given k, uniform continuity at $\varepsilon = 1/((2A+1)(2k+2))$ supplies a j, and from $n = j + 1$ on the sums lie within $\varepsilon |b - a| \le 1/(2k+2)$ of S_n^A, hence within $1/(k+1)$ of one another. So the sums form a Cauchy sequence of points; nothing is selected, since the Cauchy condition asks only for some index at each k. Corollary 12.35, with one countable choice at pairs of ratios, gives the limit. The sums do not depend on A: added cells have weight zero, and shared cells are translates. □

The mean value theorems

Theorem 12.86 (An approximate mean value point costs nothing)**.** *Let g be a uniform derivative of f on $[0,1]$. For every k some point ξ of $[0,1]$ has $g(\xi)$ within $1/(k+1)$ of $f(1)-f(0)$. No omniscience principle and no choice principle is used.*

Proof. Write $c = f(1)-f(0)$ and $\varepsilon = 1/(2k+2)$. Let J be the larger of the numbers that uniform continuity of g (Lemma 12.81) and the derivative condition supply at $2k+1$, and let $x_i = i/(J+1)$ and $h = 1/(J+1)$. Then $g(x_i)$, $g(x_{i+1})$ are within ε and $|f(x_{i+1}) - f(x_i) - g(x_i)h| \le \varepsilon h$. For each $i \le J$, cotransitivity at $c-2\varepsilon < c-\varepsilon$ and at $c+\varepsilon < c+2\varepsilon$ gives one of: (L) $g(x_i) < c-\varepsilon$; (H) $g(x_i) > c+\varepsilon$; (M) $c-2\varepsilon < g(x_i) < c+2\varepsilon$. A finite search finds an i in case (M), which serves as ξ, or labels every i with (L) or (H). The second outcome is impossible. Neighbours labelled (L) and (H) would have values more than 2ε apart, so all labels agree. If all are (L), telescoping gives

$$c = \sum_{i\le J}\big(f(x_{i+1}) - f(x_i)\big) \le \sum_{i\le J}\big(g(x_i)+\varepsilon\big)h < \sum_{i\le J} c\,h = c,$$

and if all are (H) the reversed estimate gives $c > c$. □

Theorem 12.87 (Rolle's theorem and the mean value theorems cost LLPO)**.** *Consider the following assertions, each for all functions f, g on the points with uniform derivatives f', g' on $[0,1]$:*

(A) (Rolle.) If $f(0) = f(1)$, some c in $[0,1]$ has $f'(c) = 0$.

(B) (The mean value theorem.) Some c in $[0,1]$ has $f'(c) = f(1) - f(0)$.

(C) (Cauchy's form.) Some c in $[0,1]$ has $\big(g(1)-g(0)\big)f'(c) = \big(f(1)-f(0)\big)g'(c)$.

1. *Each of them implies LLPO. The proof uses no choice principle.*
2. *Assuming AC_ω, LLPO implies all three. Countable choice is used through Theorems 12.60 and 12.54.*
3. *The forms with $0 < c < 1$ imply these, and so they imply LLPO.*

Proof. Assertion (C) with $g(x) = x$ is (B), and (B) with $f(0) = f(1)$ is (A); so for the first statement it suffices that (A) implies LLPO. Let a be a point, $A = \max(a,0)$, $B = \min(a,0)$, $h_1(x) = x(1-x)(2-x)$ and $h_2(x) = x(1-x)(1+x)$. Since

$$h_1(y) - h_1(x) - (2 - 6x + 3x^2)(y-x) = (y-x)^2(y+2x-3),$$
$$h_2(y) - h_2(x) - (1 - 3x^2)(y-x) = -(y-x)^2(y+2x),$$

with both last factors in $[-3,3]$ on $[0,1]$, the function $f = Ah_1 + Bh_2$ has the uniform derivative $f' = Ah_1' + Bh_2'$, and $f(0) = f(1) = 0$. Let $f'(c) = 0$ with c in $[0,1]$. The factorizations

$$h_1'(c) + \tfrac{37}{400} = 3\big(c - \tfrac{9}{20}\big)\big(c - \tfrac{31}{20}\big), \qquad h_2'(c) - \tfrac{37}{400} = 3\big(\tfrac{11}{20} - c\big)\big(\tfrac{11}{20} + c\big)$$

give $h_1'(c) \le -37/400$ for $9/20 \le c \le 1$ and $h_2'(c) \ge 37/400$ for $0 \le c \le 11/20$. Cotransitivity at $9/20 < 11/20$ gives $9/20 < c$ or $c < 11/20$. In the first case $a > 0$ would give $A = a$, $B = 0$ and $f'(c) = ah_1'(c) < 0$; so $a \le 0$. In the second case $a < 0$ would give $f'(c) = ah_2'(c) < 0$; so $a \ge 0$. This is LLPO by Corollary 12.18, and c was compared once.

For the second statement let $f(0) = f(1)$. By Lemma 12.81 and Theorem 12.60, applied to f' and to $-f'$, there are c_1, c_2 in $[0,1]$ with $f'(c_1) \le f'(y) \le f'(c_2)$ for every y in $[0,1]$. Part 2 of Proposition 12.82, applied to $f(x) - f'(c_1)x$ and to $f'(c_2)x - f(x)$ at $0 \le 1$, gives $f'(c_1) \le 0 \le f'(c_2)$. Theorem 12.54, applied to $t \mapsto f'\big(c_1 + t(c_2 - c_1)\big)$, uniformly continuous since $|c_2 - c_1| \le 1$, gives a root t, and $c = c_1 + t(c_2 - c_1)$. This is (A). Applied to $f(x) - \big(f(1) - f(0)\big)x$ it gives (B), and applied to $\big(g(1) - g(0)\big)f - \big(f(1) - f(0)\big)g$ it gives (C). The third statement holds because $0 < c < 1$ gives $0 \le c \le 1$. □

For the open-interval forms no converse is proved: an extremal point of f' may sit at an end of the interval, and moving it inside is not a decision that LLPO supplies by this route.

The exponential function

Proposition 12.88 (The exponential function is free)**.** *For every point x the partial sums $E_N(x) = \sum_{m<N} x^m/m!$ converge. Their limit $\exp(x)$ defines a function on the points, and*

1. $\exp(0) = 1$ *and* $\exp(x + y) = \exp(x)\exp(y)$ *for all points x, y;*
2. $|\exp(h) - 1 - h| \le |h|^2$ *whenever* $|h| \le 1$*;*
3. $\exp$ *has derivative* $\exp(x)$ *at every point x, and it is continuous at every point; on* $[0,1]$*, and on every interval* $[a,b]$*, it is a uniform derivative of itself;*
4. $1 + x \le \exp(x)$ *for* $x \ge 0$*, so for every point M some point N has* $M \le \exp(x)$ *whenever* $x \ge N$*.*

No omniscience principle and no choice principle is used.

Proof. Take a natural number $V \ge 1$ with $|x| \le V$. For $m + 1 \ge 2V$ the term $V^{m+1}/(m+1)!$ is at most half of $V^m/m!$, and $V^N/N! \le V^{2V}2^{-(N-2V)} = (2V)^{2V}2^{-N}$; so $|E_{N+d}(x) - E_N(x)| \le 2(2V)^{2V}2^{-N}$ for $N \ge 2V$. The points $E_N(x)$ are computed from one regular sequence naming x by the ring operations, so at the indices given by this modulus they form a Cauchy family whose diagonal names the limit (Theorem 12.25). Another sequence naming x gives the same points and so the same limit: exp is a function on the points, and nothing is chosen.

1. By the binomial theorem $E_N(x)E_N(y) - E_N(x+y)$ is the sum of the terms $x^i y^j/(i!\,j!)$ with $i, j < N \le i + j$, at most a tail of the series at $|x| + |y|$ in absolute value; so the limits agree. 2. For $N \ge 2$, $|E_N(h) - 1 - h| \le |h|^2 \sum_{2 \le m < N} 1/m! \le |h|^2$, and the bound passes to the limit (Lemma 12.52, item 2). 3. By part 1, $\exp(y) - \exp(x) - \exp(x)(y - x) = \exp(x)\big(\exp(y - x) - 1 - (y - x)\big)$, which part 2 bounds by $A|y - x|^2 \le |y - x|/(k + 1)$ when $A \ge |\exp(x)|$ is a natural number and $|y - x| \le 1/((A + 1)(k + 1))$; a derivative at a point gives continuity there. On an interval $[a,b]$ take a natural number $V \ge 1$ with $|a| \le V$ and $|b| \le V$. For $|x| \le V$ every term satisfies $V^m/m! \le (2V)^{2V}2^{-m}$ (for $m \le 2V$ because $V^m \le V^{2V}$, and beyond by the halving above), so

$|E_N(x)| < 2(2V)^{2V}$ and $|\exp(x)| \le 2(2V)^{2V}$. The one number $A = 2(2V)^{2V}$ therefore serves every x of $[a,b]$ at once, and j with $j+1 \ge (A+1)(k+1)$ is a modulus for the whole interval: this is the condition of Definition 12.80(1) on $[a,b]$ in place of $[0,1]$. 4. For $x \ge 0$ the terms of $E_N(x) - 1 - x$ are nonnegative; and $x \ge |M|$ gives $M \le x < 1 + x \le \exp(x)$. □

Three more limits

Theorem 12.89 (Monotone limits, open-interval roots and images)**.** *Consider the assertions:*

(i) every nondecreasing sequence (x_n) of points tends to infinity (for every point M some N has $M \le x_n$ for every $n \ge N$) or converges;

(ii) for every f uniformly continuous on $[0,1]$ and every point v with $f(0) < v < f(1)$, some c with $0 < c < 1$ has $f(c) = v$;

(iii) for every f uniformly continuous on $[0,1]$ there are points m, M with $m \le f(y) \le M$ for every y in $[0,1]$, such that every v with $m \le v \le M$ is a value $f(x)$ at a point x of $[0,1]$.

Assertion (i) implies LPO, and (ii) and (iii) each imply LLPO, with no choice principle. Conversely, LPO and AC_ω give (i), and LLPO and AC_ω give (ii) and (iii).

Proof. (i) A sequence bounded by b does not tend to infinity, since $M = b + 1$ would give $b + 1 \le x_n \le b$; so (i) gives monotone convergence, hence LPO (Theorem 12.45). Conversely, fix regular sequences naming the terms, by countable choice. For each natural number M, Lemma 12.42(a) gives a term above M or the bound $x_n \le M$ for all n; countable choice collects these decisions into a binary sequence, and LPO applied to it gives either a term above every natural number, and then the sequence, being nondecreasing, tends to infinity, or a natural bound, and then Theorem 12.45 gives a limit.

(ii) For a point a let $f(x) = \min\bigl(x - \frac{1}{3}, 0\bigr) + \max\bigl(x - \frac{2}{3}, 0\bigr) + a\,x(1-x)$, uniformly continuous on $[0,1]$ with $f(0) = -\frac{1}{3} < 0 < \frac{1}{3} = f(1)$. Let $0 < c < 1$ with $f(c) = 0$, so that $c(1-c) > 0$. Cotransitivity gives $\frac{1}{3} < c$, where the first two terms add up to at least 0, so that $a > 0$ would make $f(c)$ positive, or $c < \frac{2}{3}$, where they add up to at most 0, so that $a < 0$ would make $f(c)$ negative. So $a \le 0$ or $a \ge 0$, which is LLPO. Conversely, Theorem 12.54 applied to $f - v$ gives c in $[0,1]$ with $f(c) = v$. Uniform continuity gives a j such that points of $[0,1]$ within $1/(j+1)$ of 0 have values below v, and cotransitivity at $1/(2j+2) < 1/(j+1)$ gives $c > 1/(2j+2)$, the other case being excluded. In the same way $c < 1$.

(iii) A point x with $f(x) = M$ is a maximum point, so Theorem 12.60 gives LLPO. Conversely, that theorem applied to f and $-f$ gives c_1, c_2 with $m = f(c_1) \le f(y) \le f(c_2) = M$, and Theorem 12.54 applied to $t \mapsto f\bigl(c_1 + t(c_2 - c_1)\bigr) - v$ gives the point for v. □

Finite cores of two limit theorems

A sequence is Cauchy when, for every k, its terms from some index on lie within $1/(k+1)$ of one another. Its no-counterexample form [55] asks only that for every k and every proposed spacing g some window $[N, N + g(N)]$ be stable, its terms within $1/(k+1)$ of one another. This is *metastability*; for monotone sequences it comes with a bound on where to look [56].

Theorem 12.90 (Metastability with an explicit rate)**.** *Let (x_n) be nondecreasing with $x_n \le x_0 + K$ for every n, K a natural number. Let k be a natural number and g a function from the natural numbers to themselves, and put $N_0 = 0$, $N_{i+1} = N_i + g(N_i)$. Then some $i \le K(2k+2)$ has x_m, x_n within $1/(k+1)$ for all m, n in $[N_i, N_i + g(N_i)]$. Consequently:*

1. *every bounded nondecreasing sequence is* metastable*: for every k and g some N has the terms with indices from N to $N + g(N)$ within $1/(k+1)$ of one another;*
2. *for every sequence bounded above and all k, g some N has $x_m \le \max(x_0, \dots, x_N) + 1/(k+1)$ for every $m \le N + g(N)$.*

None of this uses an omniscience principle or a choice principle. The assertion that every bounded nondecreasing metastable sequence is Cauchy implies LPO, with no choice principle, and follows from LPO and AC_ω.

Proof. Let $d_i = x_{N_{i+1}} - x_{N_i} \ge 0$. Cotransitivity gives $d_i < 1/(k+1)$ or $d_i > 1/(2k+2)$, and a search over $i \le K(2k+2)$ finds a first i of the first kind or shows that all are of the second. In the second case $x_{N_{K(2k+2)+1}} - x_0 = \sum_{i \le K(2k+2)} d_i > K$, against the bound. In the first, for m, n in $[N_i, N_{i+1}]$ monotonicity gives $x_{N_i} \le x_m, x_n \le x_{N_{i+1}} \le x_{N_i} + 1/(k+1)$. For item 1 an upper bound lies below $x_0 + K$ for a natural number K; for item 2 apply item 1 to the running maxima (Proposition 12.37). By item 1 the last assertion makes every bounded nondecreasing sequence Cauchy, which gives LPO by Theorem 12.46; conversely, LPO and AC_ω give a limit (Theorem 12.45). □

The bound $K(2k+2)$ does not depend on g. Sequential compactness (Theorem 12.47) has a finite core of the same kind.

Proposition 12.91 (A finite Bolzano–Weierstrass theorem)**.** *Let (x_n) be a sequence of points of $[0,1]$, and let k, M be natural numbers. Some indices $n_0 < n_1 < \cdots < n_M \le 3^{k+1}M$ have terms pairwise within $1/(k+1)$. No omniscience principle and no choice principle is used. If the terms are given by regular sequences, a program finds indices $n_0 < n_1 < \cdots < n_M \le (3^{k+2}+1)M$ with terms pairwise within $1/(k+1)$, by reading one stage of each of the first $(3^{k+2}+1)M + 1$ terms.*

Proof. Put $m = k+1$ and cover $[0,1]$ by the windows $W_q = [q/3^m, (q+2)/3^m]$, $q < 3^m$, of width $2/3^m \le 1/(k+1)$. A point y of $[0,1]$ is placed in a window by going through q with cotransitivity at $(q+1)/3^m < (q+2)/3^m$: the first q with $y < (q+2)/3^m$, or the last window, contains y. By induction each of the $3^m M + 1$ indices $0, \dots, 3^m M$ is assigned a window. There are 3^m windows, so one of them holds $M+1$ of these indices, and their terms are pairwise within $1/(k+1)$ by Lemma 12.41(a).

For the program put $D = 3^{k+2}$, and let r_n be stage $D-1$ of the regular sequence of x_n, so that $\eta(r_n)$ is within $1/D$ of x_n and $-1/D \le r_n \le 1 + 1/D$. Label n by the least integer $q \ge -1$ with $r_n \le (q+2)/D$, a comparison of ratios; then $q \le D-1$ and $q/D \le r_n \le (q+2)/D$. Among the $(D+1)M+1$ indices $n \le (D+1)M$ some $M+1$ share one of the $D+1$ labels. Their stages lie within $2/D$ of one another, so their terms lie within $4/D \le 1/(k+1)$, since $4(k+1) \le 3^{k+2}$. □

The infinite pigeonhole step, some window holds infinitely many terms, costs LPO (Theorem 12.75).

A unique root costs nothing

What LLPO pays for in Theorem 12.54 is a decision between roots. With a modulus of uniqueness, approximate roots converge.

Theorem 12.92 (Roots from a modulus of uniqueness)**.** *Let F be uniformly continuous on $[0,1]$, with a* modulus of uniqueness *μ: any two points of $[0,1]$ at which F is within $1/(\mu(k)+1)$ of 0 are within $1/(k+1)$. Let regular sequences $\xi_0, \xi_1, \ldots$ name points of $[0,1]$, with F within $1/(k+1)$ of 0 at the point of ξ_k. Put $\nu(0) = \mu(0)$ and $\nu(k+1) = \nu(k) + \mu(k+1) + 1$. Then the diagonal of the family $\xi_{\nu(0)}, \xi_{\nu(1)}, \ldots$ names a root of F in $[0,1]$. If moreover $F(0) \le 0 \le F(1)$, F has a modulus of uniform continuity given as a function, and regular sequences name the values of F at the points $j/3^n$, then the root is computed from these data. No omniscience principle and no choice principle is used.*

Proof. ν is nondecreasing with $\nu(k) \ge \mu(k)$ and $\nu(k) \ge k$. For $m, n \ge k$ the values of F at the points of $\xi_{\nu(m)}$ and $\xi_{\nu(n)}$ are within $1/(\mu(k)+1)$ of 0, so these points are within $1/(k+1)$: a Cauchy family. Theorem 12.25 gives its limit x, which lies in $[0,1]$ (Lemma 12.52, item 2). Given k, take j from uniform continuity at $2k+1$ and $m = \max(j, 2k+1)$: $F(x)$ is within $1/(2k+2)$ of F at the point of $\xi_{\nu(m)}$, which is within $1/(2k+2)$ of 0. So $F(x) = 0$ (Corollary 12.24).

In the presented case let ω be the given modulus, fix k, and take n with $3^{-n} \le 1/(\omega(2k+1)+1)$. Read stage $4k+3$ of the given sequence of each value $F(j/3^n)$, $j \le 3^n$. A stage above $-3/(4k+4)$ gives $F(j/3^n) > -1/(k+1)$, and a stage at or below it gives $F(j/3^n) \le -1/(2k+2)$. With these comparisons of ratios in place of cotransitivity, the search of Theorem 12.55 on the grid $j/3^n$ returns a grid ratio at which F is within $1/(k+1)$ of 0; its constant sequence serves as ξ_k. □

With Theorem 12.55 and one countable choice of regular sequences, every uniformly continuous F with $F(0) \le 0 \le F(1)$ and a modulus of uniqueness therefore has a root, at no omniscience price, as in the strictly increasing case of Theorem 12.56.

Banach's fixed point theorem

Theorem 12.93 (Banach's fixed point theorem needs no omniscience)**.** *Let T map $[0,1]$ into itself with $|Tx - Ty| \le r|x - y|$ for x, y in $[0,1]$, where $r = p/(q+1)$ for natural numbers $p \le q$. Write T^n for the nth iterate and $N(k) = (q+1)(k+1)$.*

1. *For x in $[0,1]$ and $m \le m'$, $|T^m x - T^{m'} x| \le r^m$; also $r^{N(k)} \le 1/(k+1)$, and T has at most one fixed point in $[0,1]$.*
2. *If a map $\hat{T}$ of regular sequences gives T, in that $\hat{T}s$ names T of the point of s, then for every regular s naming a point of $[0,1]$ the diagonal of the sequences $\hat{T}^{N(k)}s$ names a fixed point of T.*
3. *If regular sequences name the points $x, Tx, T^2x, \ldots$ of one orbit, x in $[0,1]$, then T has a fixed point in $[0,1]$.*

None of this uses an omniscience principle or a choice principle. Assuming AC_ω, every such T has a fixed point in $[0,1]$; countable choice is used once, for the representatives of one orbit.

Proof. 1. By induction $|T^n u - T^n v| \le r^n |u - v|$ on $[0,1]$; take $u = x$ and $v = T^{m'-m}x$, which are within 1. If $p = 0$, then $r^{N(k)} = 0$. If $p \ge 1$, then $q \ge 1$ and $r \le q/(q+1)$, and Bernoulli's inequality gives $(1+1/q)^{q+1} \ge 1+(q+1)/q \ge 2$, so $r^{q+1} \le 1/2$ and $r^{N(k)} \le 2^{-(k+1)} \le 1/(k+1)$. Fixed points a, b have $|a-b| \le r|a-b|$ with $r < 1$, so $a = b$.

2. By part 1 the points $T^{N(k)}x$ of the sequences $\hat{T}^{N(k)}s$ form a Cauchy family. Theorem 12.25 gives a point L of $[0,1]$ with $T^{N(k)}x$ within $1/(k+1)$ of L, and

$$|TL - L| \le |TL - T^{N(k)+1}x| + |T^{N(k)+1}x - T^{N(k)}x| + |T^{N(k)}x - L| \le \frac{3}{k+1}$$

for every k, so $TL = L$. 3. The same, with the given sequences. Countable choice, applied once, supplies them. □

The theorem is Banach's [54], read on $\mathbb{R}_\delta$. The choice in part 3 concerns one orbit only. Countable choice at pairs of ratios serves equally: by part 1 the orbit $x, Tx, T^2x, \ldots$ is a Cauchy sequence of points, Corollary 12.35 gives its limit with one such choice, and the estimate of part 2, taken at a large enough index, makes the limit a fixed point. Without unique choice, excluded middle with search-choice does not replace countable choice here, already for maps that send points within $1/(k+1)$ to values within $1/(4k+4)$, as every map with $r \le 1/4$ does.

Theorem 12.94 (Without unique choice, excluded middle does not give Banach's fixed point)**.** *In the theory of Theorem 12.63, with functions on the points written as formulas, the following is not provable: every function on the points that maps* $[0,1]$ *into itself and, for every* k*, sends points of* $[0,1]$ *within* $1/(k+1)$ *to values within* $1/(4k+4)$ *has a fixed point in* $[0,1]$*. The proof reasons in a classical metatheory.*

Proof. In the model of computable sequences, with H, G and the point c of the proof of Theorem 12.63, put $T(x) = H\big(G(x)/8\big)$. The slope bounds $4/3$ for H and $3/2$ for G give $|T(x) - T(y)| \le \frac{1}{4}|x - y|$. For x in $[0,1]$, $G(0) \le G(x)/8 \le 1/8$, because $G(0) \le 0$ and $G(x) \le G(1) = 1$; since H is increasing with $H(G(0)) = 0$ and $H(1) = 1$, $T(x)$ lies in $[0,1]$. A fixed point has $G(x)/8 = G(T(x)) = G(x)$, so $G(x) = 0$ and $x = c$. A computable point differs from c, so $G(x)/8$ is a computable point other than 0, where H is affine with rational coefficients, as in that proof; so T sends computable points to computable points. Its graph is the formula $F_T(\beta, \beta')$: some δ, δ' satisfy $F_{15}(\beta, \delta)$, $F_{15}(\beta', \delta')$, and the stages of δ' are those of δ divided by 8. At F_T the hypotheses hold in the model, and the conclusion would give a computable point x of $[0,1]$ with $x = c$. The instance is false in the model, so it is not a theorem. □

The table

In Table 12.4, f' is a uniform derivative of f on $[0,1]$; in the rows about values and roots f is uniformly continuous on $[0,1]$; "continuous" and "injective" have the meanings of Theorem G.9.

What the classical proofs move along an interval by finite partitions is free. In this table the points that compactness supplies, a critical point, a mean value point, a value taken in the open interval and a point of the image, cost LLPO; a root with a modulus of uniqueness and the fixed point of a contraction cost nothing beyond countable choice.

Assertion on $\mathbb{R}_\delta$	Price	Countable choice
A uniform derivative is uniformly continuous; the mean value inequality; $f' \geq 0$, $f' = 0$, $f' > 0$ make f nondecreasing, constant, strictly increasing (Lemma 12.81, Proposition 12.82)	none	not used
$f(1) - f(0)$ is the integral of f'; the integral of x^n; parts; substitution (Theorem 12.84)	none	not used
A function uniformly continuous on the line has integrals over intervals (Proposition 12.85)	none	used once, for the limit, at pairs of ratios
they add over adjacent intervals, and $F'(b) = f(b)$ where f is continuous (Proposition 12.85)	none	not used
exp exists, $\exp' = \exp$, and $\exp(x + y) = \exp(x)\exp(y)$ (Proposition 12.88)	none	not used
An approximate mean value point (Theorem 12.86)	none	not used
Rolle's theorem, the mean value theorem and Cauchy's form, the point in $[0, 1]$ (Theorem 12.87)	LLPO	in the converse
A value strictly between $f(0)$ and $f(1)$ is taken in the open interval; the values of f fill the interval from a minimum to a maximum (Theorem 12.89)	LLPO	in the converse
A root from a modulus of uniqueness and given approximate roots (Theorem 12.92)	none	not used
A nondecreasing sequence tends to infinity or converges (Theorem 12.89)	LPO	in the converse
A bounded nondecreasing sequence is metastable: a stable window starts at one of $N_0, \ldots, N_{K(2k+2)}$ (Theorem 12.90)	none	not used
... and Cauchy (Theorem 12.90)	LPO	in the converse
$M + 1$ of the first $3^{k+1}M + 1$ terms of a sequence in $[0, 1]$ lie pairwise within $1/(k + 1)$ (Proposition 12.91)	none	not used
A continuous injective map of the line is strictly monotone (Theorem G.9)	$\mathrm{MP}_{\mathrm{bin}}$	not used
A contraction of $[0, 1]$ given on regular sequences has a fixed point (Theorem 12.93)	none	not used
A contraction of $[0, 1]$ has a fixed point (Theorems 12.93 and 12.94)	none	used once, for one orbit (or once at pairs of ratios, Corollary 12.35); excluded middle with search-choice does not replace it (Theorem 12.94)

Table 12.4. The calculus on the line built from ratios, read as Table 12.3: "Price" is the principle equivalent to the assertion, "none" means that the assertion is proved outright, from countable choice where the last column says it is used, and in every priced row the passage to the principle uses no choice. The open-interval forms of the mean value theorems imply LLPO; no converse is proved for them.

12.11 Integrals over the whole line and space, and what completeness costs

How much of the classical calculus of π survives on $\mathbb{R}_\delta$ with no principle at all? The Gaussian integral, the value of $\int |y|e^{-|y|}\,d^3y$, $\zeta(2)$, $\zeta(4)$ and $\zeta(6)$ do, each with the line's own π. What the classical proofs take from completeness is a different matter, and the last part of this section prices it: countable choice of natural numbers gives Cauchy completeness, while completeness, even with unique choice, does not give that choice back over intuitionistic second-order arithmetic.

Two conventions run through the section. The *quarter period* q is the point with $0 < q \le 2$, $\cos q = 0$ and $\sin q = 1$, for the circle functions of Definition 21.6; by Theorem 21.8, $4q = 2\pi_\delta$, and we write π for $2q$. The bound $q \le 2$ matters: $5q$ also has cos $= 0$ and sin $= 1$, since $4q$ is a period of both functions. An *improper integral* is an iterated limit of midpoint sums. On the line, v is the integral of f when the integrals of f over $[-L, L]$, in the sense of Proposition 12.85, come within any $1/(k+1)$ of v for all large natural L. In space, write $\Sigma_s^N(F)$ for the midpoint sum of F over the cube $[-s, s]^3$ cut into $(N+1)^3$ equal cells; W is the *space value* of F when for every k there is S_0 such that for every $s \ge S_0$ some N_0 gives $|\Sigma_s^N(F) - W| \le 1/(k+1)$ for all $N \ge N_0$.

The Gaussian integral, and integrals over space

Theorem 12.95 (The Gaussian integral). *For every point $p > 0$ and every point c,*

$$\int_{-\infty}^{\infty} e^{-py^2+cy}\,dy = \gamma e^{c^2/(4p)}, \qquad \int_{-\infty}^{\infty} y e^{-py^2+cy}\,dy = \frac{c}{2p}\,\gamma e^{c^2/(4p)},$$

where $\gamma > 0$ is the point with $\gamma^2 p = \pi$, as improper integrals on $\mathbb{R}_\delta$; and the improper integral is homogeneous: if v is the integral of f, then Cv is the integral of Cf. No omniscience principle and no choice principle is used.

Proof. The Gaussian has no elementary antiderivative on the line, but in the plane $e^{-|y|^2}$ is the divergence of the field $y(1 - e^{-|y|^2})/(2|y|^2)$, because $\int_0^\rho te^{-t^2}\,dt = (1 - e^{-\rho^2})/2$. The proof follows that field. (i) The midpoint sum of $e^{-u^2-v^2}$ over a square grid is exactly the square of the midpoint sum of e^{-x^2} over the side. (ii) A discrete divergence theorem on the square grid turns the square sum into sums over the four edges; the field is regularized near the origin, within 2ε of the integrand. (iii) On an edge the field is, up to the factor $(1 - e^{-s^2-w^2})/2$, which tends to $\frac{1}{2}$, the flux density $s/(s^2 + w^2)$ of a point source in the plane, whose edge sum scales exactly to $\int_{-1}^{1} dw/(1+w^2) = \arccos(-1/\sqrt{2}) - \arccos(1/\sqrt{2}) = \pi/2$, with the line's arccosine. With the factor $\frac{1}{2}$ each edge gives $\pi/4$, and four edges give π, so the line sums tend to $\sqrt{\pi}$. (iv) Midpoint grids scale exactly, which gives the factor $p^{-1/2}$. For every c, complete the square and move the centre: the derivative in the centre of $\sum e^{-p(y-c')^2}$ is minus a sum of y-derivatives, so it changes only by boundary terms of size $e^{-p(L-|c'|)^2}$, and the range of integration never moves. (v) The integral of Proposition 12.85 uses dyadic left sums; on 2^m cells they differ from midpoint sums by $O(2^{-m})$ for a Lipschitz integrand. The first moment follows from $y\Phi = (c/2p)\Phi - (1/2p)\Phi'$, with $\Phi = e^{-py^2+cy}$, and the fundamental theorem for

left sums. Every step is an estimate with explicit constants, and each limit has an explicit modulus. □

Theorem 12.96 (Radial integration and an elementary space value)**.** *Let F be a function on $[0,\infty)$ with $|F(r)| \le B$ and $|F(r')-F(r)| \le \Lambda|r'-r|$, and let H satisfy $H(0) = 0$, have the derivative $r^2F(r)$ with a uniform quadratic remainder on every $[0,R]$, and tend to H_∞. Then $F(|y|)$ has the space value $4\pi H_\infty$. In particular $\int_{\mathbb{R}^3} |y|e^{-|y|}\,d^3y = 24\pi$ as a space value. No omniscience principle and no choice principle is used.*

Proof. The structure is that of Theorem 12.95 one dimension up. Away from the origin $F(|y|)$ is the divergence of the radial field $\Phi(y) = yH(|y|)/|y|^3$, since $H' = r^2F$. (i) On the line $1/|y|$ has no value at $y = 0$, so the field is regularized with $\sqrt{|y|^2+\varepsilon^2}$ in place of $|y|$; its divergence differs from $F(|y|)$ by at most a constant times ε everywhere, by the Lipschitz bound on F. (ii) A discrete divergence theorem on the cubic grid: the box midpoint sum of a divergence equals the sum of the face midpoint sums of the field up to an error of order $1/N$, whenever the field has uniform quadratic remainders along coordinate lines; the remainders come from sums, products, the chain rule, $1/x$, $\sqrt{x}$ and e^{-x}, each with an explicit constant. (iii) On a face $y_0 = s$ the field is $sH(\rho)/\rho^3$; since $H(\rho)$ tends to H_∞, the face sum is H_∞ times the face flux of the inverse-square field $y/|y|^3$, up to a deficit that the tail bound on H controls. Midpoint grids scale exactly, so that flux does not depend on s: it is the midpoint sum of $(1+u^2+v^2)^{-3/2}$ over $[-1,1]^2$. (iv) That sum tends to $2\pi/3$, the solid angle of a face of the cube: the inner integral has the antiderivative $v/(A\sqrt{A+v^2})$ with $A = 1+u^2$, so the inner integral over $[-1,1]$ is $2/(A\sqrt{A+1})$, and the outer one has the antiderivative $-2\arccos\bigl(u/\sqrt{2+2u^2}\bigr)$, so the outer integral is $2\bigl(\arccos(-\frac{1}{2}) - \arccos(\frac{1}{2})\bigr) = 2\pi/3$, with the line's arccosine. The six faces give 4π. For the particular value take $F(r) = re^{-r}$, so that $H(r) = 6 - e^{-r}(r^3+3r^2+6r+6)$ and $H_\infty = 6$: the space value is $24\pi = 48q$. □

The zeta values with the line's π

Theorem 12.97 (Three zeta values)**.** *On $\mathbb{R}_\delta$, with no omniscience principle and no choice principle,*

$$\sum_{n\ge1}\frac{1}{n^2} = \frac{\pi^2}{6}, \qquad \sum_{n\ge1}\frac{1}{n^4} = \frac{\pi^4}{90}, \qquad \sum_{n\ge1}\frac{1}{n^6} = \frac{\pi^6}{945},$$

as limits of their partial sums. The third statement is false if $\pi = 2q$ is read with q any point with $q > 0$, $\cos q = 0$ and $\sin q = 1$.

Proof. The route is Hofbauer's doubling [209]. For $c = \csc^2 x$, the cosecants $a = \csc^2(x/2)$ and $b = \csc^2(q - x/2)$ satisfy $a + b = 4c$ and $ab = 4c$, by the double-angle formulas. Summing over the 2^n angles $(2k+1)q/2^{n+1}$ gives exact values: $\sum \csc^2 = 2\cdot 4^n$, and for the fourth and sixth powers, from $a^2+b^2 = 16c^2 - 8c$ and $a^3+b^3 = 64c^3 - 48c^2$, closed forms such as $15\sum \csc^6 = 64\cdot 64^n + 40\cdot 16^n + 16\cdot 4^n$. On $[0,2]$ the bounds $1 \le x^2\csc^2 x \le 1 + 8x^2$, raised to the needed power, put $\sum_{k<2^n}(2k+1)^{-2j}$ within $c_j 2^{-n}$ of its limit, which is $q^2/2$, $q^4/6$ and $q^6/15$ for $j = 1,2,3$. For the partial sums $Z(M)$ of $\sum n^{-2j}$, the even terms give $Z(2M) = O(M) + Z(M)/4^j$, where $O(M)$ is the sum over the odd $n \le 2M$; so along $M = 2^n$ the defect from the claimed

value is the odd defect plus a fixed fraction of the previous defect, it contracts to 0, and the monotone partial sums converge. The sine bounds use the series of Definition 21.6 on $[0, 2]$, which is why $q \le 2$ enters.

The refutation. If the value held for every q with $q > 0$, $\cos q = 0$ and $\sin q = 1$, it would hold at the quarter period q and at $5q$; one sequence would converge to $(2q)^6/945$ and to $(10q)^6/945$, and limits are unique, so $(10q)^6 = (2q)^6$, against $q > 0$. The same argument, with the exponents 2 and 4, refutes the first two statements under that reading. □

Two explicit remainders and a step that needs choice

Proposition 12.98 (Remainders with explicit constants)**.** *For points $|u| \le 1$ and $|z| \le 1$,*

$$\left|1 - \cos u - \frac{u^2}{2} + \frac{u^4}{24}\right| \le \frac{|u|^5}{50}, \qquad \left|\cosh z - 1 - \frac{z^2}{2} - \frac{z^4}{24}\right| \le \frac{|z|^6}{600}.$$

If Φ has the derivative f on $[a, b]$ with a uniform quadratic remainder of constant C, the midpoint sum of f with $N + 1$ cells differs from $\Phi(b) - \Phi(a)$ by at most $C(b - a)^2/(2N + 2)$; in particular $\int_0^\infty t^3 e^{-t}\, dt = 6$ as an iterated limit of midpoint sums. No omniscience principle and no choice principle is used.

Proof. The two remainders bound the tails of the alternating and of the positive series beyond the stated terms, with the terms compared to a geometric series on $|u| \le 1$. For the midpoint sums, each cell of width $2w$ contributes $\Phi(e_{n+1}) - \Phi(e_n) - 2w f(m_n)$, which the remainder bounds by $2Cw^2$ on each half; summing over the cells gives the bound. For $\int_0^R t^3 e^{-t}\, dt$ take $\Phi(t) = -e^{-t}(t^3 + 3t^2 + 6t + 6)$; the value on $[0, R]$ is $6 - e^{-R}(R^3 + 3R^2 + 6R + 6)$, which tends to 6. □

The mean value step from pointwise derivatives is different.

Proposition 12.99 (Taylor's step from pointwise derivatives)**.** *Assume countable choice of natural numbers. Let f have the derivative $g(t)$ at every point t with $|t| \le \delta$, in the pointwise sense of Definition 12.80, let $M \ge 0$ and $|g(t) - g(0)| \le M|t|$ there. Then $|f(h) - f(0) - hg(0)| \le Mh^2$ for $|h| \le \delta$. With a uniform derivative in place of the pointwise one the statement holds with no choice.*

Proof. With a uniform derivative this is the mean value inequality of Proposition 12.82. With pointwise derivatives the classical proof bisects: each halving keeps a half on which the increment exceeds its share, and the nested dyadic intervals close down on a point at which the pointwise derivative contradicts that excess. Each halving is a comparison decided only up to a tolerance, so its outcome is asserted to exist, not computed; the halvings form a sequence of natural numbers, and one application of countable choice of natural numbers collects them. The goal is an inequality, a negative statement, but that does not remove the choice: it would need a double-negation shift over the whole sequence. □

Completeness and countable choice

Write $\mathrm{AC}_{\mathbb{N}}$ for countable choice of natural numbers: if every n has some m with $R(n,m)$, there is a sequence f with $R(n, f(n))$ for every n. *Cauchy completeness* of the line says that every Cauchy sequence of points converges.

Theorem 12.100 (Completeness from countable choice of natural numbers, and not back)**.**

1. $\mathrm{AC}_{\mathbb{N}}$ *implies Cauchy completeness of* $\mathbb{R}_\delta$*, with no omniscience principle.*
2. *Over intuitionistic second-order arithmetic with unique choice, Cauchy completeness does not give* $\mathrm{AC}_{\mathbb{N}}$*: no derivation in HAS from finitely many hypotheses, each an instance of Cauchy completeness or of unique choice or the universal closure of one, derives the sentence*

$$\forall X\Big(\forall n\,\exists m\,J(n,m)\in X \to \exists S\big(\forall n\,\exists m\,J(n,m)\in S \wedge \mathrm{Fun}(S) \\ \wedge\ \forall n\,\forall m\,(J(n,m)\in S \to J(n,m)\in X)\big)\Big),$$

where $\mathrm{Fun}(S)$ *says that* $J(n,m)\in S$ *and* $J(n,m')\in S$ *give* $m=m'$*. The same holds for countable choice of pairs of ratios.*

In part 2 a point *is a set S of codes $J(n,c)$, total and single-valued in n, with c the code of a ratio $S(n)$ and $|S(m)-S(n)|\le 1/(m+1)+1/(n+1)$; points S and T are* equivalent *when for every k some N has $|S(n)-T(n)|\le 1/(k+1)$ for all $n\ge N$; and* $\mathrm{Near}_k(S,T)$ *says $|S(n)-T(n)|\le 1/(k+1)+2/(n+1)$ for every n. A formula $P(n,S)$, with a number variable n, a set variable S and any parameters,* names a sequence of points, $\mathrm{Seq}(P)$*, when for every n some point satisfies $P(n,\cdot)$, every set that satisfies it is a point, any two such are equivalent, and every point equivalent to one that satisfies it satisfies it. The instance of Cauchy completeness at P is*

$$\mathrm{Seq}(P)\wedge\forall k\,\exists N\,\forall m,n\ge N\,\forall S,T\big(P(m,S)\wedge P(n,T)\to \mathrm{Near}_k(S,T)\big) \\ \to \exists L\Big(L \text{ is a point}\wedge\forall k\,\exists N\,\forall m\ge N\,\forall S\big(P(m,S)\to\mathrm{Near}_k(S,L)\big)\Big).$$

Conditions and scope.

Base and premises

Part 1: $\mathbb{R}_\delta$ with $\mathrm{AC}_{\mathbb{N}}$ as a hypothesis. Part 2: HAS (Definition 7.14), with a sequence of points named by a formula $P(n,S)$ as displayed above; proved in classical mathematics with the open sets of the real line as truth values.

Conclusion

Completeness costs at most countable choice of natural numbers, applied twice per sequence, to the stages and to the Cauchy indices, and over HAS it does not give that choice back. So "completeness is priced at exactly countable choice" is refuted in its reverse direction.

Proof. (1) Let (x_n) be Cauchy: for every k there is an N with x_m, x_n within $1/(k+1)$ for $m,n\ge N$. Each x_n is a class of regular sequences, and each regular sequence is determined by its stages, which are ratios coded by natural numbers. Apply $\mathrm{AC}_{\mathbb{N}}$ once to the relation between $\langle n,j\rangle$

and the code of a ratio within $1/(j+1)$ of x_n, which holds for some code because x_n is a point, and once to the relation between k and a Cauchy index N for $1/(k+1)$. The chosen ratios, read along the chosen indices, form a regular sequence (Theorem 12.25), and its point is the limit. No representative of a point is chosen beyond these stages, which is why choice into the sequences themselves is not needed.

(2) Take the open sets of $\mathbb{R}$ as truth values (the sheaf model of Fourman and Hyland [59]). Every instance of unique choice has the value $\top$, being part of comprehension. Every instance of Cauchy completeness has the value $\top$ too. On the open set O where its hypotheses hold, read the m-th point at each $z \in O$ as a classical real, the limit of the stages of any member of its class at z. A set that codes a sequence has constant stages on every connected open set on which it does so, so this real is constant on the connected component I of a given point of O; the constants form a classical Cauchy sequence, and a regular sequence of codes for its classical limit, with values $\emptyset$ or the whole space, witnesses the conclusion on all of I. By Lemma 7.21 it suffices that the displayed sentence does not have the value $\top$. Let X have, at the code $J(n,m)$, the open set of points z such that m codes a ratio r with $|r-z| < 1/(n+1)$. Every n has such an m near every z, so the premise has the value $\top$. Suppose an open neighbourhood of 0 lay in the value of the conclusion, with a set S. On a ball around 0 of radius ε, S is total and single-valued, so each n-th value is locally constant, hence constant on the ball, which is connected: one ratio for all z in the ball. For $1/(n+1) < \varepsilon/2$ no ratio lies within $1/(n+1)$ of both $\varepsilon/2$ and $-\varepsilon/2$. For pairs of ratios the argument is the same, with a pair in place of one code. □

Theorem 12.101 (Box integrals and completeness)**.** *Let q be the quarter period, and let F have a modulus of uniform continuity on the zone $[-\pi,\pi]^3$.*

1. *Cauchy completeness implies that F has a zone average: the midpoint averages over $(N+1)^3$ cells converge, and the corner-grid averages converge to the same point. Hence $\mathrm{AC}_{\mathbb{N}}$ implies it.*
2. *If the modulus is given as a function, the zone average exists given only completeness for sequences with the modulus $k \mapsto k$.*
3. *If moreover F has period 2π in each coordinate and v is its zone average, the averages over the box's own modes $2\pi m/(N+1)$ converge to v, with no principle.*

Proof. The midpoint averages form a Cauchy sequence with a modulus computed from the modulus of continuity, with no principle: two grids are compared through a common refinement, cell by cell. Completeness supplies the limit. The corner part compares the corner grid with the midpoint grid cell by cell in the same way. In (2), a modulus function lets the Cauchy indices be computed rather than chosen, so completeness at the fixed modulus $k \mapsto k$ suffices. In (3), the mode grid of a periodic function is a shifted midpoint grid, and the shift changes each average by at most the modulus of continuity at the cell width. □

The fan theorem decides nothing

Theorem 12.102 (The fan theorem adds no omniscience)**.** *Write the decidable fan theorem as a sentence* FAN *of HAS: every decidable binary tree, given as a set of node codes, that every path*

leaves is finite. Then FAN *has the value* $\top$ *in the open sets of every topological space. Consequently HAS derives none of* FAN $\wedge$ MP $\to$ LLPO, FAN $\wedge$ LLPO $\to$ WLPO *and* FAN $\wedge$ WLPO $\to$ MP.

Proof. Fix a space and an open set on which the tree T is decidable and barred. At a point x of it, the nodes whose membership value contains x form a classical decidable tree T_x, since each membership value is open and closed on the open set. Every classical path is a decidable set in the model, with values $\emptyset$ or the whole space, so the bar hypothesis makes it leave T_x. By Kőnig's lemma in classical mathematics [15], T_x has no node of some length N. Decidability at x puts x in the complement value of each of the finitely many nodes of length N; the intersection V of these finitely many open sets is an open neighbourhood of x, and on V, by the tree property, no node of length at least N lies in the tree. So x lies in the value of the conclusion, with the bound N. So the value of FAN is $\top$. The non-derivations follow from Table 7.2 and Theorem 7.42: the one-point compactification of an uncountable set validates MP and not LLPO, the remainder $\beta\mathbb{N} \setminus \mathbb{N}$ validates LLPO and not WLPO, and $\beta\mathbb{N}$ validates WLPO and not MP, and FAN holds in all three. □

Theorem 13.6 makes Heine–Borel for $[0, 1]$ cost exactly the decidable fan theorem. Its direction from the fan theorem to Heine–Borel uses no choice principle and handles only ratios, finite strings and the given sequences, so it goes through in HAS with sets for sequences and covers. So Heine–Borel for $[0, 1]$ buys none of the omniscience principles over HAS either.

Proposition 12.103 (Confined motion for all time)**.** *Let a polynomial vector field on* $\mathbb{R}^n_\delta$ *with ratio coefficients have a polynomial first integral* F *that is coercive:* $|x|^2 \le a + bF(x)$ *for natural numbers* a *and* b*. Then every state* y *with ratio coordinates lies on a motion* $X : \mathbb{R}_\delta \to \mathbb{R}^n_\delta$ *of the field with* $X(0) = y$*, uniformly differentiable on bounded intervals. No omniscience principle and no choice principle is used.*

Proof. The local flow. Fix a box radius R. On the box of radius $R + 1$ the field and its first derivatives are bounded by ratios M and Λ read off its coefficients. Choose k with $2^{-k}M \le 1$ and $2^{-k}\Lambda \le 1$. The field rescaled by 2^{-k} is then a law given by a formula that meets the hypotheses of the Picard–Lindelöf theorem on the box, and from every state y with $|y_i| \le R$ its Euler polygons on $[0, 1]$, computed on regular sequences naming y, stay in the box of radius $R + 1$ and converge uniformly with a modulus fixed by M and Λ. Their limit is a motion through y of the rescaled field, that is, a motion of the field on $[0, 2^{-k}]$. The polygons are computed on the sequences themselves and the limit has an explicit modulus, so the flow Φ is a function of the state formed with no choice, as in part 2 of Theorem 12.93.

All time. Along a motion the first integral is constant, so a motion from y stays in the ball $|x|^2 \le a + bF(y)$; take a natural number R with $R^2 \ge a + bF(y)$, which exists because y has ratio coordinates. The same k serves at every state of that ball. Apply Φ at y, then at the end point, and so on, on the intervals $[j2^{-k}, (j + 1)2^{-k}]$, and in the other time direction with the field reversed; the pieces agree at their end points. They glue to a motion on the whole line, defined on representatives: at a ratio time the piece that contains it is found by comparing ratios, and at a shared end point the two pieces give the same state; along the motion the speed is bounded by a ratio read off M, so the glued map is uniformly continuous on ratio times, and at every time it is the limit of its values along a regular sequence naming that time.

On each piece's interval this limit is the piece itself, which is continuous. A bounded interval meets finitely many pieces, so the motion is uniformly differentiable there. □

Remark 12.104 (Open questions about completeness and motion)**.** Three statements are not settled here.

1. *The converse of Theorem 12.101(1).* Does the existence of zone averages for every F with a modulus of uniform continuity on the zone imply completeness for sequences of points with the modulus $k \mapsto k$? The evident encoding of a sequence into one uniformly continuous function needs the function's values near an accumulation point, which are limits of points without representatives.

2. *Taylor's step with no choice.* Does Proposition 12.99 hold without countable choice of natural numbers? Its exact price is not known.

3. *Completeness from choice, inside HAS.* Does HAS derive every instance of Cauchy completeness, written as in Theorem 12.100(2), from the displayed sentence of countable choice of natural numbers? On $\mathbb{R}_\delta$ the implication holds (Theorem 12.100(1)); inside HAS it would follow from two steps: that sentence gives countable choice of natural numbers for every formula, and each instance of Cauchy completeness follows from one instance of that schema.

Monotonicity from a nonnegative derivative holds in the model of named objects of the computable calculus, where points and sequences have computable names (Section 28.7). That is a fact about the model, proved in classical mathematics; whether monotonicity is free on $\mathbb{R}_\delta$ is open (Section 28.7).

Questions to work through

1. Starting from (12.2), clear the positive denominators and recover (12.1). Identify where positivity is needed to preserve the direction of the inequality.

2. In the proof of Lemma 12.5, explain why the later stage 2^{N+1} is available once a finite search has found the first event N. Why is deciding whether any event exists unnecessary for constructing each jump stage?

3. Reconstruct both directions of Theorem 12.6, then identify the exact step that requires LPO instead of WLPO in Theorem 12.7. Use Proposition 12.13 and Theorem 12.11 to show that this step, taken alone, costs exactly $\mathrm{MP}_{\mathrm{bin}}$.

4. Explain why the interleaved sequence e in Theorem 12.8 need not satisfy LLPO's premise. Prove that retaining only its first event supplies that premise. Trace the two uses of parity in the converse proof.

5. Prove the converse half of Lemma 12.10 in integer arithmetic. Where is decidability of a single stage used, and why does the proof not need to decide $P(x)$?

6. Derive the statement of Corollary 12.12 for N from the statement for P. Check that replacing each q_n by $-q_n$ preserves (12.1).

7. In Theorem 12.45, show that the test sequence is nondecreasing and bounded. The proof uses one limit point and one index N. Explain why using them requires no choice principle.

8. The proof of Theorem 12.48 never decides whether L equals $\eta(0)$ or $\eta(1)$. Explain why cotransitivity is enough. Then, before reading the proof of Theorem 12.49, assume in addition that every ratio below L is exceeded by some term, and show that the same test sequence yields LPO.

Part IV

Compactness, algebra and computation

Part IV asks what three tools of analysis and algebra cost on the line built from ratios, namely compactness, linear algebra and the computation of solutions of differential equations, and what a calculus of δ's own objects can derive about them. Each price is an equivalence proved in ordinary constructive mathematics and stated with the choice it uses. Heine–Borel for compact sets presented with their nets, and positive lower bounds and infima of uniformly continuous maps that come with names of their values and a modulus, are exactly the decidable fan theorem of Chapter 13, with no choice principle; for bare uniformly continuous functions the passage back is proved with countable choice (Theorem 13.31). The linear-algebra prices of Chapter 14 use no choice from an assertion to its principle and at most unique choice in the other direction, which the book's reading of maps contains; the one exception is dominated division, priced LLPO, whose converse uses countable choice (Theorem 14.22).

Chapter 15 computes the solutions of polynomial differential equations whose computed trajectory passes a finite region certificate. The certificate is checked by computation; it is not an assumption about an exact solution. Chapter 16 builds a calculus of δ's own objects. In its computable form, whose terms are maps computed by programs, it shows that statements are not derivable by building a model: in that model LPO holds, while the decidable fan theorem and Heine–Borel for presented compact sets, written with equations, fail. The full calculus, whose terms may carry any map, derives LPO, $\mathrm{WLPO}_{\mathrm{seq}}$ and the scalar pair division of Chapter 14 outright, so its separations are proved for the computable calculus. The chapter reasons about its models in classical mathematics, as Chapters 7 and 12 do.

Chapter 13

What compactness costs

Suppose a sequence of open intervals with ratio endpoints covers $[0,1]$: every point of the interval lies in one of them. Classical analysis keeps finitely many of them. On $\mathbb{R}_\delta$ the cover is given, and so is the knowledge that each point is caught by some interval. What is missing is one number N such that the first N intervals already catch every point. What does it take to produce that number?

Here is a small case. Let $I_0 = (-1, \frac{1}{2})$, $I_1 = (\frac{1}{4}, \frac{3}{4})$ and $I_2 = (\frac{1}{2}, 2)$, and let the later intervals be anything. Halve $[0,1]$ repeatedly, and call a piece $[v/2^m, (v+1)/2^m]$ *caught* when, widened by its own length on each side, it lies strictly inside one of the intervals I_k with $k < m$. Whether a piece is caught is a comparison of ratios. At depth $m = 4$ every one of the sixteen pieces is caught: the widened piece $[(v-1)/16, (v+2)/16]$ lies inside I_0 for $v \leq 5$, inside I_1 for $6 \leq v \leq 9$, and inside I_2 for $v \geq 10$. So the halving stops, and the first three intervals cover $[0,1]$.

For a single point the halving always stops: once the pieces containing it are small enough, the widened piece fits inside an interval that contains the point. The difficulty is uniformity. Different points may need deeper pieces, and nothing in the cover says when to stop. The pieces not yet caught form a binary tree, every branch of it ends, and the question is whether the whole tree ends at one depth. Its answer is a fan theorem.

Heine–Borel for $[0,1]$ is equivalent to the decidable fan theorem FAN_Δ, with no choice principle in either direction (Theorem 13.6). FAN_Δ is not an omniscience principle: it follows from weak König's lemma, hence from LLPO with countable choice and from WLPO with unique choice, but excluded middle without unique choice, even with all the countable choice that a search can witness, does not prove it (Theorem 13.11). It is also the price of positive lower bounds and positive infima on every compact set that comes with its finite nets, for functions that come with names of their values and a modulus of uniform continuity. Uniform continuity of pointwise continuous functions implies FAN_Δ; for the converse we name further data that suffice. Bishop's compactness asserts the nets without handing them over, and asks completeness for Cauchy sequences of points rather than named families; every presented set is Bishop compact exactly when every Cauchy sequence of points converges, with no choice either way (Theorem 13.37). Table 13.1 collects the prices.

Two conventions hold throughout. A ratio compared with a point, or added to one, stands for its point: $a < x$ means $\eta(a) < x$, and $x \leq y + 1/(k+1)$ means $x \leq y + \eta(1/(k+1))$. Binary strings, $\bar{p}(n)$ and decidable binary trees are those of Definition 12.71. We write $\emptyset$ for the empty string, st for the string s followed by the string t, $s{\restriction}m$ for the initial segment of s of length $m \leq |s|$, and $s0^\omega$ for the binary sequence that begins with s and continues with zeros. The number $\nu(s)$ has s as its binary numeral, most significant digit first, and $w_0, w_1, \ldots$ lists all binary strings, by length and, within one length, by numeral.

13.1 Bars and the fan theorems

A set of binary strings can be read as a set of stopping points: a binary sequence stops when one of its initial segments lies in the set.

Definition 13.1 (Bars)**.** A set B of binary strings is a *bar* when every binary sequence p has an n with $\bar{p}(n) \in B$. It is a *uniform bar* when one bound serves all sequences: some N has the property that every binary sequence p has an $n \leq N$ with $\bar{p}(n) \in B$. A set of strings is *decidable* when it is given by a map D from binary strings to $\{0, 1\}$; we use D also for the set of strings s with $D(s) = 1$.

A bar asserts, for each sequence, that a stopping index exists. It supplies no map from sequences to indices. A uniform bar supplies one number for all sequences at once.

Definition 13.2 (Fan theorems)**.** The *decidable fan theorem*, FAN_Δ, states that every decidable bar is a uniform bar. The *c-set* of a decidable D consists of the strings s with $D(st) = 1$ for every string t; FAN_c states that whenever the c-set of a decidable D is a bar, it is a uniform bar. A Π^0_1 *set* of strings is given by a map E from pairs of a string and a number to $\{0, 1\}$: the string s belongs to it when $E(s, n) = 1$ for every n. The set is *monotone* when s belonging implies that sb belongs for each digit b, and E is a *monotone presentation* when $E(s, n) = 1$ implies $E(sb, n) = 1$ for all s, b and n. The Π^0_1 *fan theorem* $\mathrm{FAN}_{\Pi^0_1}$ states that every Π^0_1 bar is a uniform bar; the *monotone* Π^0_1 *fan theorem* states this for monotone Π^0_1 bars, and the Π^0_1 *fan theorem for monotone presentations* for Π^0_1 bars given by a monotone presentation. The *full fan theorem*, FAN, states that every bar, given by an arbitrary property of strings, is a uniform bar.

Brouwer introduced the fan theorem [29]. Its decidable and c-set forms, and the Π^0_1 forms between them and the full theorem, are the yardsticks of compactness in constructive reverse mathematics [32, 31, 34, 35].

Theorem 13.3 (The tree form of the decidable fan theorem)**.** *Say that a binary sequence p* leaves *a tree T when $\bar{p}(n) \notin T$ for some n. Then* FAN_Δ *holds if and only if every decidable binary tree that every binary sequence leaves has a length at which it has no member. Neither direction uses a choice principle or an omniscience principle.*

Proof. Assume FAN_Δ, and let T be a decidable binary tree that every binary sequence leaves. The strings outside T form a decidable bar, so some N has the property that every binary sequence has an initial segment of length at most N outside T. Whether T has a member of length N is decided by inspecting the 2^N strings of that length; suppose s is one. The sequence $s0^\omega$ has an initial segment $s{\restriction}n$ with $n \leq N$ outside T. But $s{\restriction}n$ is an initial segment of the member s, and T is closed under initial segments, so $s{\restriction}n \in T$. This contradiction shows that T has no member of length N.

Conversely, assume the tree form, and let D be a decidable bar. If $D(\emptyset) = 1$, the bound $N = 0$ serves. Otherwise say that s is *seen* when $D(s{\restriction}n) = 1$ for some $n \leq |s|$, a search through $|s| + 1$ initial segments, and let A consist of the strings that are not seen. A contains $\emptyset$, and it is closed under initial segments, since an extension of a seen string is seen; so A is a decidable binary tree. Every binary sequence p leaves A: the bar gives n with $D(\bar{p}(n)) = 1$, so $\bar{p}(n)$ is seen. By the tree form, A has no member of some length N. For a binary sequence p, the

string $\bar{p}(N)$ is therefore seen: some $n \le N$ has $D(\bar{p}(N)\restriction n) = D(\bar{p}(n)) = 1$. So N is a uniform bound. Every step is a finite inspection of data already given. □

The set of strings outside a bar need not be a tree, which is why the proof passes through the strings that are not yet seen. The forms of the fan theorem are ordered by strength.

Proposition 13.4 (From the full fan theorem down to the decidable one)**.** *Each of the following principles implies the next:* FAN*;* $\mathrm{FAN}_{\Pi^0_1}$*; the monotone* Π^0_1 *fan theorem; the* Π^0_1 *fan theorem for monotone presentations;* FAN_c*;* FAN_Δ*. No choice principle is used.*

Proof. A Π^0_1 set is a property of strings, so FAN gives $\mathrm{FAN}_{\Pi^0_1}$; and the monotone forms are special cases. If each approximant $E(\cdot, n)$ is closed under one-digit extension, so is the set of strings s with $E(s, n) = 1$ for every n; so a Π^0_1 set with a monotone presentation is monotone, which gives the third implication.

For the fourth, let D be decidable, and put $E(s, n) = D(w_n)$ if s is an initial segment of w_n and $E(s, n) = 1$ otherwise. Then $E(s, n) = 1$ for every n says exactly that $D(st) = 1$ for every string t, since every extension st is some w_n; so the Π^0_1 set of E is the c-set of D. The presentation is monotone: if sb is an initial segment of w_n, so is s, and then $E(s, n) = 1$ means $D(w_n) = 1$, which is $E(sb, n)$; otherwise $E(sb, n) = 1$. A c-set that is a bar is therefore a Π^0_1 bar with a monotone presentation, and its uniform bound is the one FAN_c asks for.

For the last, let D be a decidable bar, and let S be the set of seen strings of the proof of Theorem 13.3. It is decidable and closed under extension, so its c-set is S itself, and it is a bar because D is. FAN_c gives a uniform bound N for S, and a seen initial segment $\bar{p}(m)$ with $m \le N$ has an initial segment $\bar{p}(n)$, $n \le m$, with $D(\bar{p}(n)) = 1$. □

We prove no converse. Lubarsky and Diener separate the fan theorem from several of these weakenings by models of intuitionistic set theory [34], and Kawai shows that the monotone Π^0_1 fan theorem is equivalent to a strong continuity principle for complete separable metric spaces [35].

13.2 Heine–Borel on $[0, 1]$ is the decidable fan theorem

The covers of the opening are countable and have ratio endpoints. Every open set of the line is a union of such intervals, so nothing is lost for the question at hand, and every finite subcover lies inside an initial segment of the cover.

Definition 13.5 (Ratio covers and cover-compact sets)**.** A *ratio cover* is a sequence of pairs of ratios (a_k, b_k); its kth interval consists of the points x with $a_k < x < b_k$. It *covers* a set K of points when every member of K lies in one of its intervals. The set K is *cover-compact* when every ratio cover of K has an N such that every member of K lies in one of the first N intervals. *Heine–Borel for* $[0, 1]$ is the assertion that $[0, 1]$ is cover-compact.

Theorem 13.6 (Heine–Borel is the decidable fan theorem)**.** *The interval* $[0,1]$ *is cover-compact if and only if* FAN_Δ *holds. Neither direction uses a choice principle or an omniscience principle.*

Proof. By Theorem 13.3 it suffices to show that $[0,1]$ is cover-compact exactly when every decidable binary tree that every binary sequence leaves has a length with no member. We call this the *tree form.*

From the tree form to compactness. Let (a_k, b_k) be a ratio cover of $[0,1]$. A string s of length m stands for the dyadic piece $[\nu(s)/2^m, (\nu(s)+1)/2^m]$. Call s *caught* when some $k < m$ has

$$a_k < \frac{\nu(s)-1}{2^m} \quad \text{and} \quad \frac{\nu(s)+2}{2^m} < b_k,$$

so that the piece, widened by its length on each side, lies inside interval k; this is decided by comparing ratios. Let H consist of the strings none of whose initial segments, the string itself included, is caught. H contains $\emptyset$, which is not caught because there is no $k < 0$, and it is closed under initial segments; so H is a decidable binary tree.

Every binary sequence leaves H. Let p be one, and let x be the point named by the partial sums $c_n = \sum_{i<n} p(i)2^{-(i+1)}$; they form a regular sequence, since $0 \le c_n - c_m \le 2^{-m} \le 1/(m+1)$ for $m \le n$. With $\nu_n = \nu(\bar{p}(n)) = 2^n c_n$, every $m \ge n$ has $\nu_n/2^n \le c_m \le (\nu_n+1)/2^n$, and c_m is within $1/(m+1)$ of x (Lemma 12.52, item 4); so item 2 of that lemma gives $\nu_n/2^n \le x \le (\nu_n+1)/2^n$. In particular x lies in $[0,1]$, hence in some interval k_0 of the cover. By item 1 of the same lemma there are m_1 and m_2 with $a_{k_0} + 1/(m_1+1) < x < b_{k_0} - 1/(m_2+1)$. Put $n = k_0 + 2(m_1+m_2) + 3$ and $\nu = \nu_n$. Then $n > k_0$, and $2/2^n < 2/n$ is smaller than both $1/(m_1+1)$ and $1/(m_2+1)$. Hence

$$a_{k_0} < x - \frac{1}{m_1+1} \le \frac{\nu+1}{2^n} - \frac{1}{m_1+1} < \frac{\nu-1}{2^n}, \qquad \frac{\nu+2}{2^n} \le x + \frac{2}{2^n} < x + \frac{1}{m_2+1} < b_{k_0}.$$

So $\bar{p}(n)$ is caught by the interval $k_0 < n$, and $\bar{p}(n) \notin H$.

An empty level gives the subcover. By the tree form, H has no member of some length N. Let x lie in $[0,1]$. By Proposition 12.62, x has a signed-digit expansion, so some integer z satisfies $(z-1)/2^N \le x \le (z+1)/2^N$. Put $w = 0$ if $z < 0$, $w = 2^N - 1$ if $z \ge 2^N$, and $w = z$ otherwise. Using $0 \le x \le 1$ in the first two cases,

$$\frac{w-1}{2^N} \le x \le \frac{w+2}{2^N}.$$

The string t of length N with $\nu(t) = w$ is not in H, so some initial segment $t{\restriction}m$, $m \le N$, is caught by an interval $j < m$: with $u = \nu(t{\restriction}m)$, we have $a_j < (u-1)/2^m$ and $(u+2)/2^m < b_j$. Since $w = u2^{N-m} + r$ with $0 \le r < 2^{N-m}$,

$$\frac{u-1}{2^m} \le \frac{w-1}{2^N} \quad \text{and} \quad \frac{w+2}{2^N} \le \frac{(u+1)2^{N-m}+1}{2^N} \le \frac{u+2}{2^m}.$$

Hence $a_j < x < b_j$ with $j < N$. So every point of $[0,1]$ lies in one of the first N intervals.

From compactness to the tree form: the Cantor cells. Write $u_n = 1/(8 \cdot 4^n)$. For a string s of length n let $\kappa(s)$ be the number whose base-four digits are $3s_0, \dots, 3s_{n-1}$. The *Cantor point* of s is $c(s) = \kappa(s)/4^n$, and with $\nu = \kappa(s)$ its *Cantor interval* is $J(s) = [8\nu u_n, (8\nu+8)u_n]$. So $c(s)$ is

the left end of $J(s)$, and the intervals $J(s0) = [8v, 8v+2]u_n$ and $J(s1) = [8v+6, 8v+8]u_n$ lie inside $J(s)$, separated by the *gap* $(8v+2, 8v+6)u_n$. The open *cells* $C(s)$, intervals with ratio endpoints, are defined by recursion:

$$C(\emptyset) = (-1, 2), \qquad C(s0) = \big(\ell(s), (8v+5)u_n\big), \qquad C(s1) = \big((8v+3)u_n, r(s)\big),$$

where $\ell(s)$ and $r(s)$ are the ends of $C(s)$. The cells of the two children overlap in $(8v+3, 8v+5)u_n$, inside the gap. Figure 13.1 shows the first two levels. Three facts follow.

(a) *$J(s)$ lies inside $C(s)$, with room at both ends, and $C(sb) \subseteq C(s)$.* By induction on s: $J(\emptyset) = [0, 1]$ lies inside $(-1, 2)$. If $J(s)$ lies inside $C(s)$ with room, the new end $(8v+5)u_n$ of $C(s0)$ exceeds the right end $(8v+2)u_n$ of $J(s0)$ and lies below the right end $(8v+8)u_n$ of $J(s)$, hence inside $C(s)$; the left end of $C(s0)$ is $\ell(s)$, below the common left end of $J(s)$ and $J(s0)$. The string $s1$ is symmetric.

(b) *If $s \neq t$ have the same length, $C(s)$ and $J(t)$ are disjoint.* By induction on the common length; at length 0 there is nothing to prove. Write $s = s'b$ and $t = t'b'$. If $s' \neq t'$, the induction hypothesis applies, because $C(s) \subseteq C(s')$ and $J(t) \subseteq J(t')$. If $s' = t'$, with $v = \kappa(s')$ and $n = |s'|$, then $b \neq b'$: the cell $C(s'0)$ lies below $(8v+5)u_n$, while $J(s'1)$ lies above $(8v+6)u_n$; and $C(s'1)$ lies above $(8v+3)u_n$, while $J(s'0)$ lies below $(8v+2)u_n$. Consequently, *if $|t| \geq |s|$ and $c(t) \in C(s)$, then s is an initial segment of t*: the point $c(t)$ lies in $J(t) \subseteq J(t{\restriction}|s|)$, so $t{\restriction}|s| = s$.

(c) *Every point x of $[0, 1]$ has an address*, a binary sequence p with $x \in C(\bar{p}(n))$ for every n. This is an existence statement about one point, so we may use one regular sequence naming x; nothing is selected. For a string s of length n with $v = \kappa(s)$, let q be the stage $2^{2n+5} - 1$ of that sequence, which is within $2^{-(2n+5)}$ of x (Lemma 12.52, item 4), and give s the digit 0 if $q \leq (32v+16)/2^{2n+5}$ and the digit 1 otherwise. Let $p(n)$ be the digit of $\bar{p}(n)$. If $x \in C(s)$ and the digit is 0, then

$$x \leq q + 2^{-(2n+5)} \leq \frac{32v+17}{2^{2n+5}} < \frac{32v+20}{2^{2n+5}} = (8v+5)u_n,$$

so $x \in C(s0)$; if the digit is 1, then $x \geq q - 2^{-(2n+5)} > (32v+15)/2^{2n+5} > (8v+3)u_n$, so $x \in C(s1)$. Since $x \in C(\emptyset)$, induction gives $x \in C(\bar{p}(n))$ for every n.

From compactness to the tree form: the dead cover. Let T be a decidable binary tree that every binary sequence leaves. The *dead cover* has as its kth interval the empty interval $(0, 0)$ if $w_k \in T$, and the cell $C(w_k)$ if $w_k \notin T$. It covers $[0, 1]$: an address p of x leaves T at some n, and x lies in $C(\bar{p}(n))$, the interval whose index k has $w_k = \bar{p}(n)$. By compactness some N has every point of $[0, 1]$ in one of the first N intervals. Put $d = \sum_{k<N}(|w_k| + 1)$, so that $|w_k| < d$ for every $k < N$. Whether T has a member of length d is decided by inspection; suppose t is one. The point $c(t)$ lies in $[0, 1]$, so in some interval $k < N$. That interval is not empty, so $w_k \notin T$ and $c(t) \in C(w_k)$. As $|w_k| < |t|$, fact (b) makes w_k an initial segment of t, and T, closed under initial segments, contains w_k: a contradiction. So T has no member of length d.

Every step in both directions is a comparison of ratios, a finite inspection, or the use of one regular sequence naming one point. □

The tree H is the halving of the opening example, its members the pieces not yet caught. The second half runs backward: a tree becomes the cover by the cells of its dead strings, and a deep member supplies a Cantor point that no early dead cell contains.

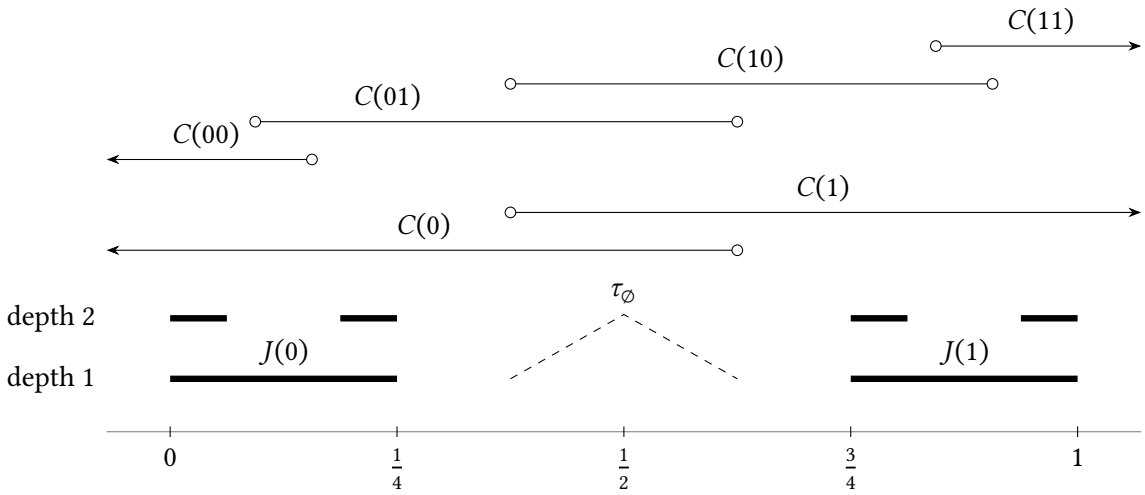

Figure 13.1. The first two levels of the Cantor intervals $J(s)$ (thick) and the open cells $C(s)$ (thin, open ends marked by circles; arrows continue to -1 and 2). The cells of two children overlap only inside the gap of their parent, where no Cantor interval of a later level reaches. The dashed tent $\tau_\varnothing$ of Section 13.4 rises over the overlap of $C(0)$ and $C(1)$.

13.3 Where the fan theorem sits

Weak König's lemma is the statement of Definition 12.71: every infinite decidable binary tree has a path. The fan theorem asks the opposite question about a tree that has no path. The link between them is a tree that is infinite for a reason that needs no decision.

Theorem 13.7 (Weak König's lemma gives the decidable fan theorem)**.** *Weak König's lemma implies* FAN_Δ. *No choice principle, no omniscience principle and no Markov principle is used.*

Proof. We prove the tree form. Let T be a decidable binary tree that every binary sequence leaves. The *padded tree* P consists of the strings s such that, for every $k \le |s|$, either $s{\restriction}k \in T$ or T has no member of length k. Both alternatives are decided by inspection. P contains $\varnothing$ and is closed under initial segments.

P is infinite, with no principle. Given n, decide whether T has a member of length n. If it has one, that member lies in P. If not, find the least $d \le n$ at which T has no member; $d \ge 1$ because $\varnothing \in T$. Take a member e of T of length $d-1$ and pad it with zeros to length n. Its initial segments of length less than d lie in T, and T has no member of any length $k \ge d$, because such a member would have an initial segment of length d in T. So the padded string lies in P.

Weak König's lemma gives a path p through P. Since p leaves T, some n has $\bar{p}(n) \notin T$, and $\bar{p}(n) \in P$ at $k = n$ then says that T has no member of length n. □

Applying weak König's lemma to T itself would need T to be infinite, which is the negation of what we want. The padded tree is infinite outright, and the empty level is read off the path, so no unbounded search for it is made. Ishihara gives a direct proof of the same implication [33].

Weak König's lemma has an exact price of its own, sharper than Theorem 12.72. It needs the omniscience principles for a whole sequence of questions at once.

Definition 13.8 (Omniscience for sequences of rows)**.** Let $A(i,n)$ be a double sequence of bits, with rows $A(i,\cdot)$. $\mathrm{WLPO}_{\mathrm{seq}}$ states that for every such A there is a binary sequence f with $f(i)=1$ exactly when $A(i,n)=0$ for every n. $\mathrm{LLPO}_{\mathrm{seq}}$ states that for every such A whose rows each have at most one entry 1 there is a binary sequence f such that $f(i)=1$ implies $A(i,2k)=0$ for every k, and $f(i)=0$ implies $A(i,2k+1)=0$ for every k.

Each single principle of Definition 7.8 is the case of one row. Conversely, AC_{ω} collects the answers for the rows into one sequence.

Proposition 13.9 (Weak König's lemma is LLPO for sequences)**.** *Weak König's lemma holds if and only if* $\mathrm{LLPO}_{\mathrm{seq}}$ *holds. No choice principle is used in either direction.*

Proof. Assume weak König's lemma, and let A have rows with at most one entry 1. Let S consist of the strings s such that, for every $i<|s|$, $s_i=1$ implies $A(i,m)=0$ for every even $m<|s|$, and $s_i=0$ implies $A(i,m)=0$ for every odd $m<|s|$. Membership is a finite inspection; S contains $\emptyset$ and is closed under initial segments, since a shorter string meets fewer conditions. S is infinite: for a length n, put $s_i=0$ if $A(i,m)=1$ for some even $m<n$, and $s_i=1$ otherwise. In the first case the single entry 1 of row i sits at an even place, so every odd entry is 0. Let f be a path through S. If $f(i)=1$ and k is given, the member $\bar{f}(n)$ with $n>\max(i,2k+1)$ gives $A(i,2k)=0$; if $f(i)=0$, it gives $A(i,2k+1)=0$. So f is the sequence that $\mathrm{LLPO}_{\mathrm{seq}}$ asks for.

Conversely, assume $\mathrm{LLPO}_{\mathrm{seq}}$, and let T be an infinite decidable binary tree. The proof of Theorem 12.72 attaches to each string s a binary sequence γ_s with at most one entry 1, built by bounded searches, and shows: if every even entry of γ_s is 0, then $s0$ is extendable whenever s is; if every odd entry is 0, then $s1$ is extendable whenever s is. Apply $\mathrm{LLPO}_{\mathrm{seq}}$ once, to the double sequence whose row i is γ_{w_i}. It gives f; put $c_s=0$ if $f(i)=1$ and $c_s=1$ if $f(i)=0$, where $s=w_i$. Then sc_s is extendable whenever s is. Let $s_0=\emptyset$ and $s_{d+1}=s_d c_{s_d}$. By induction every s_d is extendable, hence a member of T, and $p(d)=c_{s_d}$ defines a path. The children are named for all strings at once, so nothing is collected. □

Theorem 12.72 is the case in which countable choice turns LLPO into $\mathrm{LLPO}_{\mathrm{seq}}$; that is where its one use of AC_{ω} goes.

Corollary 13.10 (Principles that give the decidable fan theorem)**.**

1. $\mathrm{LLPO}_{\mathrm{seq}}$ *implies* FAN_{Δ}*, with no choice principle. In particular LLPO and* AC_{ω} *imply* FAN_{Δ}*; countable choice is used once, inside Theorem 12.72.*
2. $\mathrm{WLPO}_{\mathrm{seq}}$ *implies* $\mathrm{LLPO}_{\mathrm{seq}}$*, with no choice principle.*
3. *WLPO together with unique choice for relations from numbers to* $\{0,1\}$ *implies* $\mathrm{WLPO}_{\mathrm{seq}}$*, and hence* FAN_{Δ}*. Unique choice is used once, to collect the decisions of WLPO for the rows into one sequence.*

Proof. Item 1 combines Proposition 13.9 with Theorem 13.7, and Theorem 12.72 with Theorem 13.7.

For item 2, let the rows of A have at most one entry 1. Apply $\mathrm{WLPO}_{\mathrm{seq}}$ to the even parts, the double sequence $(i,k)\mapsto A(i,2k)$, to obtain f. If $f(i)=1$, every even entry of row i is 0. If

$f(i) = 0$, the even entries are not all 0, and every odd entry is 0: each is decidable, and an entry 1 at an odd place would be the only 1 of the row, making every even entry 0.

For item 3, WLPO decides for each row i whether it is identically 0. So the relation "$b = 1$ and row i is identically 0, or $b = 0$ and it is not" has exactly one b in $\{0, 1\}$ for each i, and unique choice turns it into a binary sequence. Items 2 and 1 finish. □

Under the reading of maps of Appendix C, which contains unique choice, WLPO therefore gives FAN_Δ with no countable choice. Without unique choice, excluded middle does not give the fan theorem. The witness is a tree of Kleene's, read in the model of computable sequences that Theorem 12.63 uses.

Theorem 13.11 (Without unique choice, excluded middle does not give the fan theorem)**.** *Consider the theory of Theorem 12.63: arithmetic with variables for sequences, induction for every formula, excluded middle for every formula, and countable choice for the relations whose witnesses a search can find. Write $v < w$ for $\exists z\,(v + Sz = w)$, $\langle n, v\rangle$ for the pairing term $(n + v)\cdot(n + v) + v$, and $\mathrm{Bin}(\alpha)$ as in the proof of Theorem 12.22. The decidable fan theorem, written as the sentence*

$$\forall\tau\Big[\Big(\tau\langle 0,0\rangle \neq 0 \wedge \forall n\,\forall v\,\forall b\,\big((b = 0 \vee b = 1) \to \tau\langle Sn, v + v + b\rangle \neq 0 \to \tau\langle n, v\rangle \neq 0\big)$$
$$\wedge\ \forall\alpha\,\big(\mathrm{Bin}(\alpha) \to \forall\gamma(\gamma(0) = 0 \wedge \forall n\,\gamma(Sn) = \gamma(n) + \gamma(n) + \alpha(n) \to \exists n\,\tau\langle n, \gamma(n)\rangle = 0)\big)\Big)$$
$$\to\ \exists N\,\forall\epsilon\,\big(\epsilon(0) = 1 \wedge \forall n\,\epsilon(Sn) = \epsilon(n) + \epsilon(n) \to \forall v(v < \epsilon(N) \to \tau\langle N, v\rangle = 0)\big)\Big],$$

is not provable in that theory, nor in any theory with fewer axioms. The proof reasons in a classical metatheory.

The sentence reads as follows. The sequence τ codes a set of strings: the string of length n with numeral v belongs when $\tau\langle n, v\rangle \neq 0$. The first two clauses say that the set contains $\emptyset$ and is closed under initial segments. In the third, $\gamma(n)$ is the numeral of $\bar{\alpha}(n)$, so the clause says that every binary sequence leaves the tree. In the conclusion, $\epsilon(N) = 2^N$, so some length has no member. This is the tree form of Theorem 13.3.

Proof. Use the model of the proof of Theorem 12.63: numbers range over the natural numbers, sequences over the total computable functions, and truth is classical. That proof shows that every theorem of the theory is true in the model. It suffices to find a computable τ at which the sentence is false.

Fix the enumeration of programs and the notation $\{e\}(a)$ of the proof of Theorem 12.22. *Kleene's tree* T_K consists of the strings l such that, for every $e < |l|$ for which program e halts on input 0 within $|l|$ steps with an output o, the digit l_e is 1 if $o = 0$ and 0 if $o \neq 0$ [51, 4]. Membership is computed by running $|l|$ programs for $|l|$ steps. T_K contains $\emptyset$, and it is closed under initial segments, because a program that halts within n steps halts within $n + 1$ steps with the same output, so a constraint visible at a length stays visible at every larger length.

T_K has a member of every length N: the string whose digit $e < N$ is 1 exactly when program e halts on input 0 within N steps with output 0 meets every constraint at length N.

Every computable binary sequence p leaves T_K. The function $(x, a) \mapsto p(x)$ is computable, so Kleene's recursion theorem [19] gives a program e with $\{e\}(a) = p(e)$ for every a. In

particular program e halts on input 0, within some k steps, with output $p(e)$. At every length $n > \max(e, k)$ the constraint on digit e asks for 1 if $p(e) = 0$ and for 0 if $p(e) = 1$, while $\bar{p}(n)$ has the digit $p(e)$ there. So $\bar{p}(n) \notin T_K$.

Let $\tau\langle n, v\rangle = 1$ when $v < 2^n$ and the string of length n with numeral v lies in T_K, and let τ be 0 at every other number; distinct pairs have distinct values $\langle n, v\rangle$. Then τ is computable, and the premises of the sentence hold in the model: the root and closure clauses hold because T_K is a tree and $v + v + b < 2^{n+1}$ forces $v < 2^n$, and the third clause holds because the binary sequences of the model are the computable ones, each of which leaves T_K. The conclusion fails, since T_K has a member of every length. So the sentence is false in the model and is not a theorem. □

The theorem concerns the fan sentence itself. With Theorem 13.6 it shows that the principle that prices Heine–Borel for $[0, 1]$ is not an omniscience principle. The model lacks a path that no program computes, much as the model of Theorem 12.63 lacks a point that no program names. In the computable calculus of δ's own objects, whose terms are maps computed by programs, the same computable reading applies to FAN_Δ, FAN_c, weak König's lemma for decidable trees and the presented forms of Heine–Borel, of the positive lower bounds and infima and of Heine–Cantor in this chapter, each written with equations between the calculus's terms: none of them is derivable from LPO, even with every instance of excluded middle added as a base rule (Chapter 16). The full calculus, whose terms may carry any map, derives each of them, because each is classically true.

13.4 Uniform continuity

The second classical consequence of compactness is that continuity on a compact set is uniform. On $\mathbb{R}_\delta$ this splits in two. Uniform continuity of pointwise continuous functions implies FAN_Δ; our proofs of the converse use data that pointwise continuity does not supply.

Definition 13.12 (Continuity on a set and on Cantor space)**.** Let f be a function on the points of $\mathbb{R}_\delta$ and K a set of points. The function is *pointwise continuous on K* when for every member x of K and every k there is a j such that every member y of K within $1/(j+1)$ of x has $f(y)$ within $1/(k+1)$ of $f(x)$. It is *uniformly continuous on K* when for every k one j serves all pairs: members x, y of K within $1/(j+1)$ have $f(x)$ and $f(y)$ within $1/(k+1)$. *Heine–Cantor on K* is the assertion that every function pointwise continuous on K is uniformly continuous on K.

A map a from binary sequences to natural numbers is *pointwise continuous* when every p has an n such that $a(q) = a(p)$ whenever $\bar{q}(n) = \bar{p}(n)$, and *uniformly continuous* when one n serves all p and q. A map F from binary sequences to points is *uniformly continuous* when for every k some n has $F(p)$ and $F(q)$ within $1/(k+1)$ whenever $\bar{p}(n) = \bar{q}(n)$.

For $K = [0, 1]$, uniform continuity is the notion of Table 12.3. In Bishop's mathematics continuity on a compact interval is defined as uniform continuity [14]; we name the pointwise notion separately because the two differ in price.

Theorem 13.13 (Heine–Cantor on $[0,1]$ gives the decidable fan theorem)**.** *If every function pointwise continuous on* $[0,1]$ *is uniformly continuous on* $[0,1]$*, then* FAN_Δ *holds. No choice principle is used beyond the unique choice that is part of the reading of maps, which defines the test function below.*

Proof. Let T be a decidable binary tree that every binary sequence leaves; by Theorem 13.3 it suffices to find a length with no member of T. We keep the notation of the proof of Theorem 13.6. For a string s of length n with $v = \kappa(s)$, let $g(s) = (8v+4)u_n$ be the centre of the gap of s, let $O(s) = \big((8v+3)u_n, (8v+5)u_n\big)$ be the overlap of the cells of its children, and let

$$\tau_s(x) = \max\big(0,\ 1 - |x - g(s)|/u_n\big)$$

be its *tent*. The tent has the value 1 at $g(s)$. At a point x not in $O(s)$ it has the value 0, because $|x - g(s)| < u_n$ would put x in $O(s)$, so $|x - g(s)| \geq u_n$. Points within $1/(j+1)$ have tent values within $8 \cdot 4^n/(j+1)$, by Lemma 12.52, item 5, and multiplication by the ratio $1/u_n$.

Two more facts about the overlaps. (d) *Overlaps of different strings are disjoint, and no Cantor point lies in an overlap.* By fact (b) and $J(s) \subseteq C(s)$, Cantor intervals of different strings of one length are disjoint, and $O(s)$ lies inside $J(s)$ but meets neither $J(s0)$ nor $J(s1)$. Let $s \neq s'$. If neither extends the other, they extend rb and rb' with $b \neq b'$ for some string r, and $O(s) \subseteq J(rb)$ is disjoint from $O(s') \subseteq J(rb')$. If s' extends s, it extends sb for a digit b, and $O(s') \subseteq J(sb)$ misses $O(s)$. A Cantor point does not change when zeros are appended to its string, so for $c(t)$ and $O(s)$ we may assume $|t| > |s|$; then $c(t)$ lies in $J(t{\restriction}(|s|+1))$, which is $J(s0)$, $J(s1)$, or disjoint from $J(s)$. (e) *If $u \notin T$ has length d, every tent τ_s of a member s of T with $|s| \geq d$ vanishes on $C(u)$.* Indeed $s{\restriction}d \neq u$, because T is closed under initial segments, so by fact (b) the cell $C(u)$ misses $J(s{\restriction}d)$, which contains $O(s)$.

The test function. For $N \geq 0$ let $H_N = \sum \tau_s$, summed over the members s of T of length less than N: a finite sum of tents. For a point x let $x' = \max(0, \min(x, 1))$, a point of $[0,1]$. From a regular sequence naming x', fact (c) computes an address p of x'; it leaves T, and we let d be the least n with $\bar{p}(n) \notin T$. Since x' lies in $C(\bar{p}(d))$, fact (e) gives $H_N(x') = H_d(x')$ for every $N \geq d$. Another regular sequence naming x' gives a depth d' with the same property, and $H_d(x') = H_{\max(d,d')}(x') = H_{d'}(x')$. So $f(x) = H_d(x')$ depends only on x. This prescription gives exactly one output for each point, so it defines a function on the points (Appendix C); if functions are required instead to be operations given in advance, this is the one place where unique choice is used, to make the least depth a function of the name. For every point y of $[0,1]$ we have $y' = y$, so $f(y) = H_N(y)$ for every N beyond the depth of some name of y.

Continuity on $[0,1]$. Let x lie in $[0,1]$, let d be its depth for one name, and $u = \bar{p}(d) \notin T$, so that $x \in C(u)$. By Lemma 12.52, item 3, some j_0 has every point within $1/(j_0+1)$ of x in $C(u)$. For such a point y of $[0,1]$, fact (e) gives $H_N(y) = H_d(y)$ for $N \geq d$, so $f(y) = H_d(y)$; likewise $f(x) = H_d(x)$. The function H_d is a sum of fewer than 2^d tents of strings shorter than d. Given k, choose $j \geq j_0$ with $2^d \cdot 8 \cdot 4^d/(j+1) \leq 1/(k+1)$. Then every y in $[0,1]$ within $1/(j+1)$ of x has $f(y)$ within $1/(k+1)$ of $f(x)$.

Values at Cantor points and gap centres. For every string t the point $c(t)$ lies in $[0,1]$ and in no overlap, so every tent vanishes there and $f(c(t)) = 0$. For every member s of T the point $g(s)$ lies in $O(s)$ and in no other overlap, so $H_N(g(s)) = \tau_s(g(s)) = 1$ for $N > |s|$, and $f(g(s)) = 1$.

Uniformity leaves no deep member. By hypothesis f is uniformly continuous on $[0,1]$, so at the tolerance $\frac{1}{2}$ some j has points of $[0,1]$ within $1/(j+1)$ with values within $\frac{1}{2}$. Whether T has a member of length $n = j+1$ is decided by inspection. If s were one, the points $c(s)$ and $g(s)$ of $[0,1]$ would be $4u_n = 2^{-(2n+1)} \leq 1/(j+1)$ apart, while their values 0 and 1 are not within $\frac{1}{2}$. So T has no member of length $j+1$. □

That Heine–Cantor on compact spaces implies the decidable fan theorem is known in Bishop-style analysis [36, 35]; the proof above works on $\mathbb{R}_\delta$ with one explicit test function. Our proof of the converse uses the local radii of continuity collected along one cover. A *control presentation* of f at the tolerance $1/(k+1)$ is a ratio cover (a_n, b_n) of $[0,1]$ together with a sequence of numbers r_n such that, for every n, members x of $[0,1]$ in interval n and members y of $[0,1]$ within $1/(r_n+1)$ of x have $f(x)$ and $f(y)$ within $1/(k+1)$.

Proposition 13.14 (Heine–Cantor from the fan theorem and control presentations)**.** *Assume that every function pointwise continuous on* $[0,1]$ *has a control presentation at every tolerance. Then Heine–Cantor on* $[0,1]$ *holds if and only if* FAN_Δ *holds. The passage from* FAN_Δ *uses no choice principle; the passage to it is Theorem 13.13.*

Proof. Assume FAN_Δ, let f be pointwise continuous on $[0,1]$, and fix k. Take a control presentation at $1/(k+1)$. By Theorem 13.6 the first N intervals of its cover cover $[0,1]$. Put $j = \max_{n<N} r_n$. If x and y in $[0,1]$ are within $1/(j+1)$, then x lies in some interval $n < N$ and y is within $1/(r_n+1)$ of x, so $f(x)$ and $f(y)$ are within $1/(k+1)$. □

On Cantor space the same question has a sharper answer.

Theorem 13.15 (Uniform continuity on Cantor space)**.**

1. FAN_c *implies that every pointwise continuous map from binary sequences to natural numbers is uniformly continuous. No choice principle is used.*
2. *If every pointwise continuous map from binary sequences to natural numbers is uniformly continuous, then* FAN_Δ *holds. Unique choice, part of the reading of maps, is used once, to make the first hit of a bar a map.*

Proof. For item 1, let a be pointwise continuous, and write $e(s) = a(s0^\omega)$. Let S be the decidable set of strings s with $e(s0) = e(s)$ and $e(s1) = e(s)$. The c-set of S is a bar: if $a(q) = a(p)$ whenever $\bar{q}(n) = \bar{p}(n)$, then for every extension s of $\bar{p}(n)$ and each digit b the sequences $s0^\omega$ and $sb0^\omega$ agree with p in their first n digits, so $e(sb) = a(p) = e(s)$, and every extension of $\bar{p}(n)$ lies in S. FAN_c gives N such that every p has an $n \leq N$ with $\bar{p}(n)$ in the c-set. If u is in the c-set, then $e(ut) = e(u)$ for every string t, by induction on t. Moreover $a(p) = e(\bar{p}(n))$ whenever $\bar{p}(n)$ is in the c-set: continuity at p gives an m, and with $K = \max(n,m)$ the sequence $\bar{p}(K)0^\omega$ agrees with p in m digits, so $a(p) = e(\bar{p}(K)) = e(\bar{p}(n))$. Now let $\bar{p}(N) = \bar{q}(N)$, and take $n \leq N$ with $\bar{p}(n)$ in the c-set. Then $\bar{q}(n) = \bar{p}(n)$, and $a(q) = e(\bar{q}(n)) = e(\bar{p}(n)) = a(p)$.

For item 2, let D be a decidable bar. For each p there is exactly one least n with $D(\bar{p}(n)) = 1$, the *first hit* $h(p)$; the bar gives a hit and the least one is unique. The relation "n is the first hit of p" has exactly one output for each p, so it is a map by the reading of maps; this is the use of unique choice. The map h is pointwise continuous: a sequence q that agrees with p in

its first $h(p)$ digits has the same first hit. If h is uniformly continuous with bound N, it takes at every p the value $h(\bar{p}(N)0^\omega)$, so it is bounded by the largest of the 2^N values $h(s0^\omega)$ with $|s| = N$, and that largest value is a uniform bound for D. □

Our converse of item 1 uses one more hypothesis.

Definition 13.16 (Last exits)**.** Let D be decidable and p a binary sequence. A number n is a *last exit* of p when $D(\bar{p}(m)) = 1$ for every $m \geq n$, and for every $j < n$ some $m \geq j$ has $D(\bar{p}(m)) = 0$. *Last-exit selection* states that for every decidable D whose c-set is a bar there is a map L from binary sequences to natural numbers such that $L(p)$ is a last exit of p for every p.

Lemma 13.17 (Last exits are unique)**.** *If the c-set of a decidable D is a bar, every binary sequence has exactly one last exit. No choice principle is used.*

Proof. The bar gives N with $\bar{p}(N)$ in the c-set, so $D(\bar{p}(m)) = 1$ for every $m \geq N$. A search below N finds the last $m < N$ with $D(\bar{p}(m)) = 0$; then $m + 1$ is a last exit, and if there is no such m, 0 is one. If $n < n'$ were both last exits, the second clause for n' at $j = n$ would give some $m \geq n$ with $D(\bar{p}(m)) = 0$, against the first clause for n. □

Theorem 13.18 (FAN_c is uniform continuity with last-exit selection)**.** FAN_c *holds if and only if every pointwise continuous map from binary sequences to natural numbers is uniformly continuous and last-exit selection holds. In particular, under last-exit selection* FAN_c *is equivalent to the uniform continuity of these maps. No choice principle is used.*

Proof. Assume FAN_c. Theorem 13.15 gives uniform continuity. For selection, let the c-set of D be a bar, with uniform bound N. Every p has $\bar{p}(n)$ in the c-set for some $n \leq N$, so the search of Lemma 13.17 can always stop at N. Let $L(p)$ be one more than the last $m < N$ with $D(\bar{p}(m)) = 0$, or 0 if there is none. This is a map, computed by a finite search, and $L(p)$ is a last exit.

Conversely, let the c-set of D be a bar, and let L select last exits. L is pointwise continuous: take N with $\bar{p}(N)$ in the c-set; a sequence q with $\bar{q}(N) = \bar{p}(N)$ has $\bar{q}(N)$ in the c-set too, and the searches below N that find the last exits of p and of q read the same digits, so $L(q) = L(p)$ by uniqueness. By uniform continuity L is bounded, as in the proof of Theorem 13.15, by some B. Then $\bar{p}(B)$ lies in the c-set for every p: for a string t, the sequence $r = (\bar{p}(B)t)0^\omega$ has its last exit at most $B \leq |\bar{p}(B)t|$, so $D(\bar{p}(B)t) = D(\bar{r}(|\bar{p}(B)t|)) = 1$. □

Theorem 13.18 keeps the selection as a hypothesis and uses no unique choice of its own. Last-exit selection is an instance of unique choice. The principle of unique choice for relations from binary sequences to numbers states: if a relation R has, for every binary sequence p, exactly one number n with $R(p, n)$, then some map L from binary sequences to numbers has $R(p, L(p))$ for every p.

Corollary 13.19 (FAN_c is uniform continuity on Cantor space)**.** *Assume unique choice for relations from binary sequences to numbers. Then* FAN_c *holds if and only if every pointwise continuous map from binary sequences to natural numbers is uniformly continuous. The passage from* FAN_c *uses no choice principle; the converse uses unique choice once, to select last exits.*

Proof. The passage from FAN_c is item 1 of Theorem 13.15. For the converse, let the c-set of a decidable D be a bar, and let $R(p, n)$ say that n is a last exit of p. By Lemma 13.17 this relation has exactly one output for each binary sequence, so unique choice, applied to it, gives a map L with $L(p)$ a last exit of p for every p. This is last-exit selection for D, and Theorem 13.18 gives FAN_c. □

Under the reading of maps of Appendix C, which contains unique choice, FAN_c is therefore exactly the uniform continuity of pointwise continuous maps from binary sequences to numbers. This is Berger's equivalence. The c-set form is his, and in Bishop's constructive mathematics he proves FAN_c equivalent to that uniform continuity [31, Section 6, Proposition 8]; his earlier paper matches FAN_Δ with uniform continuity for maps that come with a pointwise continuous modulus [30].

Theorem 13.20 (Positive lower bounds on Cantor space)**.**

1. *Suppose that every uniformly continuous map F from binary sequences to points with $F(p) > 0$ for every p has a k with $F(p) \geq 1/(k+1)$ for every p. Then* FAN_Δ *holds. Unique choice, part of the reading of maps, is used once, to make the first hit of a bar a map.*

2. *Assume* FAN_Δ*. Let F map binary sequences to points, with $F(p) > 0$ for every p, and suppose that F comes with* endpoint names*, a map R from strings to regular sequences such that $R(s)$ names $F(s0^\omega)$, and with a* modulus*, a map μ from numbers to numbers such that $F(p)$ and $F(q)$ are within $1/(k+1)$ whenever $\bar{p}(\mu(k)) = \bar{q}(\mu(k))$. Then some k has $F(p) \geq 1/(k+1)$ for every p. No choice principle is used.*

Proof. For item 1, let D be a decidable bar with first hit h, a map as in Theorem 13.15, and put $F(p) = 1/(h(p)+1)$. It is positive. It is uniformly continuous: if $\bar{p}(k) = \bar{q}(k)$, either $h(p) \leq k$ and then $h(q) = h(p)$, or both first hits exceed k and both values lie in $(0, 1/(k+2)]$. A bound $F \geq 1/(k+1)$ gives $h(p) \leq k$ for every p.

For item 2, let a string s pass when some $k \leq |s|$ has $\mu(k) \leq |s|$ and stage $2|s|+1$ of $R(s)$ at least $3/(k+1)$; this is decidable. The passing strings form a bar. Given p, take g with $1/(g+1) < F(p)$ (Lemma 12.52, item 1), put $k = 8g+7$, $n = \max(k, \mu(k))$ and $s = \bar{p}(n)$. The sequences $s0^\omega$ and p agree in $n \geq \mu(k)$ digits, so $F(s0^\omega)$ is within $1/(k+1)$ of $F(p)$, and stage $2n+1$ of $R(s)$ is within $1/(2n+2) \leq 1/(k+1)$ of $F(s0^\omega)$ (Lemma 12.52, item 4). So that stage is at least $1/(g+1) - 2/(k+1) = 3/(4g+4) > 3/(k+1)$, and s passes. FAN_Δ gives N such that every p has a passing $\bar{p}(n)$ with $n \leq N$, with its $k \leq n$. Then $F(p)$ is within $1/(k+1)$ of $F(\bar{p}(n)0^\omega)$, which is at least $3/(k+1) - 1/(2n+2)$, so $F(p) \geq 1/(k+1) \geq 1/(N+1)$. □

Lemma 13.21 (Finitely many cylinders suffice)**.** *Assume* FAN_Δ*. If* $w_0', w_1', \ldots$ *is a sequence of strings such that every binary sequence extends some* w_i'*, then some* N *has every binary sequence extending some* w_i' *with* $i < N$*. No choice principle is used.*

Proof. Let s pass when one of $w_0', \ldots, w_{|s|}'$ is an initial segment of s. This is decidable, and it is a bar: if p extends w_i', then $\bar{p}(i + |w_i'|)$ passes. A uniform bound N' gives, for every p, some $n \le N'$ and $i \le n$ with w_i' an initial segment of $\bar{p}(n)$; take $N = N' + 1$. □

13.5 Compact sets presented with their nets

The proofs for $[0, 1]$ used two features of the interval: names of points at every precision, and the fact that a limit of named members is again a member. A presented compact set carries both as data.

Definition 13.22 (Presented compact sets)**.** A set K of points is *presented* when it is given with a *presentation*, which consists of the following data and properties.

1. *Nets.* For every n, a finite list of regular sequences, each naming a member of K, such that every member of K is within 2^{-n} of a point named in the list.
2. *Completeness for named sequences.* Whenever regular sequences $s^{(0)}, s^{(1)}, \ldots$ name members of K and form a Cauchy family in the sense of Theorem 12.25, the point named by their diagonal belongs to K.

The lists are handed over with the set; they are not merely asserted to exist. A presented set is decidably empty or inhabited: if the list at $n = 0$ is empty, no member exists, since each would lie within 1 of an entry. The empty set is presented by empty lists. The interval $[0, 1]$ is presented: at n take the names of the ratios $i/2^{n+1}$ for $0 \le i \le 2^{n+1}$. As in the proof of Lemma 12.57, cotransitivity at consecutive grid points places each y of $[0, 1]$ between two grid points $2/2^{n+1}$ apart, so y is within $1/2^{n+1}$ of the grid point between them. A Cauchy family naming points of $[0, 1]$ names a limit of those points (Theorem 12.25), and that limit lies in $[0, 1]$ by Lemma 12.52, item 2.

One decidable test of closeness is used repeatedly. Say that regular sequences s and t *pass the test at* g when $|s_j - t_j| \le 3/(4g + 4)$ at the stage $j = 8g + 7$. If their points are within $1/(2g + 2)$, they pass, by Lemma 12.23, since $1/(2g + 2) + 2/(j + 1) = 3/(4g + 4)$. If they pass, their points are within $1/(g + 1)$: regularity gives, at every stage n,

$$|s_n - t_n| \le |s_n - s_j| + |s_j - t_j| + |t_j - t_n| \le \frac{2}{n+1} + \frac{2}{j+1} + \frac{3}{4g+4} = \frac{1}{g+1} + \frac{2}{n+1},$$

and Lemma 12.23 applies.

Proposition 13.23 (Presented sets are closed)**.** *Let K be presented, and let x be a point such that for every k some member of K is within $1/(k+1)$ of x. Then x belongs to K. No choice principle is used.*

Proof. The conclusion is a proposition about one point, so we may use one regular sequence r naming x. For each n, let β_n be the first entry of the net at precision $2^{-(n+3)}$ that passes the test against r at $g = 2^{n+1} - 1$, and the first entry if none passes. Some entry passes: a member y of K lies within $2^{-(n+3)}$ of x, an entry lies within $2^{-(n+3)}$ of y, and that entry is within $2^{-(n+2)} = 1/(2g+2)$ of x. So each β_n names a member of K within $2^{-(n+1)}$ of x. For $m, n \geq k$ the points of β_m and β_n are within $2^{-(m+1)} + 2^{-(n+1)} \leq 1/(k+1)$, so the β_n form a Cauchy family. By completeness for named sequences the point of its diagonal lies in K. By Theorem 12.25 that point is a limit of the points of the β_n, which converge to x; limits are unique (Theorem 12.26), so it is x. □

A presented set with an inhabitant can be parametrized by Cantor space, uniformly and onto, by a map computed from its names. We build the map from *named nets* of a set K: a regular sequence b naming a member of K, and for every k a finite list L_k of regular sequences naming members of K, such that every member of K is within $1/(k+1)$ of a point named in L_k. A presented set with a named member has named nets: the member and the nets of its presentation, since $2^{-k} \leq 1/(k+1)$.

The construction. Fix a coding $\langle m, i \rangle$ of pairs of numbers by numbers, one-to-one, with a decoding that recovers m and i and assigns a pair to every number. Write $g(n) = 2^n - 1$, $B(n) = 4g(n+1) + 3$ and $M(n) = 4B(n) + 3$. For a binary sequence p, the *candidate* $\chi_n(p)$ at stage n is the entry of $L_{M(n)}$ at the largest index i, below the length of that list, with $p(\langle n, i \rangle) = 1$; it is the entry at index 0 if there is no such i, and b if the list is empty. The *branch* is $\rho_0 = \chi_0(p)$, and $\rho_{n+1} = \chi_{n+1}(p)$ if ρ_n and $\chi_{n+1}(p)$ pass the test at $g(n+1)$, while $\rho_{n+1} = \rho_n$ otherwise. Each ρ_n names a member of K, and consecutive terms have points within $1/(g(n+1)+1) = 2^{-(n+1)}$; adding these bounds, the points of ρ_n and ρ_{n+d} are within 2^{-n}, so the branch is a Cauchy family. The *Cantor map* sends p to the point $\varphi(p)$ named by the diagonal of the branch. Let $R(n)$ be the least number above every code $\langle m, i \rangle$ with $m \leq n$ and i below the length of $L_{M(m)}$, and put $\pi(k) = R(2k+1)$.

Lemma 13.24 (The Cantor map of named nets)**.** *Let K have named nets, with Cantor map φ and the numbers $\pi(k)$ as above.*

1. *If K is presented, $\varphi(p)$ belongs to K for every binary sequence p.*
2. *Every member of K is $\varphi(p)$ for some p.*
3. *If $\bar{p}(\pi(k)) = \bar{q}(\pi(k))$, then $\varphi(p)$ and $\varphi(q)$ are within $1/(k+1)$.*
4. *For every string s a regular sequence naming $\varphi(s0^\omega)$ is computed from s.*
5. *If K is presented, then for every n there is a j such that any two members x, y of K within $1/(j+1)$ are $\varphi(p)$ and $\varphi(q)$ for some p, q with $\bar{p}(n) = \bar{q}(n)$.*

No choice principle and no omniscience principle is used.

Proof. Item 1 is completeness for named sequences, applied to the branch. Item 4 holds because the diagonal of the branch of $s0^\omega$ is computed from s.

For item 2, let x be a member and r one regular sequence naming it. The *target sequence* σ_r has the digit 1 at a number whose decoding is (n, i) exactly when $L_{M(n)}$ has an entry at index i and that entry passes the test against r at $2B(n) + 1$. Some entry of $L_{M(n)}$ is within $1/(M(n) + 1) = 1/(4B(n) + 4)$ of x and passes; so the candidate $\chi_n(\sigma_r)$, the entry at the largest passing index, passes, and its point is within $1/(2B(n) + 2)$ of x. By induction the branch of σ_r accepts every candidate: if $\rho_n = \chi_n(\sigma_r)$, then ρ_n and $\chi_{n+1}(\sigma_r)$ are within $2/(2B(n) + 2) = 1/(4g(n + 1) + 4)$, which is at most $1/(2g(n + 1) + 2)$, so they pass the test at $g(n + 1)$. The points of the branch therefore converge to x, since $B(n) \geq n$. By Theorem 12.25 and uniqueness of limits, $\varphi(\sigma_r) = x$.

For item 3, the branch up to stage n is computed from the candidates at stages $m \leq n$, which read only the digits at the codes below $R(n)$. If $\bar{p}(R(n)) = \bar{q}(R(n))$, the branches agree up to stage n. By Theorem 12.25, $\varphi(p)$ and $\varphi(q)$ are each within $1/(n + 1)$ of the point of that common term ρ_n. With $n = 2k + 1$ they are within $1/(k + 1)$.

For item 5, let c be the largest first component among the decodings of the numbers below n, or 0 if $n = 0$, and put $j = 2B(c) + 1$. Let x, y be members within $1/(j + 1)$, named by r and t. The *hybrid* sequence σ takes the digit of σ_r at numbers whose decoding has first component at most c, and the digit of σ_t elsewhere. Then $\bar{\sigma}(n) = \bar{\sigma}_r(n)$ and $\varphi(\sigma_r) = x$. The candidates of σ are those of σ_r up to stage c and those of σ_t afterwards, so its branch agrees with that of σ_r up to stage c, where its point is within $1/(2B(c) + 2)$ of x, hence within $1/(B(c) + 1) = 1/(4g(c + 1) + 4)$ of y. The candidate at stage $c + 1$ is within $1/(2B(c + 1) + 2) \leq 1/(8g(c + 1) + 8)$ of y. The two are within $3/(8g(c + 1) + 8) < 1/(2g(c + 1) + 2)$, so the candidate is accepted, and from there on the branch accepts every candidate of σ_t, as in item 2. So $\varphi(\sigma) = y$, and $p = \sigma_r$, $q = \sigma$ serve. □

The map is far from one-to-one: digits at codes $\langle m, i\rangle$ with i beyond the length of $L_{M(m)}$ are never read.

13.6 Heine–Borel, positive bounds and infima for presented sets

With the Cantor map, the theorems for $[0, 1]$ extend to every presented set. For Heine–Borel, and for maps presented with names of their values and a modulus, every choice premise disappears, because the data that a choice would select are part of the presentations of the set and of the map. For bare uniformly continuous maps the passage from the fan theorem back to the bounds is proved with countable choice, or with the pullback data that it selects (Theorem 13.31).

Theorem 13.25 (Heine–Borel for presented sets)**.** *Every presented set is cover-compact if and only if* FAN_Δ *holds. Neither direction uses a choice principle or an omniscience principle.*

Proof. If every presented set is cover-compact, so is the presented $[0,1]$, and Theorem 13.6 gives FAN_Δ.

Conversely, assume FAN_Δ, let K be presented, and let (a_i, b_i) be a ratio cover of K. If K is empty, $N = 0$ serves. Otherwise the first entry of the net at $n = 0$ names a member, and Lemma 13.24 gives the Cantor map φ, onto K, with the numbers $\pi(k)$. For a string s and a number k let $e_k(s)$ be stage k of the computed name of $\varphi(s0^\omega)$; it is a ratio within $1/(k+1)$ of $\varphi(s0^\omega)$.

Enumerate all triples (r, s, i) of a number, a string and an index, and *flag* a triple when $\pi(2r+1) \le |s|$ and, with $e = e_{2r+1}(s)$,

$$a_i < e - \frac{1}{r+1} \quad \text{and} \quad e + \frac{1}{r+1} < b_i,$$

a comparison of ratios. If (r, s, i) is flagged and p extends s, then $\varphi(p)$ is within $1/(2r+2)$ of $\varphi(s0^\omega)$, which is within $1/(2r+2)$ of e; so $\varphi(p)$ lies in interval i. Every p extends the string of some flagged triple: $\varphi(p)$ lies in some interval i, and by Lemma 12.52, item 3, some k' has every point within $1/(k'+1)$ of $\varphi(p)$ in that interval; with $r = 2k'+1$ and $s = \bar{p}(\pi(2r+1))$, the ratios $e \pm 1/(r+1)$ are within $2/(r+1) = 1/(k'+1)$ of $\varphi(p)$, so (r, s, i) is flagged. Some triple is flagged, since K is inhabited, and we fix one, (r^*, s^*, i^*). List the triples in order, replacing each unflagged one by (r^*, s^*, i^*); this gives strings w_n' with labels $\lambda(n)$ such that every binary sequence extends some w_n', and every sequence extending w_n' is sent into interval $\lambda(n)$. By Lemma 13.21 some N' has every binary sequence extending some w_n' with $n < N'$. Let N be one more than the largest label $\lambda(n)$ with $n < N'$. Every member of K is $\varphi(p)$ for some p, and p extends some w_n' with $n < N'$, so the member lies in interval $\lambda(n) < N$. □

A positive lower bound turns into a finite subcover through one function.

Lemma 13.26 (The cover series)**.** *Let $c = (a_i, b_i)$ be a ratio cover. Put*

$$\theta_i(x) = \max\bigl(0, \min(1, x - a_i, b_i - x)\bigr), \qquad \omega_i = \frac{1}{i+1} - \frac{1}{i+2}, \qquad H_n = \sum_{i<n} \omega_i \theta_i.$$

1. *The points $H_0(x), H_1(x), \ldots$ have names computed from a name of x, and they form a Cauchy family; the point $f_c(x)$ named by its diagonal does not depend on the name of x. So f_c is a function on the points, and a name of $f_c(x)$ is computed from a name of x. Moreover f_c has a* modulus*: a map μ from numbers to numbers such that any two points within $1/(\mu(k)+1)$ have values within $1/(k+1)$.*

2. *If x lies in an interval of c, then $f_c(x) > 0$.*

3. *If $f_c(x) \ge 1/(k+1)$ for every member x of a set K, then for some N every member of K lies in one of the first N intervals of c.*

No choice principle is used.

Proof. Each θ_i is built from translation, negation, max and min, so by Lemma 12.52, item 5, points within $1/(j+1)$ have values within $1/(j+1)$; and $0 \le \theta_i \le 1$. Since $\sum_{n \le i < m} \omega_i = 1/(n+1) - 1/(m+1)$, the points $H_m(x)$ and $H_n(x)$ are within $1/(n+1)$ for $m \ge n$, and weighting the bounds for the θ_i shows that $H_n(x)$ and $H_n(y)$ are within $1/(j+1)$ whenever x and y are. Names of the $H_n(x)$ are computed from a name of x by the operations on regular sequences, so they form a Cauchy family, and its diagonal names a limit of the points $H_n(x)$ (Theorem 12.25). Two names of x give limits of the same points, which coincide (Theorem 12.26). The value $f_c(x)$ is within $1/(n+1)$ of $H_n(x)$; with $n = 4k+3$ and x, y within $1/(2k+2)$, the values are within $1/(4k+4) + 1/(2k+2) + 1/(4k+4) = 1/(k+1)$. So $\mu(k) = 2k+1$ is a modulus.

For item 2, if $a_i < x < b_i$, then $\min(1, x - a_i, b_i - x) > 0$ and $\theta_i(x) > 0$, by Lemma 12.52, item 6. So $H_{i+1}(x) \ge \omega_i \theta_i(x) > 0$, and $f_c(x) \ge H_{i+1}(x)$ by item 2 of that lemma, since $H_m(x) \ge H_{i+1}(x)$ for $m \ge i+1$.

For item 3, put $N = 2k+1$. Then $H_N(x) \ge f_c(x) - 1/(N+1) \ge 1/(2k+2) > 0$. A positive finite sum has a positive term: if $0 < u + v$, cotransitivity at the point u gives $0 < u$ or $u < u + v$, that is $v > 0$. So some $i < N$ has $\theta_i(x) > 0$; then the min is positive, so $x - a_i > 0$ and $b_i - x > 0$, and x lies in interval i. □

The cover series is an example of a map that comes with its data.

Definition 13.27 (Presented uniform maps)**.** Let K be a set of points. A *presented uniform map* on K is a function f on the points together with a *transformer*, a map T sending each regular sequence r that names a member of K to a regular sequence naming f of that member, and a *modulus*, a map μ from numbers to numbers such that members x, y of K within $1/(\mu(k)+1)$ have $f(x)$ and $f(y)$ within $1/(k+1)$.

A uniformly continuous function asserts a j for each k; a presented uniform map hands over the function μ and the names. By Lemma 13.26, the cover series f_c, with its names and its modulus, is a presented uniform map on every set.

Theorem 13.28 (Positive lower bounds for presented maps)**.** FAN_Δ *holds if and only if, for every presented set K and every presented uniform map f on K with $f(x) > 0$ at every member x, some k has $f(x) \ge 1/(k+1)$ for every member x of K. Neither direction uses a choice principle.*

Proof. Assume the bound principle, let K be presented, and let c be a ratio cover of K. The cover series f_c is a presented uniform map, positive at every member of K (Lemma 13.26, item 2). A bound $f_c \ge 1/(k+1)$ on K puts every member in one of the first N intervals for some N (item 3). So every presented set is cover-compact, and Theorem 13.25 gives FAN_Δ.

Conversely, assume FAN_Δ, and let f, with transformer T and modulus μ_f, be positive on the presented set K. If K is empty, any k serves. Otherwise take the Cantor map φ of Lemma 13.24 and put $F(p) = f(\varphi(p))$. It is positive. Its endpoint names are T applied to the computed names of the points $\varphi(s0^\omega)$, which are members of K, and $k \mapsto \pi(\mu_f(k))$ is a modulus. Theorem 13.20, item 2, gives k with $F \ge 1/(k+1)$, and since φ maps onto K, $f \ge 1/(k+1)$ on K. □

For a presented uniform map the infimum itself is constructed.

Theorem 13.29 (The infimum of a presented map)**.** *Let K be presented, let f be a presented uniform map on K with transformer T and modulus μ, and let b name a member of K. Let S_n be the stagewise minimum of $T(b)$ and of $T(r)$ for the entries r of the net at precision $2^{-\mu(n)}$. Then $S_0, S_1, \ldots$ is a Cauchy family, and the point m^* named by its diagonal is an* infimum *of f on K: $m^* \le f(x)$ for every member x, and every point a with $a \le f(x)$ for every member x satisfies $a \le m^*$. No choice principle and no omniscience principle is used.*

Proof. The stagewise minimum of finitely many regular sequences is regular and names the minimum of their points, as in the proof of Lemma 12.52, item 6. So S_n names the minimum of finitely many values of f at members of K, and every lower bound a of f on K satisfies $a \le S_n$. For a member x, some entry r of the net at precision $2^{-\mu(n)} \le 1/(\mu(n)+1)$ names a point within that distance of x, so f there is within $1/(n+1)$ of $f(x)$, and $S_n \le f(x) + 1/(n+1)$. Hence $S_n - 1/(n+1)$ is a lower bound of f on K, and $S_n - 1/(n+1) \le S_m$ for all m and n. For $m, n \ge k$ this makes S_m and S_n within $1/(k+1)$: the family is Cauchy. Its diagonal point m^* is within $1/(n+1)$ of S_n for every n (Theorem 12.25). At $n = 2k+1$, the point $S_n - 1/(n+1)$ lies below $f(x)$ and within $1/(k+1)$ of m^*, so $m^* \le f(x)$ by Lemma 12.52, item 2. A lower bound a lies below every S_k, each within $1/(k+1)$ of m^*, so $a \le m^*$ by the same item. □

The theorem gives no point at which the infimum is attained, and none can be had for free: the negative of the test function in the proof of Theorem 12.60 is a presented uniform map on $[0,1]$, so attained minima of presented maps would give LLPO. For $[0,1]$ and a uniformly continuous function, Theorem 12.58 uses countable choice at pairs of ratios to turn the cut of the supremum into a point; a presented map needs none.

Corollary 13.30 (Positive infima for presented maps)**.** FAN_Δ *holds if and only if every presented uniform map that is positive at every member of an inhabited presented set K has an infimum $m > 0$ on K. Neither direction uses a choice principle.*

Proof. Assume FAN_Δ. The statement to prove is a proposition, so one name of one member serves as b. Theorem 13.28 gives $f \ge 1/(k+1)$ on K, and the infimum m^* of Theorem 13.29, a greatest lower bound, satisfies $m^* \ge 1/(k+1) > 0$. Conversely, a positive infimum m exceeds some ratio $1/(k+1)$ (Lemma 12.52, item 1), which is then a lower bound; empty sets, decided by the net at $n = 0$, need nothing. So the bound principle of Theorem 13.28 holds, and with it FAN_Δ. □

For $[0,1]$ and uniformly continuous functions, the equivalence of positive infima with the decidable fan theorem FAN_Δ is due to Julian and Richman [37, Corollary 2.6], in Bishop's constructive mathematics. The presented forms extend it to every presented set and separate what the set supplies, its names and nets, from what the theorems ask of the map, its names and its modulus.

Bare maps. Without the data of the map, one direction still uses no choice. Write (LB) for the assertion that for every presented set K and every function f uniformly continuous on K with $f(x) > 0$ at every member, some k has $f \ge 1/(k+1)$ on K, and (INF) for the assertion that every such f on an inhabited presented K has an infimum $m > 0$ on K. The *pullback data* principle states: for every presented set K, all named nets of K with Cantor map φ, and every f uniformly continuous on K, the map $p \mapsto f(\varphi(p))$ has endpoint names and a modulus, as in Theorem 13.20.

Theorem 13.31 (Bare uniformly continuous maps)**.**

1. *Each of (LB) and (INF) implies* FAN_Δ*. No choice principle is used.*
2. *Assume the pullback data principle. Then (LB), (INF) and* FAN_Δ *are equivalent, with no further choice.*
3. *Assuming* AC_ω*, the pullback data principle holds, so (LB), (INF) and* FAN_Δ *are equivalent. Countable choice is used for regular sequences, to select endpoint names, and for numbers, to select a modulus.*
4. *Assume that every Cauchy sequence of points converges. Then every function uniformly continuous on an inhabited presented set has an infimum on it, and (INF) is equivalent to (LB).*

Proof. For item 1, the cover series of a cover of a presented set is uniformly continuous and positive there, and a lower bound gives a finite subcover (Lemma 13.26); so (LB) makes every presented set cover-compact, and Theorem 13.25 applies. As in the proof of Corollary 13.30, (INF) implies (LB).

For item 2, assume FAN_Δ and the pullback data. For (LB), let K be presented. If K is empty, which the net at $n = 0$ decides, every k serves. Otherwise take a named member and the Cantor map, and apply Theorem 13.20, item 2, to $F = f \circ \varphi$ with its endpoint names R and modulus μ; since φ maps onto K, the bound holds on K. For (INF), let S_n be the stagewise minimum of the $R(s)$ over the strings s of length $\mu(n)$. Every p has $F(p)$ within $1/(n+1)$ of $F(\bar{p}(\mu(n))0^\omega)$, so the argument of Theorem 13.29 shows that the diagonal of the S_n names an infimum of F, which is an infimum of f on K because φ maps into K and onto it. By (LB) it is at least some $1/(k+1)$. Item 1 gives the remaining implications.

For item 3, the strings are enumerated, and for each string s some regular sequence names $F(s0^\omega)$; countable choice gives R. For each k, uniform continuity of f on K gives some j, and then $\pi(j)$ works for F at k; countable choice gives μ. Item 2 finishes.

For item 4, let K be inhabited, with a member x_0, and let z_n be the minimum of $f(x_0)$ and of f at the points of the net at precision 2^{-n}: a sequence of points, defined from the data with no choice. Given k, uniform continuity gives one j, used inside this proof only; for $n \geq j$ every member x is within $1/(j+1)$ of a net point, so $z_n \leq f(x) + 1/(k+1)$, and for $m, n \geq j$ the minima z_m and z_n are within $1/(k+1)$. So (z_n) is Cauchy and has a limit L. As in the proof of Theorem 13.29, $L \leq f(x)$ for every member x, and every lower bound lies below every z_n, hence below L. Then a positive lower bound $1/(k+1)$ gives $L \geq 1/(k+1) > 0$, and a positive infimum gives a positive lower bound as in item 1. □

By Theorem 12.26, the hypothesis of item 4 follows from AC_ω, used once to select representatives.

13.7 Heine–Cantor for presented sets

Heine–Cantor for presented sets lies between FAN_Δ and the full fan theorem. Under two bridges between continuity on a presented set and continuity on Cantor space, it is exactly FAN_c.

Theorem 13.32 (Heine–Cantor for presented sets lies between FAN_Δ and FAN)**.**

1. *If every function pointwise continuous on a presented set is uniformly continuous on it, then* FAN_Δ *holds. No choice principle is used beyond the unique choice that defines the test function of Theorem 13.13.*

2. *The full fan theorem implies Heine–Cantor for presented sets and the assertion (LB) of Theorem 13.31. No choice principle is used.*

Proof. For item 1, the hypothesis applies to the presented $[0,1]$, and Theorem 13.13 finishes.

For item 2, let f be pointwise continuous on a presented set K, and fix k. If K is empty there is nothing to prove; otherwise take named nets and the Cantor map φ. Let B be the set of strings s for which there are a member z of K and a number $j \le |s|$ such that $\varphi(q)$ is within $1/(2j+2)$ of z for every q extending s, and every member y of K within $1/(j+1)$ of z has $f(y)$ within $1/(2k+2)$ of $f(z)$. This is a property of strings, not a decidable set. It is a bar: for a sequence p, let $z = \varphi(p)$, let j be given by continuity of f at z at the tolerance $1/(2k+2)$, and let $n = \max(j, \pi(2j+1))$; every q extending $\bar{p}(n)$ agrees with p in $\pi(2j+1)$ digits, so $\varphi(q)$ is within $1/(2j+2)$ of z, and $\bar{p}(n) \in B$. The full fan theorem gives N such that every p has an $n \le N$ with $\bar{p}(n) \in B$.

Let x and y be members within $1/(2N+2)$. By Lemma 13.24, $x = \varphi(p)$ for some p; take $n \le N$ with $\bar{p}(n) \in B$, and its z and $j \le n \le N$. Then x is within $1/(2j+2)$ of z, and y, within $1/(2N+2) \le 1/(2j+2)$ of x, is within $1/(j+1)$ of z. So $f(x)$ and $f(y)$ are both within $1/(2k+2)$ of $f(z)$, hence within $1/(k+1)$ of each other, and $2N+1$ serves at k.

For (LB), let f be uniformly continuous and positive on a presented K. If K is empty, which the net at $n = 0$ decides, every k serves. Otherwise take named nets and φ as before. Let B be the set of strings s for which some $g \le |s|$ has $f(\varphi(q)) \ge 1/(g+1)$ for every q extending s. It is a bar: given p, take g_0 with $1/(g_0+1) < f(\varphi(p))$, put $g = 2g_0 + 1$, let j be given by uniform continuity at the tolerance $1/(g+1)$, and let $n = \max(g, \pi(j))$. For q extending $\bar{p}(n)$,

$$f(\varphi(q)) \ge f(\varphi(p)) - \frac{1}{g+1} > \frac{1}{g_0+1} - \frac{1}{2g_0+2} = \frac{1}{g+1}.$$

The full fan theorem gives N, and every member $x = \varphi(p)$ has $f(x) \ge 1/(N+1)$. □

Definition 13.33 (Two bridges)**.** The *pullback approximation principle* states: for every presented set K, all named nets of K with Cantor map φ, every function f pointwise continuous on K, and every k, there is a pointwise continuous map a from binary sequences to numbers such that $a(p) = a(q)$ implies that $f(\varphi(p))$ and $f(\varphi(q))$ are within $1/(k+1)$.

A *Cantor presentation* of a set K is a map ψ from binary sequences into K and onto K, together with a map π' from numbers to numbers such that $\psi(p)$ and $\psi(q)$ are within $1/(k+1)$ whenever

$\bar{p}(\pi'(k)) = \bar{q}(\pi'(k))$. It *reflects prefixes* when for every n some j has: $\psi(p)$ and $\psi(q)$ within $1/(j+1)$ force $\bar{p}(n) = \bar{q}(n)$. It *realizes last exits* when for every decidable D whose c-set is a bar some function g on the points has, for every p, $g(\psi(p)) = n$ for a last exit n of p. The *last-exit realization principle* states that some presented set has a Cantor presentation that reflects prefixes and realizes last exits.

Theorem 13.34 (Heine–Cantor and FAN_c through the bridges)**.**

1. *Assume* FAN_c*. Then Heine–Cantor for presented sets holds if and only if the pullback approximation principle holds.*
2. *Under the last-exit realization principle, Heine–Cantor for presented sets implies* FAN_c*.*
3. *Under both principles, Heine–Cantor for presented sets is equivalent to* FAN_c*.*

No choice principle is used.

Proof. For item 1, assume Heine–Cantor for presented sets, and let K, its named nets with Cantor map φ, f and k be given. Some j has members within $1/(j+1)$ with values within $1/(k+1)$. Let $a(p)$ be the index of $\bar{p}(\pi(j))$ in the list $w_0, w_1, \ldots$. It is pointwise continuous, and $a(p) = a(q)$ puts $\varphi(p)$ and $\varphi(q)$ within $1/(j+1)$, so their values are within $1/(k+1)$. Conversely, assume the pullback approximation, let f be pointwise continuous on a presented K, and fix k. If K is empty there is nothing to prove; otherwise take named nets, the Cantor map φ, and an approximation a at k. By Theorem 13.15, a is uniformly continuous, with some bound n; so $\bar{p}(n) = \bar{q}(n)$ gives $a(p) = a(q)$ and values $f(\varphi(p))$, $f(\varphi(q))$ within $1/(k+1)$. By Lemma 13.24, item 5, some j has any two members within $1/(j+1)$ of the form $\varphi(p)$, $\varphi(q)$ with $\bar{p}(n) = \bar{q}(n)$. So j serves at k.

For item 2, let K, ψ and π' be as in the realization principle, assume Heine–Cantor for presented sets, let the c-set of a decidable D be a bar, and let g realize its last exits. The function g is pointwise continuous on K. A member x is $\psi(p)$ for some p; take N with $\bar{p}(N)$ in the c-set, and j from prefix reflection at N. A member y within $1/(j+1)$ of x is $\psi(q)$ for some q with $\bar{q}(N) = \bar{p}(N)$, and, as in the proof of Theorem 13.18, p and q have the same last exit; so $g(y) = g(x)$. By Heine–Cantor, g is uniformly continuous on K; at the tolerance $\frac{1}{2}$ some j has members within $1/(j+1)$ with values within $\frac{1}{2}$. If $\bar{p}(\pi'(j)) = \bar{q}(\pi'(j))$, then $\psi(p)$ and $\psi(q)$ are within $1/(j+1)$, so the last exits of p and q, numbers whose points are within $\frac{1}{2}$, are equal. So the last exit of p is at most the largest last exit B of the sequences $s0^\omega$ with $|s| = \pi'(j)$, and as in the proof of Theorem 13.18, $\bar{p}(B)$ lies in the c-set for every p. Item 3 combines the first two. □

Proposition 13.35 (What the realization bridge requires)**.**

1. *The last-exit realization principle implies last-exit selection. No choice principle is used.*
2. *If a Cantor presentation ψ sends two binary sequences p and q with $\bar{p}(n) \neq \bar{q}(n)$ for some n to the same point, it neither reflects prefixes nor realizes last exits.*

Proof. For item 1, let g realize last exits on ψ. A point equal to a natural number n determines n: every regular sequence s naming it has $|s_7 - n| \le 1/8$ (Lemma 12.52, item 4), so n is the integer nearest to s_7 for every name. So $L(p)$, the number with $g(\psi(p)) = L(p)$, is computed from that point, and L selects last exits.

For item 2, if ψ reflected prefixes, the j given at n would force $\bar{p}(n) = \bar{q}(n)$, since $\psi(p) = \psi(q)$. Suppose ψ realizes last exits, and let D reject exactly the string $s = \bar{p}(n)$. Its c-set is a bar, since every string of length $n + 1$ lies in it. The last exit of p is $n + 1$, because $D(\bar{p}(m)) = 0$ only at $m = n$, and the last exit of q is 0, because $\bar{q}(n) \neq s$. A realizing g would take the values $n + 1$ and 0 at the same point. □

So a bridging presentation must be one-to-one, and the Cantor map of Lemma 13.24 is not. We do not decide here whether FAN_c gives the pullback approximation, whether a bridging presentation exists, or whether FAN_Δ alone gives Heine–Cantor on $[0, 1]$. So this chapter locates the price of Heine–Cantor for presented sets only between FAN_Δ and FAN.

13.8 Bishop compactness

Bishop's compact sets have finite nets and are complete [38, 14]. Read on $\mathbb{R}_\delta$ without names, the nets exist at each precision without being handed over, and completeness concerns sequences of points rather than named families.

Definition 13.36 (Bishop compactness)**.** A set K of points has *internal nets* when for every k there is a finite list of members of K such that every member of K is within $1/(k + 1)$ of one of them. It is *complete* when every Cauchy sequence of members of K converges to a member of K. It is *Bishop compact* when it has internal nets and is complete.

Theorem 13.37 (Forgetting the presentation costs Cauchy completeness)**.** *Every presented set is Bishop compact if and only if every Cauchy sequence of points of $\mathbb{R}_\delta$ converges. Neither direction uses a choice principle. By Theorem 12.26, every presented set is therefore Bishop compact under AC_ω, with countable choice used once, to select representatives.*

Proof. Assume that Cauchy sequences converge, and let K be presented. The net at precision $2^{-k} \le 1/(k + 1)$ is a list of members, so K has internal nets. A Cauchy sequence of members converges to some L; every tolerance has a member within it of L, so L belongs to K by Proposition 13.23.

Conversely, assume that every presented set is Bishop compact. Then the presented $[0, 1]$ is complete. Let (x_n) be a Cauchy sequence of points, take N such that x_m and x_n are within 1 for $m, n \ge N$, put $a = x_N$, and let $y_n = (x_{\max(n,N)} - a + 1)/2$. Each y_n lies in $[0, 1]$, and (y_n) is Cauchy, so it converges to some L in $[0, 1]$. Then (x_n) converges to $2L + a - 1$. The index N is used inside this proof only. □

The proof shows that $[0, 1]$ is Bishop compact exactly when every Cauchy sequence of points converges.

Assertion	Price	Choice
$[0,1]$ is cover-compact (Theorem 13.6)	FAN_Δ	not used
Every presented set is cover-compact (Theorem 13.25)	FAN_Δ	not used
A presented map positive on a presented set has a positive lower bound, and on an inhabited one a positive infimum (Theorem 13.28, Corollary 13.30)	FAN_Δ	not used
… for a bare map (Theorem 13.31)	FAN_Δ	in the converse
Every Bishop compact set is cover-compact (Theorem 13.39)	FAN_Δ	AC_ω, both directions
Pointwise continuous maps from binary sequences to numbers are uniformly continuous, and last exits can be selected (Theorem 13.18)	FAN_c	not used
Pointwise continuous maps from binary sequences to numbers are uniformly continuous (Theorems 13.15 and 13.18, Lemma 13.17, Corollary 13.19)	FAN_c	unique choice, in the converse
Functions pointwise continuous on $[0,1]$ are uniformly continuous there (Theorem 13.13)	implies FAN_Δ	unique choice
… on every presented set (Theorem 13.32)	between FAN_Δ and FAN	unique choice
Positive uniformly continuous maps from binary sequences to points have positive lower bounds (Theorem 13.20)	implies FAN_Δ	unique choice
A presented map on an inhabited presented set has an infimum (Theorem 13.29)	none	not used
A bare map on an inhabited presented set has an infimum (Theorem 13.31)	none	used once, for representatives
Every presented set is Bishop compact (Theorem 13.37)	none	used once, for representatives
Every two-point set is complete (Proposition 13.38)	LLPO	in the converse
Uniformly continuous images of Bishop compact sets are Bishop compact (Proposition 13.38)	implies LLPO	not used
Weak König's lemma for decidable binary trees (Proposition 13.9)	$\mathrm{LLPO}_{\mathrm{seq}}$	not used
FAN_Δ (Corollary 13.10, Theorem 13.11)	below $\mathrm{LLPO}_{\mathrm{seq}}$; not from excluded middle without unique choice	from WLPO, with unique choice

Table 13.1. Compactness on the line built from ratios and on Cantor space. A presented map is a presented uniform map, and a bare map a function uniformly continuous on the set. "Price" is the principle equivalent to the assertion; "implies" and "between" record the proved implications, "below P" means implied by P, and "none" means that no omniscience or fan principle is needed. The last column says which choice principle is used and where ("in the converse": on the way from the principle back to the assertion); unique choice, part of the reading of maps, makes a uniquely determined value, such as the first hit of a bar or the last exit of a sequence, a map. The theorems named state the conditional converses.

Proposition 13.38 (Images of Bishop compact sets)**.**

1. *If K has internal nets and f is uniformly continuous on K, the image $\{f(x) : x \in K\}$ has internal nets. No choice principle is used.*

2. *If every two-point set $\{x, y\}$ is complete, LLPO holds. Hence, if the image of every Bishop compact set under every function uniformly continuous on it is Bishop compact, LLPO holds. No choice principle is used.*

3. *Assuming LLPO and AC_ω, every two-point set is complete; countable choice is used once, through Theorem 12.26.*

Proof. For item 1, given k, uniform continuity gives j; the images of an internal net at $1/(j+1)$ are members of the image, and every $f(x)$ is within $1/(k+1)$ of one of them.

For item 2, let x and y be named by s and t. Put $z_n = y$ if $t_{2n+1} \geq s_{2n+1}$ and $z_n = x$ otherwise, a sequence of members of $\{x, y\}$ defined by comparing ratios. The point $\max(x, y)$ is named by the stagewise maximum, whose stage $2n+1$ is the stage $2n+1$ of the name of z_n; by Lemma 12.23, two points whose names agree at a stage $2n+1$ are within $1/(n+1)$. So (z_n) converges to $\max(x, y)$. If $\{x, y\}$ is complete, the limit is x or y, and limits are unique, so $\max(x, y) = x$ or $\max(x, y) = y$: that is, $y \leq x$ or $x \leq y$. With $y = 0$ this is the dichotomy of Corollary 12.18, which is LLPO. For the second assertion, $\{0, 1\}$ is Bishop compact with no choice (a Cauchy sequence in it is eventually constant), and $z \mapsto x + z(y - x)$ is uniformly continuous, since $|y - x|$ lies below some integer, with image $\{x, y\}$.

For item 3, a Cauchy sequence in $\{x, y\}$ converges to some L, by Theorem 12.26. LLPO, through Corollary 12.18, gives $|L-x| \leq |L-y|$ or $|L-y| \leq |L-x|$. In the first case, for every k some term within $1/(k+1)$ of L is x or y, and either way $|L - x| \leq 1/(k+1)$; so $L = x$ by Corollary 12.24. The second case gives $L = y$. □

Under countable choice the two notions of compactness meet.

Theorem 13.39 (Bishop compactness under countable choice)**.**

1. *If every function uniformly continuous on a Bishop compact set and positive at each of its members has a lower bound $1/(k+1)$ there, then every Bishop compact set is cover-compact. No choice principle is used.*

Assume AC_ω. Then:

2. *a set has a presentation if and only if it is Bishop compact;*

3. *every Bishop compact set is cover-compact if and only if FAN_Δ holds;*

4. *the lower-bound principle of item 1 is equivalent to FAN_Δ;*

5. *the principle that every function uniformly continuous and positive on an inhabited Bishop compact set has an infimum $m > 0$ there is equivalent to FAN_Δ.*

Proof. Item 1 is Lemma 13.26: the cover series of a cover of K is uniformly continuous and positive on K, and a lower bound gives a finite subcover.

For item 2, a presented set is Bishop compact by Theorem 13.37. Conversely, let K be Bishop compact. The internal net at $k = 0$ decides whether K is empty; an empty set is presented by empty lists. Otherwise, for each n there is a finite list of members within 2^{-n} of every member, and each member has a name, so there is a list of names with the same property; AC_ω selects such a list for every n. If regular sequences naming members form a Cauchy family, their points form a Cauchy sequence of members, which converges to a member; the diagonal names a limit of the same sequence (Theorem 12.25), so it names that member. Items 3 to 5 use countable choice only through item 2 and Theorems 13.37 and 13.31.

For item 3, if FAN_Δ holds, a Bishop compact set is presented by item 2, hence cover-compact by Theorem 13.25. Conversely, $[0, 1]$ is presented, hence Bishop compact by item 2; if it is cover-compact, Theorem 13.6 gives FAN_Δ.

For item 4, the principle makes Bishop compact sets cover-compact (item 1), and item 3 gives FAN_Δ; for item 5, a positive infimum gives a positive lower bound, and empty sets need nothing. The converses are Theorem 13.31, item 3, applied to the presentation of item 2. □

The choice-free theorems on $\mathbb{R}_\delta$ belong to presented sets; Bishop's notion reaches the same prices through countable choice (Table 13.1).

Questions to work through

1. In the proof of Theorem 13.3, give a decidable bar whose complement is not a tree. Why does a length with no member of A bound the bar D itself?

2. In the proof of Theorem 13.7, where would an unbounded search for an empty level of T need Markov's principle, and how does the path through the padded tree avoid it?

3. List the members of the tree H in the proof of Theorem 13.6 for the cover of the opening example, and say which interval catches each of the sixteen pieces of length 4.

4. Explain why a search finds the first hit of a decidable bar, while the last exit of a c-set is found by a search only once FAN_c supplies a bound (Theorems 13.15 and 13.18).

5. Show that $-h$, for the test function h of Theorem 12.60, is a presented uniform map on $[0, 1]$, and that attained infima of presented maps give LLPO.

Chapter 14

What linear algebra costs

Suppose an instrument reports a few vectors, each coordinate a point of the line $\mathbb{R}_\delta$ that we can know to any precision we ask for. Gaussian elimination would reduce the list to a basis of the subspace it spans: find an entry that is not zero, divide by it, clear its column, and repeat. Every step asks whether an entry is zero. Over a field with decidable equality, a discrete field in the sense of constructive algebra [39], that question is answered by computation. Chapter 12 priced it on the line: deciding $x = \eta(0) \vee x \neq \eta(0)$ for every point is WLPO (Corollary 12.18). Does linear algebra on the line cost exactly its zero tests, or does elimination need more?

Take the smallest case. Two points a and d are two vectors (a) and (d) of the one-dimensional space $\mathbb{R}^1_\delta$. A basis of their span drawn from them is one of three things: no vector, when both are zero; the vector (a) alone, when a is not zero and d is a multiple $c\,a$; or (d) alone, in the mirror case. Both together are never independent, because $d \cdot (a) + (-a) \cdot (d) = 0$. So selecting a basis from two measured numbers means knowing that both vanish, or naming one that is not zero and divides the other. With $a = d = x$, the selection decides $x = \eta(0) \vee x \neq \eta(0)$.

This chapter shows that the smallest case carries the whole subject. Every finite family of vectors in every $\mathbb{R}^n_\delta$ has a basis drawn from it exactly when every pair of points can be divided in this sense (Theorem 14.13), and the same holds for rank and nullity (Theorem 14.14). Each of these is equivalent to WLPO (Theorem 14.16), when independence means that only the zero combination vanishes (Definition 14.1). The passage from linear algebra to WLPO uses no choice. The passage back uses the principle of unique choice to collect a table of WLPO decisions into a sequence; in this book unique choice is part of the reading of maps (Section 12.9), so under that reading the price of linear algebra on the line is exactly WLPO.

The proof that WLPO suffices divides one point by another, and division has prices of its own. Dividing b by a when $|b| \leq |a|$, with a allowed to be zero, costs exactly LLPO. Dividing by a point that is merely known not to be zero, again with $|b| \leq |a|$, costs exactly a principle that follows from LLPO and from $\mathrm{MP}_{\mathrm{bin}}$: the principle $\mathrm{MP}^\vee$, which turns $x \neq \eta(0)$ into $x \geq \eta(0) \vee x \leq \eta(0)$. In both cases the passage to the principle uses no choice; the passage back uses countable choice for LLPO and unique choice for $\mathrm{MP}^\vee$. A table at the end of the chapter collects the prices, and the last section states what remains open when unique choice is not available.

Some conventions hold throughout. We write 0 and 1 for the points $\eta(0)$ and $\eta(1)$, and a ratio q for the point $\eta(q)$ when it is used as a point. As in Chapter 12, $x \neq y$ means $\neg(x = y)$; a point is *apart from* 0 when it is positive or negative, which by item 3 of Proposition 12.19 is exactly when it has a multiplicative inverse; and $|x| = \max(x, -x)$. A vector of $\mathbb{R}^n_\delta$ is an n-tuple of points, with sums and multiples taken coordinatewise. When we say that a proof uses *no choice*, we mean that it uses neither countable choice nor unique choice: every sequence and every table it uses is computed from the data by an explicit rule, and a search that is proved to terminate counts as an explicit rule. Where a proof does use unique choice or countable choice, we say so at that step.

14.1 Selections, bases and three kinds of division

A basis drawn from a finite family is recorded by saying which members are kept. This is a finite string of bits, so it can be named without any decision about the points.

Definition 14.1 (Selections and bases)**.** Let $v_0, \dots, v_{k-1}$ be vectors of $\mathbb{R}^n_\delta$. A *selection* is a string $b \in \{0,1\}^k$; it *selects* v_i when $b_i = 1$. For points $c_0, \dots, c_{k-1}$, the combination of the selected vectors is $\sum_{b_i=1} c_i v_i$.

1. The selection is *independent* when only the zero combination vanishes: whenever $\sum_{b_i=1} c_i v_i = 0$, every selected i has $c_i = 0$.
2. It *spans* the family when every v_i is a combination of the selected vectors.
3. It is a *basis selection* when it is independent and spans the family.

The family is *independent* when the selection of all its members is independent.

Independence here is the negative form, "only the zero combination vanishes." It does not ask that a combination with some coefficient apart from 0 have a coordinate apart from 0. Constructive analysis calls that stronger form linear independence, and studies a metric form of independence beside it [41]; we use neither. The prices of this chapter depend on this choice. With the stronger form, a basis selection of the single vector (x) decides $x = 0$ or x apart from 0: if nothing is selected, spanning gives $x = 0$; if (x) is selected, the combination $1 \cdot (x)$ has a coefficient apart from 0, so x is apart from 0. Deciding this for every point is LPO, by the second row of Table 12.2. A basis selection of a family is a basis, drawn from the family, of the subspace the family spans; so the assertion that every finite family of vectors in every $\mathbb{R}^n_\delta$ has a basis selection says that every finitely generated subspace of $\mathbb{R}^n_\delta$ has a basis drawn from its generators.

An $n \times m$ matrix A has entries A_{ij} for $i < n$ and $j < m$; its columns $\mathrm{col}_j = (A_{0j}, \dots, A_{n-1,j})$ are vectors of $\mathbb{R}^n_\delta$, and it sends $x \in \mathbb{R}^m_\delta$ to Ax, with $(Ax)_i = \sum_j A_{ij} x_j$. Write $e_0, \dots, e_{m-1}$ for the unit vectors of $\mathbb{R}^m_\delta$.

Definition 14.2 (Rank and nullity)**.** *Rank–nullity data* for an $n \times m$ matrix A consist of a selection $b \in \{0,1\}^m$ of its columns and vectors $K_0, \dots, K_{m-1}$ of $\mathbb{R}^m_\delta$ such that:

(i) b is a basis selection of the columns of A;

(ii) $AK_j = 0$ for every j with $b_j = 0$;

(iii) the selection of the K_j with $b_j = 0$ is independent;

(iv) every x with $Ax = 0$ is a combination of the K_j with $b_j = 0$.

Rank–nullity is the assertion that every matrix over $\mathbb{R}_\delta$ has rank–nullity data.

The selected columns are then a basis of the column space and the unselected K_j a basis of the kernel. The two selections are complementary, so the dimension of the column space and the dimension of the kernel add up to m. The vectors K_j with $b_j = 1$ play no role.

Definition 14.3 (Three kinds of division)**.** We consider three statements about dividing one point by another.

(a) *Scalar pair division*: for all points a and b, either $a = 0$ and $b = 0$; or $a \neq 0$ and $ac = b$ for some point c; or $b \neq 0$ and $bc = a$ for some point c.

(b) *Dominated division*: for all points a and b with $|b| \leq |a|$ there is a point c with $|c| \leq 1$ and $ac = b$.

(c) *Dominated division by nonzero points*: for all points a and b with $a \neq 0$ and $|b| \leq |a|$ there is a point c with $ac = b$.

In (a) and (c) the divisor is only known not to be zero; it need not be apart from 0, and no bound on the quotient is asked for. In (b) the divisor may be zero; then $b = 0$ and any c with $|c| \leq 1$ works, but the statement does not tell us whether a is zero. The bound $|b| \leq |a|$ in (c) matters: dividing 1 by every nonzero point is the inversion of the eighth row of Table 12.2, which costs $\mathrm{MP}_{\mathrm{bin}}$.

We use some facts about absolute values; each follows from Proposition 12.19 and Lemma 12.40. The maximum $|x|$ is an upper bound of x and $-x$. It is not negative: if $|x| < 0$, then $x < 0$ and $-x < 0$, and $0 < x < 0$ is impossible. If $x \geq 0$, then $-x \leq 0 \leq x$, so x is an upper bound of x and $-x$ and $|x| = x$; likewise $x \leq 0$ gives $|x| = -x$. Conversely $|x| = x$ gives $x \geq 0$, and $|x| = -x$ gives $x \leq 0$. If $|x| = 0$, then $x \leq 0$ and $-x \leq 0$, so $x = 0$ by item 2; hence $x \neq 0$ gives $|x| \neq 0$. If x is apart from 0, then $|x| > 0$; conversely $|x| > 0$ makes x positive or $-x$ positive, by the strict form of item 5. The equations $|xy| = |x|\,|y|$, $|-x| = |x|$ and $\big||x|\big| = |x|$ follow by cases on the signs; an equation proved by cases on the order of finitely many points needs no principle (Remark 12.20). Finally, if $0 \leq c$ and $x \leq y$, then $cx \leq cy$: the product of two nonnegative points is nonnegative, as in fact (iii) of the proof of Lemma F.12, and $cy - cx = c(y - x)$.

14.2 Cancelling without inverting

A point that is only known not to be zero cannot be inverted without $\mathrm{MP}_{\mathrm{bin}}$. It can still be cancelled. The lemmas of this section do the arithmetic of the rest of the chapter, and none of them uses an omniscience principle or a choice principle.

Lemma 14.4 (Cancelling a nonzero factor)**.** *If $a \neq 0$ and $ax = ay$, then $x = y$.*

Proof. Suppose $x - y$ were apart from 0. It would have an inverse u, and then $a = a(x - y)u = (ax - ay)u = 0$, contrary to $a \neq 0$. So $x - y$ is neither positive nor negative, and Lemma F.8(c) gives $x - y = 0$, that is $x = y$. □

Lemma 14.5 (Cancelling a nonnegative nonzero factor)**.** *If $0 \leq a$, $a \neq 0$ and $ax \leq ay$, then $x \leq y$.*

Proof. Suppose $y < x$. Then $d = x - y$ is positive and has an inverse u. The point u is not negative, since $u < 0$ would make $du = 1$ negative. From $ax \leq ay$ we get $ad \leq 0$, and multiplying by $u \geq 0$ gives $a = adu \leq 0$. With $0 \leq a$ this gives $a = 0$ by item 2 of Proposition 12.19, contrary to $a \neq 0$. So $\neg(y < x)$, which is $x \leq y$. □

Lemma 14.6 (Quotients of dominated numerators). *If $a \neq 0$, $|b| \leq |a|$ and $ac = b$, then $|c| \leq 1$.*

Proof. We have $|a|\,|c| = |ac| = |b| \leq |a| = |a| \cdot 1$, with $|a| \geq 0$ and $|a| \neq 0$. Lemma 14.5 gives $|c| \leq 1$. □

Lemma 14.7 (Reversing a dominated quotient). *If $b \neq 0$, $|b| \leq |a|$ and $bc = a$, then $ad = b$ for some point d.*

Proof. Here $|b| \cdot 1 = |b| \leq |a| = |b|\,|c|$, so $1 \leq |c|$ by Lemma 14.5. Cotransitivity of $0 < 1$ at $|c|$ gives $0 < |c|$ or $|c| < 1$, and the second is excluded by $1 \leq |c|$. So $|c| > 0$, and c is apart from 0. With d its inverse (item 3 of Proposition 12.19), $ad = bcd = b$. □

Only the quotient c is inverted, never the nonzero point b. The next lemma extracts a sign from a quotient by an absolute value, again with no bound on the quotient and no decision whether x is zero.

Lemma 14.8 (A weak sign from an absolute quotient). *If $|x|\,c = x$ for some point c, then $x \geq 0$ or $x \leq 0$.*

Proof. Cotransitivity of $-1 < 1$ at c gives $-1 < c$ or $c < 1$. In the first case $x \geq 0$, that is $\neg(x < 0)$: if $x < 0$, then $|x| = -x$ is positive and $(-x)c = x = (-x)(-1)$, so cancelling the invertible point $-x$ gives $c = -1$, contrary to $-1 < c$. In the second case $x \leq 0$ by the mirror argument: if $x > 0$, then $xc = x = x \cdot 1$ gives $c = 1$, contrary to $c < 1$. □

Lemma 14.9 (Absolute quotients of nonzero points). *If $x \neq 0$ and $|x|\,c = x$, then c is apart from 0.*

Proof. Taking absolute values, $|x|\,|c| = \big||x|c\big| = |x| = |x| \cdot 1$. Since $|x| \neq 0$, Lemma 14.4 gives $|c| = 1$, so $|c| > 0$ and c is apart from 0. □

Lemma 14.10 (The affine quotient). *If $0 \leq a \leq b$, $b \neq 0$ and $bc = a$, then $0 \leq c \leq 1$. Any two such points c are equal.*

Proof. Here $b \geq 0$. From $b \cdot 0 = 0 \leq a = bc$ and $bc = a \leq b = b \cdot 1$, Lemma 14.5 gives $0 \leq c$ and $c \leq 1$. If also $bc' = a$, then $bc = bc'$ and Lemma 14.4 gives $c = c'$. □

14.3 A basis is a sequence of divisions

Gaussian elimination needs a pivot in each column it treats. We isolate exactly what a pivot provides: an entry that is not zero, together with the quotients of the other entries by it.

Lemma 14.11 (Pivots give bases)**.** *An independent selection never selects a zero vector. Moreover, suppose every finite list $a_0, \dots, a_m$ of points is either all zero or has a* pivot*: an index p with $a_p \neq 0$ and points $q_0, \dots, q_m$ with $a_p q_i = a_i$ for every i. Then every finite family of vectors in every $\mathbb{R}_\delta^n$ has a basis selection. No omniscience principle and no choice is used.*

Proof. For the first statement, suppose an independent selection b selects $v_p = 0$. The combination with $c_p = 1$ and every other coefficient 0 is $v_p = 0$, so independence gives $1 = 0$, which is false. So $b_p = 0$.

For the second we argue by induction on the number n of coordinates, for all families at once. When $n = 0$, select nothing: every vector is the empty tuple, which is the empty combination, and the empty selection is independent because it selects nothing. Let $n \geq 0$, and let $v_0, \dots, v_{k-1}$ be vectors of $\mathbb{R}_\delta^{n+1}$. If $k = 0$ there is nothing to select. Otherwise write a_i for the first coordinate of v_i and $\bar{v}_i \in \mathbb{R}_\delta^n$ for the remaining ones, and apply the hypothesis to $a_0, \dots, a_{k-1}$.

If every a_i is 0, take a basis selection of $\bar{v}_0, \dots, \bar{v}_{k-1}$, given by the induction hypothesis. It is a basis selection of the v_i, because first coordinates contribute 0 to every combination.

Otherwise let p be a pivot, with $a_p q_i = a_i$. Then $q_p = 1$, by Lemma 14.4 applied to $a_p q_p = a_p = a_p \cdot 1$. Put

$$w_i = \bar{v}_i - q_i \bar{v}_p \in \mathbb{R}_\delta^n,$$

so that $w_p = 0$. The induction hypothesis gives a basis selection b of $w_0, \dots, w_{k-1}$, and $b_p = 0$ by the first statement. Let B be b with p added. We show that B is a basis selection of the v_i.

Independence. Suppose $\sum_B c_i v_i = 0$, and put $S = c_p + \sum_b c_i q_i$. The first coordinate reads $c_p a_p + \sum_b c_i q_i a_p = S a_p = 0 = a_p \cdot 0$, so $S = 0$ by Lemma 14.4. The other coordinates read $\sum_B c_i \bar{v}_i = 0$, and therefore

$$\sum_b c_i w_i = \sum_B c_i \bar{v}_i - S \bar{v}_p = 0.$$

Independence of b gives $c_i = 0$ for every i selected by b, and then $c_p = S = 0$.

Spanning. Fix i, and take coefficients c with $w_i = \sum_b c_l w_l$. Put $S = \sum_b c_l q_l$, and use the coefficients c_l for l selected by b and $q_i - S$ at p. The first coordinate of the combination is $(q_i - S)a_p + \sum_b c_l q_l a_p = q_i a_p = a_i$. The other coordinates are

$$(q_i - S)\bar{v}_p + \sum_b c_l \big(w_l + q_l \bar{v}_p\big) = w_i + q_i \bar{v}_p = \bar{v}_i.$$

So the combination is v_i. Only the cancellation of Lemma 14.4 was used; the pivot a_p is never inverted. Every case distinction is on a bit or on an alternative already supplied. □

Lemma 14.12 (Pivots from scalar pair division)**.** *Scalar pair division gives the hypothesis of Lemma 14.11: every finite list $a_0, \dots, a_m$ of points is all zero or has a pivot. No omniscience principle and no choice is used.*

Proof. By induction on m. For one entry, divide the pair $(a_0, 0)$. The first alternative says $a_0 = 0$. The second says $a_0 \neq 0$, and then $p = 0$ is a pivot with $q_0 = 1$. The third would need $0 \neq 0$.

For $a_0, a_1, \dots, a_{m+1}$, the induction hypothesis applies to $a_1, \dots, a_{m+1}$. If these are all zero, treat a_0 as before: either the whole list is zero, or 0 is a pivot with coefficients $1, 0, \dots, 0$. If they have a pivot p with coefficients $q_1, \dots, q_{m+1}$, divide the pair (a_0, a_p). Both zero contradicts $a_p \neq 0$. If $a_0 \neq 0$ and $a_0 d = a_p$, then 0 is a pivot with coefficients $1, dq_1, \dots, dq_{m+1}$, since $a_0 dq_j = a_p q_j = a_j$. If $a_p \neq 0$ and $a_p d = a_0$, then p is a pivot of the whole list with coefficient d at 0. □

Theorem 14.13 (Basis selection is scalar pair division)**.** *The following are equivalent:*

1. *every finite family of vectors in every $\mathbb{R}^n_\delta$ has a basis selection;*
2. *scalar pair division.*

Neither direction uses an omniscience principle or a choice principle.

Proof. Lemmas 14.12 and 14.11 give the first statement from the second.

Conversely, let a and d be points, and take a basis selection b of the two vectors (a) and (d) of $\mathbb{R}^1_\delta$. If neither is selected, spanning by the empty selection gives $a = 0$ and $d = 0$. If only (d) is selected, then $d \neq 0$ by the first statement of Lemma 14.11, and spanning gives $a = cd$ for some c; this is the third alternative. If only (a) is selected, the second alternative follows in the same way. If both are selected, the combination $d \cdot (a) + (-a) \cdot (d)$ vanishes, so independence gives $-a = 0$, while $a \neq 0$ because (a) is selected; this case cannot occur. The four cases are the four values of two bits. □

Rank and nullity add nothing: a basis selection of the columns already determines a basis of the kernel by an explicit formula.

Theorem 14.14 (Rank–nullity is scalar pair division)**.** *A basis selection of the columns completes to rank–nullity data, and rank–nullity is again scalar pair division.*

1. *If b is a basis selection of the columns of an $n \times m$ matrix A, then there are vectors $K_0, \dots, K_{m-1}$ that form, with b, rank–nullity data for A.*
2. *Rank–nullity is equivalent to scalar pair division.*

Neither statement uses an omniscience principle or a choice principle.

Proof. For the first statement, spanning gives for each column j coefficients $C_{j,l}$ with $\mathrm{col}_j = \sum_{b_l=1} C_{j,l}\,\mathrm{col}_l$. These are finitely many existence statements, and induction on m combines them into one table C; no choice principle is involved. Put

$$K_j = e_j - \sum_{b_l=1} C_{j,l}\, e_l.$$

Then $AK_j = \mathrm{col}_j - \sum_{b_l=1} C_{j,l}\,\mathrm{col}_l = 0$. For j with $b_j = 0$, the coordinate of K_j at an unselected index j' is 1 if $j' = j$ and 0 otherwise, since the subtracted sum lives on selected indices.

Independence. If $\sum_{b_j=0} c_j K_j = 0$, its coordinate at an unselected j' is $c_{j'}$, so every $c_{j'}$ is 0.

The kernel. Let $Ax = 0$, and put $y = x - \sum_{b_j=0} x_j K_j$. At an unselected index j', $y_{j'} = x_{j'} - x_{j'} = 0$. Moreover $Ay = Ax - \sum_{b_j=0} x_j AK_j = 0$. Since y vanishes off the selection, $Ay = \sum_{b_l=1} y_l \operatorname{col}_l$, and independence of the selected columns gives $y_l = 0$ for every selected l. So $y = 0$, and $x = \sum_{b_j=0} x_j K_j$.

For the second statement, scalar pair division gives a basis selection of the columns of every matrix (Theorem 14.13), and the first statement completes the data. Conversely, the first clause of rank–nullity data, for the matrix whose columns are $v_0, \dots, v_{k-1}$, is a basis selection of that family, and Theorem 14.13 gives scalar pair division. □

14.4 Linear algebra costs exactly WLPO

Scalar pair division mixes two tasks: deciding which points are zero, and dividing. The first is WLPO. The second can be stated on its own, and Section 14.6 prices it.

WLPO also gives, for every point x, $x \le 0$ or $x \ge 0$. Indeed the third row of Table 12.2 decides $x \le 0$ or $\neg(x \le 0)$, and $\neg(x \le 0)$, which is $\neg\neg(x > 0)$, excludes $x < 0$. So WLPO gives LLPO, by Corollary 12.18, with no choice.

Theorem 14.15 (Scalar pair division splits)**.** *The following are equivalent:*

1. *scalar pair division;*
2. *WLPO and dominated division by nonzero points;*
3. *WLPO and dominated division.*

No choice is used. By Theorems 14.13 and 14.14, basis selection for every finite family and rank–nullity are each equivalent to WLPO together with dominated division.

Proof. From the first statement. Divide the pair (x, x). The first alternative gives $x = 0$, and the other two give $x \neq 0$. So every point satisfies $x = 0 \vee x \neq 0$, which is WLPO by Corollary 12.18. Now let $a \neq 0$ and $|b| \le |a|$, and divide the pair (a, b). The first alternative contradicts $a \neq 0$; the second is the required quotient; the third gives $b \neq 0$ and $bc = a$, and Lemma 14.7 gives d with $ad = b$.

From the second. Let a and b be points, and let WLPO decide $a = 0 \vee a \neq 0$ and $b = 0 \vee b \neq 0$. If both are zero, the first alternative holds. If $a = 0$ and $b \neq 0$, then $b \cdot 0 = a$; if $a \neq 0$ and $b = 0$, then $a \cdot 0 = b$. If both are nonzero, LLPO, which WLPO gives, compares $|a|$ and $|b|$ by the fourth row of Table 12.2. If $|b| \le |a|$, dominated division by the nonzero point a gives the second alternative; if $|a| \le |b|$, division by b gives the third.

The third statement. Assume WLPO and dominated division by nonzero points, and let $|b| \le |a|$. If $a = 0$, then $|b| \le 0$, so $|b| = 0$, $b = 0$, and $c = 0$ works. If $a \neq 0$, the quotient c with $ac = b$ has $|c| \le 1$ by Lemma 14.6. Conversely, dominated division gives dominated division by nonzero points by forgetting the bound. □

Theorem 14.16 (Linear algebra costs exactly WLPO)**.** *Consider the three assertions: scalar pair division; every finite family of vectors in every $\mathbb{R}_\delta^n$ has a basis selection; and rank–nullity.*

1. *Each of them implies WLPO. No choice is used.*
2. *WLPO implies each of them. The proof uses unique choice: in each division it performs, one table of bits, each bit the answer to a WLPO decision, is collected into a sequence. No countable choice is used.*

Under the reading of maps of this book, which contains unique choice, each of the three assertions is therefore equivalent to WLPO.

Proof. The first part is Theorem 14.15 for scalar pair division, and Theorems 14.13 and 14.14 reduce the other two assertions to it.

For the second part, assume WLPO. We first show: *if $0 \le a \le b$, then $bc = a$ for some c in $[0,1]$.* Here b may be zero. Put $g(c) = bc - a$. Item 4 of Proposition 12.19 gives a natural number $K \ge 1$ with $b \le K$. Since $|g(x) - g(y)| = b\,|x - y|$, points of $[0,1]$ within $1/(K(k+1))$ of each other have values within $1/(k+1)$, so g is uniformly continuous on $[0,1]$; and $g(0) = -a \le 0 \le b - a = g(1)$. For each pair (n, j) of natural numbers, the third row of Table 12.2 decides $g(j/2^n) \le 0$ or $\neg\big(g(j/2^n) \le 0\big)$. So the relation "$\beta = 1$ and $g(j/2^n) \le 0$, or $\beta = 0$ and $\neg(g(j/2^n) \le 0)$" has exactly one bit β for each pair. Unique choice, part of the reading of maps, turns it into a table $B(n, j)$. If $B(n, j) = 1$, then $g(j/2^n) \le 0$. If $B(n, j) = 0$, then $\neg(g(j/2^n) \le 0)$, which excludes $g(j/2^n) < 0$, so $g(j/2^n) \ge 0$. This is exactly the table that the second part of the proof of Theorem 12.54 obtains from LLPO and countable choice. The rest of that proof, from the recursion defining a_n on, uses no further choice; it gives a root c of g in $[0,1]$, that is $bc = a$.

Next, *dominated division.* Let $|b| \le |a|$. The first step, applied to $0 \le |b| \le |a|$, gives c in $[0,1]$ with $|a|\,c = |b|$. LLPO, which WLPO gives, decides $a \ge 0$ or $a \le 0$, and $b \ge 0$ or $b \le 0$. Choose signs $\varepsilon_a, \varepsilon_b \in \{1, -1\}$ accordingly, so that $|a| = \varepsilon_a a$ and $|b| = \varepsilon_b b$. Then $a(\varepsilon_a \varepsilon_b c) = \varepsilon_b |a| c = \varepsilon_b |b| = b$, and $|\varepsilon_a \varepsilon_b c| = c \le 1$.

Theorem 14.15 now gives scalar pair division, and Theorems 14.13 and 14.14 give the other two assertions. Unique choice entered only in the first step, once for each division, and each time for a relation with exactly one bit for each pair. □

Unique choice is not the only way back. Two stronger principles give linear algebra with no choice at all: LPO, and the sequence form $\mathrm{WLPO}_{\mathrm{seq}}$ of WLPO (Definition 13.8), which says that for every binary matrix $(\alpha_i(n))$ there is a binary sequence f with $f(i) = 1$ exactly when $\alpha_i(n) = 0$ for every n. It names, in one sequence, the WLPO decision for every row.

Proposition 14.17 (Two routes with no choice)**.** *LPO implies scalar pair division, and so does* $\mathrm{WLPO}_{\mathrm{seq}}$*. Neither proof uses a choice principle. Consequently each of LPO and* $\mathrm{WLPO}_{\mathrm{seq}}$ *gives basis selections for every finite family and rank–nullity, with no choice.*

Proof. Assume LPO. It gives WLPO and $\mathrm{MP}_{\mathrm{bin}}$ (Proposition 12.9). Let a and b be points, and decide $a = 0 \vee a \ne 0$. If $a \ne 0$, then $\mathrm{MP}_{\mathrm{bin}}$ makes a apart from 0 (Corollary 12.18), so a has an inverse u, and $a(ub) = b$. If $a = 0$, decide $b = 0 \vee b \ne 0$; both zero is the first alternative, and if $b \ne 0$, its inverse u' gives $b(u'a) = a$.

Assume $\mathrm{WLPO}_{\mathrm{seq}}$. Applied to a matrix all of whose rows equal a given binary sequence, it gives WLPO. As in the proof of Theorem 14.16, it suffices to divide a by b when $0 \le a \le b$, because the rest of that proof uses only WLPO. This is a statement about two given points, so we may fix regular sequences naming a and b. For each pair (n, j), listed as a natural number, the formulas for sums and products give an explicit regular sequence naming $g(j/2^n) = b \cdot j/2^n - a$. Let $\alpha_{(n,j)}(N) = 1$ when its stage N exceeds $2/(N+1)$. $\mathrm{WLPO}_{\mathrm{seq}}$ gives a binary sequence f. If $f(n,j) = 1$, the sequence has no positive stage, and since positivity belongs to the point, $g(j/2^n) \le 0$. If $f(n,j) = 0$, then $\neg(g(j/2^n) \le 0)$, and $g(j/2^n) \ge 0$ as before. The second part of the proof of Theorem 12.54, with f as its table, gives the quotient, and no choice has been made.

Theorems 14.13 and 14.14 give the last sentence. □

14.5 The sign of a nonzero point

Dividing by a point that is only known not to be zero produces a sign. Suppose $x \neq 0$ and $|x|\,c = x$. Lemma 14.8 gives $x \ge 0$ or $x \le 0$, a weak sign. LLPO gives a weak sign for every point, and $\mathrm{MP}_{\mathrm{bin}}$ gives a strict sign for every nonzero point; both principles are standard in constructive analysis [14, 40]. The weak sign of nonzero points alone has its own price.

Definition 14.18 (The disjunctive Markov principle)**.** $\mathrm{MP}^{\vee}$ states that every binary sequence α that has at most one entry equal to 1 and is not all zero satisfies

$$(\forall k,\ \alpha(2k) = 0) \quad \text{or} \quad (\forall k,\ \alpha(2k+1) = 0).$$

Its sequence form $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ states: for every binary matrix $(\alpha_i(n))$ whose rows each have at most one entry 1 and none of which is all zero, there is a binary sequence f such that $f(i) = 1$ gives $\alpha_i(2k) = 0$ for every k, and $f(i) = 0$ gives $\alpha_i(2k+1) = 0$ for every k.

$\mathrm{MP}^{\vee}$ is LLPO restricted to sequences known not to be all zero, and $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ is $\mathrm{LLPO}_{\mathrm{seq}}$ of Definition 13.8 restricted to matrices none of whose rows is all zero, with the same reading of the bits. In constructive reverse mathematics $\mathrm{MP}^{\vee}$ is known as a common weakening of Markov's principle, here $\mathrm{MP}_{\mathrm{bin}}$, and LLPO [43, 44]. In $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ the side named for each row is unique: if both sides of a row were free of events, the row would be all zero.

Theorem 14.19 (The weak sign of a nonzero point costs $\mathrm{MP}^{\vee}$)**.** *The weak sign of nonzero points and* $\mathrm{MP}^{\vee}$ *are related as follows.*

1. *Every point $x \neq 0$ of $\mathbb{R}_\delta$ satisfies $x \ge 0$ or $x \le 0$ if and only if* $\mathrm{MP}^{\vee}$ *holds.*
2. *LLPO implies* $\mathrm{MP}^{\vee}$*, and so does* $\mathrm{MP}_{\mathrm{bin}}$*.*

No choice is used.

Proof. This is the proof of Theorem 12.8 with one hypothesis carried along. Assume $\mathrm{MP}^{\vee}$ and let $x \neq 0$. The claim is a statement about one point, so we may fix a regular dyadic presentation (q_n) of x (Theorem 12.17). Form the sequence e of signed events and the first-event sequence f exactly as in that proof: $e(2k) = 1$ when stage k is a positive witness, $e(2k+1) = 1$ when

it is a negative witness, and $f(j) = 1$ when the bounded search through $e(0), \dots, e(j)$ reports its first event at j. Then f has at most one entry 1. It is not all zero: if it were, e would be all zero, since an entry $e(j) = 1$ gives by bounded search a first event $j' \le j$ with $f(j') = 1$; then x would have neither a positive nor a negative witness, and Lemma 12.10 with Theorem 12.17 would give $x = 0$. So $\mathrm{MP}^\vee$ applies to f. The proof of Theorem 12.8 turns "every even entry of f is 0" into $D(x)$, that is $x \le 0$, and "every odd entry is 0" into $U(x)$, that is $x \ge 0$.

Conversely, let β have at most one entry 1 and not be all zero, and let $j_{\sigma,\beta}$ be its jump presentation with the parity sign σ. If its point were 0, Lemma 12.5 would make β all zero; so the point is not 0, and by hypothesis it is ≥ 0 or ≤ 0, that is $U(j_{\sigma,\beta})$ or $D(j_{\sigma,\beta})$. The first half of the proof of Theorem 12.8 shows that $U(j_{\sigma,\beta})$ forces every odd entry of β to vanish and $D(j_{\sigma,\beta})$ every even entry.

For the second statement, LLPO gives $\mathrm{MP}^\vee$ by dropping a hypothesis. Under $\mathrm{MP}_{\mathrm{bin}}$, a sequence α that is not all zero has an entry $\alpha(n) = 1$; it is the only one, so every entry of the other parity is 0. □

For the real numbers of Bishop's constructive mathematics, which allows countable choice, the corresponding equivalence is known; the real-number statement goes back to Mandelkern [42, 43, 44]. On $\mathbb{R}_\delta$ no choice is needed, because the proof works from one regular sequence naming the given point.

Collecting such signs along a sequence is a different matter, and it is where unique choice enters. The relevant case of unique choice concerns relations that are confirmed by infinitely many decidable tests.

Definition 14.20 (Unique choice of bits for Π^0_1 relations)**.** Let $r(i, b, n) \in \{0, 1\}$ be given for all natural numbers i, n and bits b, and say that the bit b *passes row* i when $r(i, b, n) = 1$ for every n. *Unique choice of bits for* Π^0_1 *relations* states: if for every i exactly one bit passes row i, then some binary sequence f has $r(i, f(i), n) = 1$ for all i and n.

This is the principle of unique choice for the relations "b passes row i", so under the reading of maps of this book it holds.

Lemma 14.21 (Collecting weak sides)**.** $\mathrm{MP}^\vee$ *together with unique choice of bits for* Π^0_1 *relations implies* $\mathrm{MP}^\vee_{\mathrm{seq}}$. *No other choice is used.*

Proof. Let $(\alpha_i(n))$ be a matrix as in Definition 14.18. Put $r(i, 1, n) = 1$ when $\alpha_i(2n) = 0$, and $r(i, 0, n) = 1$ when $\alpha_i(2n + 1) = 0$, with $r = 0$ otherwise. A bit passing row i is a correct side for that row. $\mathrm{MP}^\vee$, applied to row i, gives one. Two different bits cannot both pass, because then row i would be all zero. So exactly one bit passes each row, and unique choice of bits for Π^0_1 relations gives the sequence f. □

14.6 Dividing by a nonzero point

Dominated division, with a divisor that may be zero, has the price of order dichotomy.

Theorem 14.22 (Dominated division costs LLPO)**.** *Consider dominated division, Definition 14.3(b).*

1. *Dominated division implies LLPO. No choice is used.*
2. *Assuming* AC_ω*, LLPO implies dominated division. Countable choice is used once, to tabulate one bit for every dyadic ratio.*

Proof. For a point x, $|x| \le \||x|\|$, so dominated division of x by $|x|$ gives c with $|x|\,c = x$. Lemma 14.8 gives $x \ge 0$ or $x \le 0$. This holds for every point, which is LLPO by Corollary 12.18.

Conversely, assume LLPO and AC_ω, and let $|b| \le |a|$. The function $g(c) = |a|\,c - |b|$ is uniformly continuous on $[0,1]$, as in the proof of Theorem 14.16, and $g(0) = -|b| \le 0 \le |a| - |b| = g(1)$. The second part of Theorem 12.54 gives a root c in $[0,1]$, so $|a|\,c = |b|$; countable choice is used there, once. The signs of a and b, decided by LLPO, turn c into a quotient $\varepsilon_a\varepsilon_b c$ with $a\varepsilon_a\varepsilon_b c = b$ and $|\varepsilon_a\varepsilon_b c| \le 1$, exactly as in the proof of Theorem 14.16. □

When the divisor is only known not to be zero, the bisection of Theorem 12.54 has no bits to work with: LLPO is not available. What a nonzero divisor does provide concerns two points at once. Let $0 \le a \le b$ with $b \neq 0$, and let $l < r$ be two ratios. Then $a \le b\,l$ and $b\,r \le a$ cannot both hold: together they give $b\,r \le b\,l$, and Lemma 14.5 would give $r \le l$. A search through the stages of a regular sequence for a witness that a point is positive stays silent exactly when the point is ≤ 0, because positivity belongs to the point. So the two stage tests, for $a > b\,l$ and for $b\,r > a$, cannot both stay silent; trisection uses exactly this.

Definition 14.23 (Affine trisection control)**.** For natural numbers n and p with $p + 2^n \le 3^n$, the interval $[p/3^n, (p+2^n)/3^n]$ lies in $[0,1]$ and has width $(2/3)^n$; its *trisection points* are

$$l_{n,p} = \frac{3p + 2^n}{3^{n+1}}, \qquad r_{n,p} = \frac{3p + 2^{n+1}}{3^{n+1}}.$$

Affine trisection control states: for all points a, b with $0 \le a \le b$ and $b \neq 0$ there are bits $B(n,p)$, one for every pair of natural numbers, such that whenever $p + 2^n \le 3^n$, $B(n,p) = 1$ gives $b\,l_{n,p} \le a$ and $B(n,p) = 0$ gives $a \le b\,r_{n,p}$.

Read with the quotient $c = a/b$ in mind, the bit says where c may be sought (Figure 14.1): $B(n,p) = 1$ promises $c \ge l_{n,p}$, and $B(n,p) = 0$ promises $c \le r_{n,p}$. The two promises overlap, and both can be true, so the bit is not determined by a and b; for that reason unique choice cannot collect it directly. The table covers every admissible interval, not only those that a search will visit.

Say that a function g on the points of $\mathbb{R}_\delta$ is *continuous at every point of* $[0,1]$ when for every x in $[0,1]$ and every k there is a j such that every y in $[0,1]$ within $1/(j+1)$ of x has $g(y)$ within $1/(k+1)$ of $g(x)$. A function uniformly continuous on $[0,1]$ has this property.

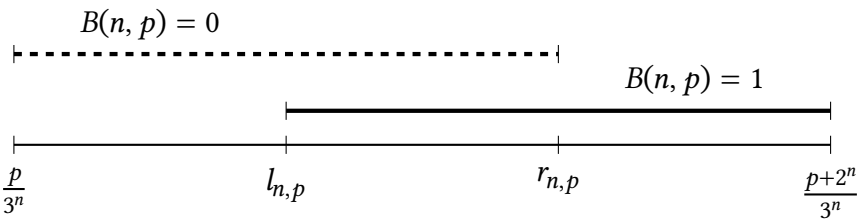

Figure 14.1. One step of trisection. The bit 1 records $b\,l_{n,p} \le a$ and keeps the solid interval $[l_{n,p}, (p + 2^n)/3^n]$; the bit 0 records $a \le b\,r_{n,p}$ and keeps the dashed interval $[p/3^n, r_{n,p}]$. Either kept interval has two thirds of the old width, and the two overlap in the middle third, so a weak side at either of two different points suffices.

Lemma 14.24 (Trisection with weak sides)**.** *Let g be continuous at every point of $[0, 1]$ with $g(0) \le 0 \le g(1)$, and let $B(n, p)$ be bits such that whenever $p + 2^n \le 3^n$, $B(n, p) = 1$ gives $g(l_{n,p}) \le 0$ and $B(n, p) = 0$ gives $g(r_{n,p}) \ge 0$. Then g has a root in $[0, 1]$. No omniscience principle and no choice is used.*

Proof. Define natural numbers p_n by recursion: $p_0 = 0$, and $p_{n+1} = 3p_n + 2^n$ if $B(n, p_n) = 1$, otherwise $p_{n+1} = 3p_n$. Put $\lambda_n = p_n/3^n$ and $\mu_n = (p_n + 2^n)/3^n$. Induction on n gives

$$p_n + 2^n \le 3^n, \qquad \mu_n - \lambda_n = (2/3)^n, \qquad g(\lambda_n) \le 0 \le g(\mu_n),$$

together with $\lambda_n \le \lambda_{n+1}$ and $\mu_{n+1} \le \mu_n$. Indeed, if $B(n, p_n) = 1$, the new interval is $[l_{n,p_n}, \mu_n]$, because $3p_n + 2^n + 2^{n+1} = 3(p_n + 2^n)$, and $g(l_{n,p_n}) \le 0$; the new bound reads $3(p_n + 2^n) \le 3^{n+1}$. If $B(n, p_n) = 0$, the new interval is $[\lambda_n, r_{n,p_n}]$ and $g(r_{n,p_n}) \ge 0$; the new bound reads $3p_n + 2^{n+1} \le 3(p_n + 2^n) \le 3^{n+1}$.

For $m \ge n$ the intervals are nested, so $|\lambda_m - \lambda_n| \le (2/3)^n$. Since $(9/4)^k \ge 1 + 5k/4 \ge k + 1$, the ratios $t_k = \lambda_{2^k}$ satisfy $|t_k - t_l| \le (4/9)^{\min(k,l)} \le 1/(k + 1) + 1/(l + 1)$, so they form a regular sequence. Let t be its point. By Lemma 12.52, item 4, λ_{2^k} is within $1/(k + 1)$ of t. The ratios μ_{2^k} and λ_{2^k} are within $(4/9)^k \le 1/(k + 1)$ of each other, so $\mu_{2(2k+1)}$ is within $1/(2k + 2) + 1/(2k + 2) = 1/(k + 1)$ of t (item 5). Every λ_n lies in $[0, 1]$, so item 2 puts t in $[0, 1]$.

Fix k, and take j as in continuity at t. The point λ_{2^j} of $[0, 1]$ is within $1/(j + 1)$ of t, so $g(\lambda_{2^j})$, which is at most 0, is within $1/(k + 1)$ of $g(t)$. Since k was arbitrary, item 2 gives $g(t) \le 0$. In the same way $g(\mu_{2(2j+1)}) \ge 0$ is within $1/(k + 1)$ of $g(t)$, so $g(t) \ge 0$, and $g(t) = 0$ by item 2 of Proposition 12.19. Every step is a recursion on given bits, a finite computation or an estimate. □

A single point gives such a table for itself, from any sequence naming it.

Lemma 14.25 (A point gives its own trisection table)**.** *Let c be a point of $[0, 1]$. There are bits $B(n, p)$ such that whenever $p + 2^n \le 3^n$, $B(n, p) = 1$ gives $l_{n,p} \le c$ and $B(n, p) = 0$ gives $c \le r_{n,p}$. No omniscience principle and no choice is used.*

Proof. The claim is a statement about the one point c, so we may fix a regular sequence s naming it. For a pair (n, p) let $m = (l_{n,p} + r_{n,p})/2$ and $h = (r_{n,p} - l_{n,p})/2 = 2^n/(2 \cdot 3^{n+1})$, and let $N = 2 \cdot 3^{n+1}$, so that $1/(N + 1) < h$. Compare the ratios s_N and m. By Lemma 12.52, item 4, the

ratio s_N is within $1/(N+1)$ of c. If $s_N \geq m$, put $B(n,p) = 1$; then $c \geq s_N - 1/(N+1) > m - h = l_{n,p}$. Otherwise put $B(n,p) = 0$; then $c \leq s_N + 1/(N+1) < m + h = r_{n,p}$. Each bit is a comparison of two ratios computed from s. □

The last ingredient divides with a sign that the division itself supplies.

Lemma 14.26 (Positive division suffices)**.** *Suppose that for all points $0 \leq a \leq b$ with $b \neq 0$ some c has $bc = a$. Then:*

1. *for all points $d \geq 0$ with $d \neq 0$ and every x with $|x| \leq d$, some r has $dr = x$;*
2. *dominated division by nonzero points holds.*

No omniscience principle and no choice is used.

Proof. For the first statement, $-x \leq |x| \leq d$ and $x \leq |x| \leq d$ give $0 \leq d + x \leq d + d$. Moreover $d + d \neq 0$: if $d + d = 0$, then $d = -d \leq 0$, so $d = 0$. The hypothesis gives c with $(d + d)c = d + x$, and then $d(c + c - 1) = (d + d)c - d = x$.

For the second, let $a \neq 0$ and $|b| \leq |a|$, and put $d = |a|$, so that $d \geq 0$ and $d \neq 0$. The first statement with $x = a$ gives s with $|a|\, s = a$, and Lemma 14.8 gives $a \geq 0$ or $a \leq 0$. The first statement with $x = b$ gives r with $|a|\, r = b$. If $a \geq 0$, then $|a| = a$ and $ar = b$; if $a \leq 0$, then $|a| = -a$ and $a(-r) = b$. No sign was decided by a principle: the weak sign of a came out of a division. □

Theorem 14.27 (Trisection control is division by nonzero points)**.** *The following are equivalent:*

1. *affine trisection control;*
2. *for all points $0 \leq a \leq b$ with $b \neq 0$ some c has $bc = a$;*
3. *dominated division by nonzero points.*

No omniscience principle and no choice is used.

Proof. From the first to the second. Let $0 \leq a \leq b$ with $b \neq 0$, take the bits of affine trisection control, and put $g(c) = bc - a$. It is uniformly continuous on $[0,1]$ (proof of Theorem 14.16), and $g(0) \leq 0 \leq g(1)$. A bit 1 gives $g(l_{n,p}) \leq 0$ and a bit 0 gives $g(r_{n,p}) \geq 0$, so Lemma 14.24 gives a root.

From the second to the third. This is Lemma 14.26.

From the third to the first. Let $0 \leq a \leq b$ with $b \neq 0$. Then $|a| = a \leq b = |b|$, and dominated division by the nonzero point b gives c with $bc = a$; it lies in $[0,1]$ by Lemma 14.10. Lemma 14.25 gives bits for c. Multiplying by $b \geq 0$ turns $l_{n,p} \leq c$ into $b\, l_{n,p} \leq bc = a$, and $c \leq r_{n,p}$ into $a \leq b\, r_{n,p}$. □

Theorem 14.28 (Division by nonzero points costs $\mathrm{MP}^\vee$)**.** *Consider dominated division by nonzero points, Definition 14.3(c), and affine trisection control.*

1. *Dominated division by nonzero points implies* $\mathrm{MP}^\vee$*. No choice is used.*
2. $\mathrm{MP}^\vee_{\mathrm{seq}}$ *implies affine trisection control, and hence dominated division by nonzero points. No choice is used.*
3. $\mathrm{MP}^\vee$*, together with unique choice of bits for* Π^0_1 *relations, implies affine trisection control and dominated division by nonzero points.*
4. $\mathrm{MP}_{\mathrm{bin}}$ *implies dominated division by nonzero points. No choice is used.*

Under the reading of maps of this book, dominated division by nonzero points and affine trisection control are therefore each equivalent to $\mathrm{MP}^\vee$*.*

Proof. The first statement. Let $x \neq 0$. Then $|x| \neq 0$ and $|x| \leq \||x|\|$, so dividing x by the nonzero point $|x|$ gives c with $|x|\,c = x$. Lemma 14.8 gives $x \geq 0$ or $x \leq 0$, and Theorem 14.19 gives $\mathrm{MP}^\vee$.

The second. Let $0 \leq a \leq b$ with $b \neq 0$. This is a statement about two given points, so we may fix regular sequences naming a and b. List the pairs (n, p) as natural numbers i. For an admissible pair, the points $u_i = a - b\,l_{n,p}$ and $v_i = b\,r_{n,p} - a$ are named by explicit regular sequences; let $\alpha_i(N) = 1$ when stage N of the sequence for u_i exceeds $2/(N+1)$, and $\beta_i(N) = 1$ when stage N of the sequence for v_i does. Since positivity belongs to the point, $u_i > 0$ exactly when α_i has an entry 1, and likewise for v_i and β_i. As shown before Definition 14.23, $u_i \leq 0$ and $v_i \leq 0$ cannot both hold; so it is impossible that both α_i and β_i are all zero.

Keep only the first event of the two rows. Let $\gamma_i(2N) = 1$ when N is the least index at which α_i or β_i has an entry 1 and $\alpha_i(N) = 1$, and $\gamma_i(2N+1) = 1$ when N is that least index, $\alpha_i(N) = 0$ and $\beta_i(N) = 1$; all other entries are 0, and each is a bounded search. For a pair that is not admissible, let γ_i have a single entry 1, at position 0. Each row γ_i has at most one entry 1, and none is all zero: if γ_i were all zero, a bounded search would show that α_i and β_i are all zero. So $\mathrm{MP}^\vee_{\mathrm{seq}}$ gives a binary sequence f.

Let i be admissible. If $f(i) = 1$, every even entry of γ_i is 0, and then $\neg\neg(v_i > 0)$. Indeed, suppose β_i were all zero. Then α_i would be all zero too: an entry $\alpha_i(N) = 1$ would give, by bounded search, a least index $N' \leq N$ at which one of the rows has an entry 1, and since $\beta_i(N') = 0$ this would be an even entry $\gamma_i(2N') = 1$. Both rows would be all zero, which is impossible. So $\neg\neg(v_i > 0)$, hence $\neg(v_i < 0)$, that is $a \leq b\,r_{n,p}$, and we put $B(n,p) = 0$. If $f(i) = 0$, the odd entries of γ_i vanish, the same argument gives $\neg\neg(u_i > 0)$, hence $b\,l_{n,p} \leq a$, and we put $B(n,p) = 1$. This is the table of affine trisection control, and Theorem 14.27 gives the division.

The third. Lemma 14.21 gives $\mathrm{MP}^\vee_{\mathrm{seq}}$; apply the second statement.

The fourth. Let $a \neq 0$ and $|b| \leq |a|$. $\mathrm{MP}_{\mathrm{bin}}$ makes a apart from 0 (Corollary 12.18), with an inverse u, and $a(ub) = b$. □

The route through $\mathrm{MP}^\vee$ sharpens the choice used in Theorem 14.16.

Corollary 14.29 (Unique choice for Π^0_1 relations suffices)**.** *WLPO, together with unique choice of bits for Π^0_1 relations, implies scalar pair division, basis selection for every finite family and rank–nullity. No other choice is used.*

Proof. WLPO gives LLPO, which gives $\mathrm{MP}^\vee$ (Theorem 14.19). The third part of Theorem 14.28 gives dominated division by nonzero points, Theorem 14.15 gives scalar pair division, and Theorems 14.13 and 14.14 give the rest. □

14.7 Signs as units

A sign can also be recorded as a unit. For a point x and a bit b, put $\sigma_1 = 1$ and $\sigma_0 = -1$, and say that *b normalizes x* when $|x|\,\sigma_b = x$. A sequence of points is *given by regular sequences* when it is presented as regular sequences $s_0, s_1, \ldots$ naming its terms (Definition 12.39).

Theorem 14.30 (Signed units)**.** *Normalizing bits, one at a time and collected along a sequence, are priced as follows.*

1. *The bit* 1 *normalizes x exactly when $x \geq 0$, and the bit* 0 *exactly when $x \leq 0$. So every point $x \neq 0$ has a normalizing bit if and only if* $\mathrm{MP}^\vee$ *holds, and under WLPO every point has a normalizing bit.*

2. *Let the points $x_0, x_1, \ldots$ be given by regular sequences, with $x_i \neq 0$ for every i. Each of the following, asserted for every such sequence, is equivalent to* $\mathrm{MP}^\vee_{\mathrm{seq}}$*:* signed-unit collection*, a binary sequence f such that $f(i)$ normalizes x_i for every i; and* absolute-quotient collection*, a sequence of points c_i with $|x_i|\,c_i = x_i$ for every i.*

No choice is used.

Proof. For the first statement, $|x| \cdot 1 = x$ says $|x| = x$, which holds exactly when $x \geq 0$, and $|x| \cdot (-1) = x$ says $|x| = -x$, which holds exactly when $x \leq 0$. Theorem 14.19 prices the weak sign of nonzero points, and WLPO gives LLPO, which gives a weak sign for every point.

For the second, let s_i name x_i. *From* $\mathrm{MP}^\vee_{\mathrm{seq}}$ *to signed units.* Form from each s_i the first-event row of the proof of Theorem 14.19, with the stages of s_i above $2/(k+1)$ or below $-2/(k+1)$ as signed events. It has at most one entry 1, and it is not all zero, because $x_i \neq 0$ and a point with neither a positive nor a negative stage is 0 (Lemma F.8). $\mathrm{MP}^\vee_{\mathrm{seq}}$ names a side for every row. If the even entries vanish, $x_i \leq 0$: a positive stage would make the first event a negative stage, and a regular sequence has no stages above $2/(m+1)$ and below $-2/(n+1)$, by the argument of Lemma 12.3. Then the bit 0 normalizes x_i. If the odd entries vanish, $x_i \geq 0$ and the bit 1 normalizes it.

From signed units to $\mathrm{MP}^\vee_{\mathrm{seq}}$. Given a matrix as in Definition 14.18, let x_i be the point of the jump presentation of row i with the parity sign; these are explicit regular sequences. Each $x_i \neq 0$ by Lemma 12.5. A normalizing bit 1 says $x_i \geq 0$, which forces every odd entry of row i to vanish, and a bit 0 says $x_i \leq 0$, which forces every even entry to vanish, as in the proof of Theorem 14.19. So $f(i) = 1$ when the bit is 0, and $f(i) = 0$ when it is 1, is the required sequence.

Assertion on $\mathbb{R}_\delta$	Price	Choice
Scalar pair division (Theorems 14.15 and 14.16)	WLPO	unique choice in the converse
Every finite family in every $\mathbb{R}_\delta^n$ has a basis selection (Theorems 14.13 and 14.16)	WLPO	unique choice in the converse
Rank–nullity (Theorems 14.14 and 14.16)	WLPO	unique choice in the converse
Every matrix has a rank, which is also the rank of its transpose (Theorem G.4)	WLPO	not used
Dominated division (Theorem 14.22)	LLPO	countable choice in the converse
Dominated division by nonzero points; affine trisection control (Theorems 14.27 and 14.28)	$\mathrm{MP}^\vee$	unique choice in the converse
Every $x \neq 0$ has $x \geq 0$ or $x \leq 0$; equivalently, a normalizing bit (Theorems 14.19 and 14.30)	$\mathrm{MP}^\vee$	not used
Signed-unit collection; absolute-quotient collection, for nonzero points given by regular sequences (Theorems 14.30 and G.10)	$\mathrm{MP}^\vee$	unique choice in the converse
Quantitative uniqueness of the roots of $c \mapsto bc - a$ (Theorem G.7)	$\mathrm{MP}_{\mathrm{bin}}$	not used
For 2×2 matrices: a nonzero determinant gives an inverse; an injective matrix is surjective (Theorem G.5)	$\mathrm{MP}_{\mathrm{bin}}$	not used
Every continuous injective map of the line is strictly monotone (Theorem G.9)	$\mathrm{MP}_{\mathrm{bin}}$	not used
k independent vectors of $\mathbb{R}_\delta^n$ have $k \leq n$; a matrix with zero kernel has no more columns than rows (Proposition G.1)	none	not used
A surjective 2×2 matrix is injective (Theorem G.5)	none	not used

Table 14.1. Linear algebra and division on the line built from ratios. "Price" is the principle equivalent to the assertion, and "none" means that the assertion is proved outright. In every priced row the passage from the assertion to the principle uses no choice. "In the converse" means that the named choice principle is used in the passage from the principle back to the assertion; unique choice is part of the reading of maps of this book, and in the rows priced $\mathrm{MP}^\vee$ and in Corollary 14.29 it is needed only for bits of Π^0_1 relations. Each row names the results that prove both directions.

Absolute quotients. Normalizing bits b_i give the quotients $c_i = \sigma_{b_i}$. Conversely, let $|x_i|\, c_i = x_i$ for every i. Each c_i is apart from 0 by Lemma 14.9. For a point c apart from 0 exactly one of $c > 0$ and $c < 0$ holds, and which one is found from any regular sequence naming c by searching for its first stage above $2/(n+1)$ or below $-2/(n+1)$; the search is proved to terminate, because c is apart from 0, and two sequences naming c give the same answer, since a point is not both positive and negative. So the sign is computed from the point itself, with no selection of representatives. If $c_i > 0$, then $x_i = |x_i|\, c_i \geq 0$, and the bit 1 normalizes x_i; if $c_i < 0$, then $x_i \leq 0$ and the bit 0 normalizes it. □

With Theorem G.10 of Appendix G, which shows that $\mathrm{MP}^\vee_{\mathrm{seq}}$ is $\mathrm{MP}^\vee$ together with unique choice of bits for Π^0_1 relations, each collection is equivalent to $\mathrm{MP}^\vee$ under the reading of maps of this book. A collection gives $\mathrm{MP}^\vee$ with no choice; unique choice is used in the converse.

14.8 The prices

Table 14.1 collects the prices of this chapter and of Appendix G. The order and field prices of the line itself are those of Table 12.2.

14.9 Without unique choice

Unique choice is part of the reading of maps of this book, and under that reading the prices of Table 14.1 are final, except that the row priced LLPO uses countable choice in the converse (Theorem 14.22). Now read maps more narrowly: a sequence must be given by an explicit rule, and a search that is proved to terminate counts as one, but a relation with exactly one witness for each number need not define a sequence. This section records which prices survive.

Every result of this chapter marked "no choice" holds over that base, including the passage from each assertion to its principle. Some passages back survive too: LPO and $\mathrm{WLPO}_{\mathrm{seq}}$ still give linear algebra (Proposition 14.17), and $\mathrm{MP}_{\mathrm{bin}}$ and $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ still give division by nonzero points (Theorem 14.28). What is lost is the step from WLPO, or from $\mathrm{MP}^{\vee}$, to a table of bits. Appendix G measures it: $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ is $\mathrm{MP}^{\vee}$ together with unique choice of bits for Π^0_1 relations (Theorem G.10), and a search for a failed test, which would name the surviving bit, costs exactly $\mathrm{MP}_{\mathrm{bin}}$ (Theorem G.11). What remains are two questions.

> *Over a base without unique choice, does WLPO imply scalar pair division, and does* $\mathrm{MP}^{\vee}$ *imply dominated division by nonzero points?*

Theorem G.12 proves the following with no choice. WLPO implies scalar pair division exactly when it implies affine trisection control; in that case Theorems 14.13, 14.14 and 14.16 make basis selection and rank–nullity each equivalent to WLPO with no choice in either direction. A second statement, that scalar pair division is equivalent to WLPO together with unique choice of bits for Π^0_1 relations with no choice in either direction, holds exactly when scalar pair division yields absolute-quotient collections. And WLPO yields unique choice of bits for Π^0_1 relations exactly when the answer to the first question is yes and the second statement holds.

Questions to work through

1. Show directly that a basis selection of the single vector (x) of $\mathbb{R}^1_\delta$ decides $x = 0 \vee x \neq 0$. Which part of Definition 14.1 gives each alternative?

2. Prove that if $x \neq 0$ and $|x|\,c = x$, then $|c| = 1$. Then use Lemma 14.8 to show that the quotient decides $x \geq 0$ or $x \leq 0$ without any bound on c given in advance.

3. In the proof of Theorem 14.16, the bit $B(n, j) = 0$ records $\neg(g(j/2^n) \leq 0)$. Show that this gives $g(j/2^n) \geq 0$, and explain why the relation used there has exactly one bit for each pair, while the bits of Theorem 12.54 need not be unique.

4. Let $0 \leq a \leq b$, $b \neq 0$, and let $l < r$ be ratios. Show that $a \leq bl$ and $br \leq a$ cannot both hold. Why does the argument fail at a single midpoint m, as in bisection?

Chapter 15

Differential equations to certified precision

Take the oscillator $y_0' = y_1$, $y_1' = -y_0$ with $y(0) = (0, 1)$. At time 1 its first coordinate is $\sin 1$. Suppose we are asked for $\sin 1$ to m bits: an integer a with $|\sin 1 - a/2^m| \le 2^{-m}$. The program of this chapter answers the request for 40 bits with 925207132232. To produce it, it takes 32 steps of a Taylor method of order 61, on dyadic numbers with 61 binary digits after the point. Asked for 400 bits, it takes the same 32 steps, now of order 421. The number of steps never changes; only the order and the working precision grow with the request.

Three questions follow. Why can the number of steps stay fixed while the precision grows? What does a request for m bits cost, counted exactly? And what does the integer that comes back certify, if no exact solution of the equation is assumed to exist? Chapter 10 asked for one program for every requested precision and warned that an execution-time claim needs its own construction and bound. Chapters 11 and 12 built the line from rational and dyadic enclosures. This chapter supplies the construction and the bound for a whole class of problems: quadratic and polynomial vector fields with rational data, each with a finite check on one computed trajectory. Its answer is a point of the line $\mathbb{R}_\delta$ given by a program with a proved modulus, an exact count of the arithmetic that program performs, and finally one fixed binary machine that, for every such problem whose check holds at the level named in the request, answers every request for m bits within $K(m+1)^\lambda$ steps. The exponent λ is the same for every problem; only the constant K depends on the problem. Appendix I constructs the machine stage by stage and proves each stage's bound.

15.1 A number is a program with a proof of its precision

The interval protocols of Chapter 10 and the regular sequences of Chapter 12 have moduli of the form $1/(n+1)$. That is enough to name a point. It is too slow for counting work. To add two interval protocols, Chapter 11 reads both operands at request $2n+1$; a sum of sums reads its leaves at about $4n$, and an expression of depth h at about $2^h n$. With a modulus 2^{-n} the same sum needs only two extra bits, and depth h costs $2h$ extra bits. The difference between multiplying and adding precision is what makes a polynomial bound possible.

Definition 15.1 (Certified real)**.** A *certified real* x is a sequence $(a_n)_{n\ge 0}$ of integers such that, for all m, n,

$$|a_m 2^n - a_n 2^m| \le 2^n + 2^m, \qquad \text{that is,} \qquad \left|\frac{a_m}{2^m} - \frac{a_n}{2^n}\right| \le 2^{-m} + 2^{-n}.$$

The integer a_n is the *answer* of x at precision n, and the ratio $a_n/2^n$ is its *stage* n.

The integer form is the definition; the rational form abbreviates it, as in Definition 12.1. A certified real is a program in the sense of Chapter 10 only when its answers are computed by one; every certified real in this chapter is given by an explicit calculation of a_n from n.

Lemma 15.2 (A certified real names a point of the line)**.** *The answers of a certified real form a regular dyadic presentation in the sense of Definition 12.1. Its stages, read as the ratio records $(a_n, 2^n)$, are therefore a regular sequence, and they name a point of $\mathbb{R}_\delta$.*

Proof. Since $n+1 \le 2^n$ for every n, we have $2^{-n} \le 1/(n+1)$. Hence

$$\begin{aligned}|a_m 2^n - a_n 2^m|(m+1)(n+1) &\le (2^n + 2^m)(m+1)(n+1)\\ &\le 2^n 2^m (n+1) + 2^m (m+1) 2^n = 2^{m+n}(m+n+2),\end{aligned}$$

which is (12.1). The remaining assertions are the remarks after Definition 12.14. □

To build certified reals we need one tool. A program usually does not know the exact value it approximates; it knows exact ratios computed from its inputs' own answers. We call such ratios *ideal values*: what the program would return with unlimited precision.

Lemma 15.3 (The ideal-value lemma)**.** *Let (a_n) be integers, let $I(M)$ be ratios for $M \in \mathbb{N}$, and let $T : \mathbb{N} \to \mathbb{N}$ and $C \in \mathbb{N}$. Suppose that*

$$\left|\frac{a_n}{2^n} - I(M)\right| \le 2^{-n} + C\,2^{-M} \qquad \text{whenever } M \ge T(n).$$

Then (a_n) is a certified real.

Proof. Fix m and n. For every $M \ge \max(T(m), T(n))$ the triangle inequality through $I(M)$ gives

$$\left|\frac{a_m}{2^m} - \frac{a_n}{2^n}\right| \le 2^{-m} + 2^{-n} + 2C\,2^{-M}.$$

Since $2^{-M} \le 1/(M+1)$, this bound holds with $2C/(k+1)$ in place of the last term for every k: take $M \ge \max(T(m), T(n), k)$. The Archimedean step of Theorem 12.17 removes it. □

No completed real number appears in this argument. The ideal values are ratios, and the conclusion is an inequality between integers.

Rounding is the only other ingredient. For a ratio q write $\operatorname{near}(q) = \lfloor q + 1/2 \rfloor$ for the nearest integer, halves rounded upward, so that $|\operatorname{near}(q) - q| \le 1/2$. For integers u and k, $\operatorname{near}(u/2^{k+1}) = \lfloor (u + 2^k)/2^{k+1} \rfloor$ is computed by one floor division. For a natural number n write $\operatorname{bl}(n)$ for its number of binary digits, with $\operatorname{bl}(0) = 0$; then $n < 2^{\operatorname{bl}(n)}$.

Proposition 15.4 (Sum and product with additive precision)**.** *Let $x = (x_n)$ and $y = (y_n)$ be certified reals. The negative $-x$ has answers $-x_n$.*

(a) Put $s_n = \operatorname{near}\big((x_{n+2} + y_{n+2})/4\big)$. For $M \ge n+2$,

$$\left|\frac{s_n}{2^n} - \left(\frac{x_M}{2^M} + \frac{y_M}{2^M}\right)\right| \le 2^{-n} + 2 \cdot 2^{-M},$$

so (s_n) is a certified real, the sum $x + y$.

(b) Put $e_x = \mathrm{bl}(|x_0|) + 1$ *and* $e_y = \mathrm{bl}(|y_0|) + 1$. *Then* $|x_M/2^M| \le 2^{e_x}$ *for every* M. *With* $k = n + 3 + e_x + e_y$, *put* $p_n = \mathrm{near}\big(x_k y_k / 2^{2k-n}\big)$. *For every* M,

$$\left|\frac{p_n}{2^n} - \frac{x_M}{2^M}\cdot\frac{y_M}{2^M}\right| \le 2^{-n} + \left(2^{e_x} + 2^{e_y}\right) 2^{-M},$$

so (p_n) *is a certified real, the product* xy.

Proof. (a) Rounding gives $|s_n/2^n - (x_{n+2} + y_{n+2})/2^{n+2}| \le 2 \cdot 2^{-(n+2)} = 2^{-(n+1)}$. The moduli of x and y give $|x_{n+2}/2^{n+2} - x_M/2^M| \le 2^{-(n+2)} + 2^{-M}$, and the same for y. Adding the three bounds gives $2^{-(n+1)} + 2^{-(n+1)} + 2 \cdot 2^{-M}$. The ideal-value lemma with $I(M) = x_M/2^M + y_M/2^M$, $T(n) = n + 2$ and $C = 2$ applies.

(b) The modulus at M and 0 gives $|x_M/2^M - x_0| \le 2^{-M} + 1$, and $|x_0| \le 2^{\mathrm{bl}(|x_0|)} - 1$. So $|x_M/2^M| \le 2^{\mathrm{bl}(|x_0|)} + 2^{-M} \le 2^{e_x}$. Rounding costs $|p_n/2^n - x_k y_k/2^{2k}| \le 2^{-(n+1)}$. For the product of stages, with $p = x_k/2^k$, $q = y_k/2^k$, $p' = x_M/2^M$, $q' = y_M/2^M$,

$$|pq - p'q'| \le |p|\,|q - q'| + |q'|\,|p - p'| \le (2^{e_x} + 2^{e_y})(2^{-k} + 2^{-M}).$$

Finally $2^{e_x} + 2^{e_y} \le 2^{e_x + e_y + 1}$, so $(2^{e_x} + 2^{e_y})2^{-k} \le 2^{-(n+2)}$ and $2^{-(n+1)} + 2^{-(n+2)} \le 2^{-n}$. The ideal-value lemma with $I(M) = (x_M/2^M)(y_M/2^M)$, $T(n) = k$ and $C = 2^{e_x} + 2^{e_y}$ applies. For the negative, the modulus is unchanged by a change of sign. □

The sum asks its inputs for $n + 2$ bits and the product for $n + 3 + e_x + e_y$, where e_x and e_y are read off the inputs' answers at precision 0. Both are n plus a constant. The line's own operations, in Proposition 12.19, read their operands at $2n + 1$ and at $2K(n + 1) - 1$. They compute the same points.

Proposition 15.5 (The certified operations are the line's operations)**.** *Write* $\bar{x}$ *for the point of* $\mathbb{R}_\delta$ *named by a certified real* x. *Then* $\overline{x + y} = \bar{x} + \bar{y}$, $\overline{-x} = -\bar{x}$ *and* $\overline{xy} = \bar{x}\,\bar{y}$, *with the operations of Proposition 12.19 on the right.*

Proof. Let u and v be the stage sequences of x and y. Stage n of the line's sum is $u_{2n+1} + v_{2n+1}$. For $n \ge 1$ we have $2n + 1 \ge n + 2$, and part (a) of Proposition 15.4 with $M = 2n + 1$ puts stage n of $x + y$ within $2^{-n} + 2 \cdot 2^{-(2n+1)} \le 2 \cdot 2^{-n} \le 2/(n + 1)$ of it. For a tolerance $1/(k + 1)$ every $n \ge \max(1, 2k + 1)$ is within it, so the two regular sequences name the same point (Definition 12.14). Stage n of the line's product is $u_j v_j$ for an index $j \ge n$, and part (b) with $M = j$ puts stage n of xy within $2^{-n} + C2^{-j} \le (1 + C)/(n + 1)$ of it, where $C = 2^{e_x} + 2^{e_y}$; Lemma F.8(a) applies. The stages of $-x$ are the negated stages of x, which are the stages of the line's negative. □

A certified real carries its error with it. In the order of the line, $\bar{x}$ and $\eta(a_m/2^m)$ are within 2^{-m} in the sense of Chapter 12: $\bar{x} \le \eta(a_m/2^m) + \eta(2^{-m})$ and $\eta(a_m/2^m) \le \bar{x} + \eta(2^{-m})$. Indeed $2^{-m} = 1/(k+1)$ for $k = 2^m - 1$, and the modulus gives $|a_n/2^n - a_m/2^m| \le 2^{-m} + 2^{-n} \le 2^{-m} + 2/(n+1)$ for every n. This is the stagewise bound of Lemma 12.23 for the stages of x and the constant sequence of $a_m/2^m$, and that lemma gives the two inequalities. A certified real is thus exactly a program that answers every precision request with an integer whose error is proved.

15.2 Carrying every rounding error forward

A long calculation rounds many times. Two tools keep the errors under control: enclosures that carry a radius with every number, and an inequality that propagates the error of a step map through many steps.

Fix a working precision w. A *ball* is a pair (c, r) of integers, read as the dyadic centre $c/2^w$ and radius $r/2^w$.

Definition 15.6 (Ball enclosure)**.** The ball (c, r) *encloses* a ratio p at precision w if $|p - c/2^w| \le r/2^w$; for $p = \langle u; e\rangle$ with $e > 0$ this is the integer inequality $|u2^w - ce| \le re$.

Sums of balls add centres and radii. Products need one floor division and a small correction for the two floors.

Lemma 15.7 (The product of two balls)**.** *If (c_1, r_1) encloses p and (c_2, r_2) encloses q at precision w, then*

$$\left(\left\lfloor \frac{c_1 c_2}{2^w} \right\rfloor,\ \left\lfloor \frac{|c_1| r_2 + |c_2| r_1 + r_1 r_2}{2^w} \right\rfloor + 2\right)$$

encloses pq at precision w.

Proof. Write $p = (c_1 + \varepsilon_1)/2^w$ and $q = (c_2 + \varepsilon_2)/2^w$ with ratios $|\varepsilon_i| \le r_i$. Then

$$2^w pq = \frac{c_1 c_2}{2^w} + \frac{c_1\varepsilon_2 + c_2\varepsilon_1 + \varepsilon_1\varepsilon_2}{2^w}.$$

Let $c = \lfloor c_1 c_2 / 2^w \rfloor$, so that $c_1 c_2/2^w = c + \theta$ with $0 \le \theta < 1$. The second fraction has absolute value at most $Q = (|c_1| r_2 + |c_2| r_1 + r_1 r_2)/2^w < \lfloor Q \rfloor + 1$. Hence $|2^w pq - c| \le \theta + Q < \lfloor Q \rfloor + 2$, which is the claim after division by 2^w. □

Interval arithmetic of this kind goes back to Moore [47]. The solver below needs a different organisation of the same idea: it keeps exact dyadic values and proves, once and for all, how far each rounding can move the result after many steps.

A *closeness relation* on a set V is a relation "a and b are within r", for $a, b \in V$ and ratios r, that is symmetric in a and b, satisfies the triangle law (if a, b are within r and b, c within s, then a, c are within $r + s$) and depends only on the value of r. The examples are ratios with $|a - b| \le r$ and vectors of $\mathbb{Q}_\delta^d$ with the sup norm, $\|a - b\| = \max_i |a_i - b_i| \le r$. A map $\Phi : V \to V$ is *g-Lipschitz* when a, b within r implies $\Phi(a), \Phi(b)$ within gr.

Theorem 15.8 (Discrete Gronwall inequality)**.** *Let Φ be g-Lipschitz on a set with a closeness relation. Suppose that Y_{k+1} is within τ of $\Phi(Y_k)$ and z_{k+1} is within ρ of $\Phi(z_k)$ for every k, and that Y_0 and z_0 are within e_0. Put $E_0 = e_0$ and $E_{k+1} = gE_k + (\tau + \rho)$. Then Y_k and z_k are within E_k for every k. If moreover $g \ge 1$ and $\delta = \tau + \rho$ and e_0 are nonnegative, then*

$$E_k \le g^k e_0 + k\, g^k \delta.$$

Proof. Induction on k. If Y_k and z_k are within E_k, then Y_{k+1} is within τ of $\Phi(Y_k)$, which is within gE_k of $\Phi(z_k)$, which is within ρ of z_{k+1}; the triangle law gives $gE_k + \tau + \rho$. For the bound, $E_{k+1} = gE_k + \delta \le g^{k+1} e_0 + k\, g^{k+1}\delta + \delta$ by induction, and $\delta \le g^{k+1}\delta$ because $g \ge 1$. □

Real vector fields are tame only on a region: a polynomial is Lipschitz on a ball, not on all of space. The error bound then needs a second fact, that the trajectories stay in the region. A margin between an inner region and the region supplies it.

Theorem 15.9 (Gronwall on a region). *Let $D_{\mathrm{in}} \subseteq D$ be subsets of a set with a closeness relation, and let Φ satisfy the Lipschitz condition with constant g for pairs of points of D. Let K be a natural number and μ a ratio such that every point within $r \le \mu$ of a point of D_{in} lies in D. Suppose that*

(i) $z_k \in D_{\mathrm{in}}$ for $k \le K$;

(ii) for $k < K$, Y_{k+1} is within τ of $\Phi(Y_k)$ whenever $Y_k \in D$, and z_{k+1} is within ρ of $\Phi(z_k)$ whenever $z_k \in D$;

(iii) Y_0 and z_0 are within e_0, and $E_k \le \mu$ for $k \le K$, with E_k as in Theorem 15.8.

Then for every $k \le K$, $Y_k \in D$ and Y_k, z_k are within E_k. If instead both Y_k and z_k are known to lie in D for every $k \le K$, condition (ii) and Y_0, z_0 within e_0 give the same bound for $k \le K$. For sup-norm balls the margin condition holds: if $\|a\| \le M - \mu$ and $\|a - b\| \le r \le \mu$, then $\|b\| \le M$.

Proof. Induction on $k \le K$, carrying both claims. At $k = 0$, Y_0 is within $e_0 = E_0 \le \mu$ of $z_0 \in D_{\mathrm{in}}$, so $Y_0 \in D$. At $k + 1 \le K$, both Y_k and z_k lie in D ($z_k \in D_{\mathrm{in}} \subseteq D$), so the step of Theorem 15.8 applies and puts Y_{k+1} within $E_{k+1} \le \mu$ of z_{k+1}; since $z_{k+1} \in D_{\mathrm{in}}$, the margin puts Y_{k+1} in D. The second form is the same induction without the membership claim. The sup-norm statement is the triangle inequality $\|b\| \le \|a\| + \|a - b\| \le M - \mu + \mu$. □

The theorem asks nothing of the region beyond the margin. Its use below is typical: the reference trajectory z is one that has been computed and checked, and the conclusion transfers that check to every finer computation.

15.3 The number of steps at a fixed order

The simplest way to follow $y' = F(y)$ is Euler's method: from y go to $\mathscr{E}_h(y) = y + hF(y)$. Its error analysis is one application of the Gronwall inequality.

Proposition 15.10 (Global error of Euler's method). *Let $F : \mathbb{Q}_\delta^d \to \mathbb{Q}_\delta^d$ satisfy $\|F(a) - F(b)\| \le L\,r$ whenever $\|a - b\| \le r$, and let $h \ge 0$. If $\|Y_{k+1} - \mathscr{E}_h(Y_k)\| \le \tau$ and $\|z_{k+1} - \mathscr{E}_h(z_k)\| \le \rho$ for every k, and $\|Y_0 - z_0\| \le e_0$, then $\|Y_k - z_k\| \le E_k$ for every k, with E_k as in Theorem 15.8 for $g = 1 + hL$.*

Proof. If $\|a - b\| \le r$, then $\|\mathscr{E}_h(a) - \mathscr{E}_h(b)\| \le \|a - b\| + h\|F(a) - F(b)\| \le (1 + hL)r$. So $\mathscr{E}_h$ is $(1 + hL)$-Lipschitz, and Theorem 15.8 applies. □

Here Y can be any sequence that follows the Euler map up to τ per step, and z the rounded sequence that a program computes. The bound grows like $e_0 + k(\tau + \rho)$ times the growth factor $(1 + hL)^k$. With T/h steps and a one-step defect of order h^2, a bound of this kind is of order h: each further certified bit halves the step and doubles the number of steps. For methods of fixed order this is in general not a weakness of the bound. The next theorem proves it for the classical fourth-order Runge–Kutta method [48], on the simplest equation

there is. It is a classical statement about real numbers: it uses the real exponential function and is proved with classical real analysis.

One Runge–Kutta step of size h for $y' = f(y)$ takes y to $y + \frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4)$, where $k_1 = f(y)$, $k_2 = f(y + \frac{h}{2}k_1)$, $k_3 = f(y + \frac{h}{2}k_2)$ and $k_4 = f(y + hk_3)$.

Theorem 15.11 (Fourth-order Runge–Kutta needs exponentially many steps)**.** *Let $K \geq 1$, and let RK_K be the result of K Runge–Kutta steps of size $1/K$ for $y' = y$ from $y(0) = 1$, in exact real arithmetic. Then*

$$e - \mathrm{RK}_K \geq \frac{1}{120K^4}.$$

Consequently, if $|e - \mathrm{RK}_K| \leq 2^{-n}$, then $2^n \leq 120K^4$.

Proof. For $f(y) = y$ the four stages are $k_1 = y$, $k_2 = y(1 + \frac{h}{2})$, $k_3 = y(1 + \frac{h}{2} + \frac{h^2}{4})$ and $k_4 = y(1 + h + \frac{h^2}{2} + \frac{h^3}{4})$, so one step multiplies y by

$$b = 1 + h + \frac{h^2}{2} + \frac{h^3}{6} + \frac{h^4}{24},$$

the Taylor polynomial of order four of e^h. Hence $\mathrm{RK}_K = b^K$ with $h = 1/K$. All terms of the exponential series are nonnegative for $h \geq 0$, so $e^h \geq b + c$ with $c = h^5/120$. The binomial expansion, whose terms are nonnegative, and $b \geq 1$ give

$$e = (e^h)^K \geq (b + c)^K \geq b^K + Kb^{K-1}c \geq \mathrm{RK}_K + Kc,$$

and $Kc = K \cdot K^{-5}/120 = 1/(120K^4)$. If the error is at most 2^{-n}, then $1/(120K^4) \leq 2^{-n}$, which is the second claim. □

So n correct bits require at least $(2^n/120)^{1/4}$ steps. The way out is to keep the step fixed and let the order grow with the request. A Taylor method of order N with step $2^{-\sigma}$, where 2^σ is large compared with the field's growth, truncates with error of order 2^{-N}. Taking $N = m$ plus a constant gives m bits with a fixed number of steps. The next two sections make this exact.

15.4 Taylor coefficients of a quadratic field

Every polynomial system can be rewritten as a quadratic one (Section 15.7), so we work with fields $y' = c + Ay + B(y, y)$ on $\mathbb{Q}_\delta^d$. The analysis uses only bounds, which we make part of the data.

Definition 15.12 (Quadratic field)**.** A *quadratic field* on $\mathbb{Q}_\delta^d$ consists of a vector c, maps $A : \mathbb{Q}_\delta^d \to \mathbb{Q}_\delta^d$ and $B : \mathbb{Q}_\delta^d \times \mathbb{Q}_\delta^d \to \mathbb{Q}_\delta^d$, and natural numbers γ, α, β, such that

(i) $\|c\| \leq \gamma$;

(ii) $\|u\| \leq P$ implies $\|Au\| \leq \alpha P$, and $\|u - u'\| \leq r$ implies $\|Au - Au'\| \leq \alpha r$;

(iii) $\|u\| \leq P$ and $\|v\| \leq P'$ imply $\|B(u, v)\| \leq \beta PP'$;

(iv) $\|u-u'\|\le r$, $\|v-v'\|\le s$, $\|v\|\le P$ and $\|u'\|\le P'$ imply $\|B(u,v)-B(u',v')\|\le \beta(rP+P's)$.

For a natural number $M\ge 1$, the *majorant ratio* on the ball of radius M is $R=\gamma+\alpha+\beta M+1$.

When A is linear and B bilinear, a power series $y(t)=\sum_k a_k t^k$ solves $y'=c+Ay+B(y,y)$ exactly when its coefficients satisfy, by comparing the coefficients of t^k,

$$(k+1)\,a_{k+1}=c\,[k=0]+Aa_k+\sum_{i=0}^{k}B(a_i,a_{k-i}),$$

where $[k=0]$ is 1 for $k=0$ and 0 otherwise. This recurrence is finite data for every k. A program that computes it must round, so we build the rounding into the definition.

Definition 15.13 (Coefficient table)**.** For a sequence $f_0,f_1,\dots$ of vectors put

$$\operatorname{next}(f,k)=\frac{1}{k+1}\Big(c\,[k=0]+Af_k+\sum_{i=0}^{k}B(f_i,f_{k-i})\Big).$$

A *rounding* is a map $\varrho:\mathbb{Q}_\delta^d\to\mathbb{Q}_\delta^d$ with $\|\varrho(u)-u\|\le u_\varrho$ for every u. The *coefficient table* at y with rounding ϱ is $a_0=y$, $a_{k+1}=\varrho(\operatorname{next}(a,k))$. With ϱ the identity these are the *exact* coefficients at y.

For the oscillator, $c=0$, $A(u_0,u_1)=(u_1,-u_0)$ and $B=0$, with $\gamma=0$, $\alpha=1$ and $\beta=0$, so $R=2$ on every ball. The exact table at $(0,1)$ is $(0,1)$, $(1,0)$, $(0,-\frac12)$, $(-\frac16,0)$, $(0,\frac{1}{24})$, …: the Taylor coefficients of $(\sin t,\cos t)$. Its entries are bounded by $1\cdot 2^k$, as the next lemma predicts.

Lemma 15.14 (Majorant of the coefficients)**.** *Let $M\ge 1$, $\|y\|\le M$ and $u_\varrho\le 1$. Then $\|a_k\|\le MR^k$ for every k.*

Proof. Strong induction on k. Suppose $\|a_i\|\le MR^i$ for every $i\le k$, and put $X=MR^k\ge 1$. Then $\|c\,[k=0]\|\le\gamma$, $\|Aa_k\|\le\alpha X$, and each of the $k+1$ terms satisfies $\|B(a_i,a_{k-i})\|\le\beta MR^i\,MR^{k-i}=\beta MX$. So

$$\|\operatorname{next}(a,k)\|\le\frac{\gamma+\alpha X+(k+1)\beta MX}{k+1}\le\gamma+\alpha X+\beta MX\le X(R-1),$$

using $\gamma\le\gamma X$. Rounding adds at most $u_\varrho\le 1\le X$, so $\|a_{k+1}\|\le XR=MR^{k+1}$. □

The second estimate compares two tables. It contains two facts in one: the coefficients depend Lipschitz-continuously on the starting point, and rounding perturbs them in a controlled way.

Lemma 15.15 (The difference law)**.** *Let a and a' be the coefficient tables at y and y' with roundings ϱ and ϱ', where $0\le u_\varrho,u_{\varrho'}\le 1$, $\|y\|,\|y'\|\le M$ and $\|y-y'\|\le e$ with $e\ge 0$. Then*

$$\|a_k-a'_k\|\le E(k+1)R^k,\qquad E=e+u_\varrho+u_{\varrho'},$$

for every k.

Proof. Strong induction on k; both tables satisfy Lemma 15.14. At $k = 0$ the bound is $\|y - y'\| \le e \le E$. Suppose it holds for every $i \le k$. The constant terms of $\mathrm{next}(a, k)$ and $\mathrm{next}(a', k)$ cancel, $\|Aa_k - Aa'_k\| \le \alpha E(k+1)R^k$, and by law (iv) of Definition 15.12

$$\|B(a_i, a_{k-i}) - B(a'_i, a'_{k-i})\| \le \beta\big(E(i+1)R^i \cdot MR^{k-i} + MR^i \cdot E(k-i+1)R^{k-i}\big) = \beta ME(k+2)R^k.$$

Summing the $k+1$ terms and dividing by $k+1$,

$$\|\,\mathrm{next}(a,k) - \mathrm{next}(a',k)\| \le \alpha ER^k + \beta ME(k+2)R^k \le E(k+2)R^k(R-1).$$

The two roundings add at most $u_\varrho + u_{\varrho'} \le E \le E(k+2)R^k$, so $\|a_{k+1} - a'_{k+1}\| \le E(k+2)R^{k+1}$. □

With $\varrho = \varrho'$ the identity, the lemma is the Lipschitz law of the exact coefficients. With $y = y'$ and ϱ' the identity, it bounds the effect of rounding every coefficient.

A Taylor step of order N and step $2^{-\sigma}$ sums the table:

$$S_N(f) = \sum_{k=0}^{N} 2^{-\sigma k} f_k.$$

The step must be small compared with $1/R$. We ask for $8R \le 2^\sigma$.

Lemma 15.16 (Taylor sums)**.** *Let $8R \le 2^\sigma$ and $g = 1 + 4R/2^\sigma$.*

(a) If $E \ge 0$ and $\|f_k - f'_k\| \le E(k+1)R^k$ for every $k \le N$, then $\|S_N(f) - S_N(f')\| \le gE$.

(b) If $\|f_k\| \le MR^k$ for every k, then $\|S_{N+j}(f) - S_N(f)\| \le M2^{-N}$ for every j.

Proof. (a) We prove by induction on N the sharper bound $E\big(1 + 4R(2^N - 1)/2^{\sigma+N}\big)$. For $N = 0$ it reads $\|f_0 - f'_0\| \le E$. The term added at $N+1$ is at most $2^{-\sigma(N+1)}E(N+2)R^{N+1}$. First, $(N+2)2^{N+1} \le 4 \cdot 8^N$, by induction on N, since $(N+3) \le \frac{3}{2}(N+2)$. Second, $(8R)^N \le 2^{\sigma N}$. Together they give $(N+2)R^{N+1}2^{\sigma+N+1} \le 4R\,2^\sigma(8R)^N \le 4R\,2^{\sigma(N+1)}$, so the new term is at most $E \cdot 4R/2^{\sigma+N+1}$, and

$$\frac{4R(2^N-1)}{2^{\sigma+N}} + \frac{4R}{2^{\sigma+N+1}} = \frac{4R(2^{N+1}-1)}{2^{\sigma+N+1}}.$$

Finally $(2^N - 1)/2^N \le 1$.

(b) Since $2R \le 2^\sigma$, each added term satisfies $\|2^{-\sigma k} f_k\| \le M(R/2^\sigma)^k \le M2^{-k}$. The terms of index $N+1$ to $N+j$ add up to at most $M(2^{-N} - 2^{-N-j}) \le M2^{-N}$. □

Write $\Phi_N(y) = S_N(a(y))$ for the exact Taylor map of order N, with $a(y)$ the exact table at y. For a working precision w, write $[q]_w$ for $\mathrm{near}(2^w q)/2^w$, applied coordinatewise to vectors; it moves each coordinate by at most $2^{-(w+1)}$. The *computed step* is

$$\Psi_{N,w}(y) = \big[S_N(a^{(w)}(y))\big]_w,$$

where $a^{(w)}(y)$ is the table at y with rounding $[\cdot]_w$: every coefficient and the final sum are rounded to w binary digits.

Lemma 15.17 (One step). *Let $8R \le 2^\sigma$, $g = 1 + 4R/2^\sigma$ and $M \ge 1$.*

(a) If $\|y\|, \|y'\| \le M$ and $\|y - y'\| \le r$ with $r \ge 0$, then $\|\Phi_N(y) - \Phi_N(y')\| \le gr$.

(b) If $\|y\| \le M$ and $N_0 \le N$, then

$$\|\Psi_{N,w}(y) - \Phi_{N_0}(y)\| \le 2^{-(w+1)} + 2^{-(w+1)}g + M2^{-N_0}.$$

Proof. (a) Lemma 15.15 without rounding gives $\|a_k(y) - a_k(y')\| \le r(k+1)R^k$; apply Lemma 15.16(a). (b) Split the difference in three. The final rounding costs $2^{-(w+1)}$. Rounded against exact coefficients, Lemma 15.15 with $e = 0$, $u_\varrho = 2^{-(w+1)}$ and $u_{\varrho'} = 0$, followed by Lemma 15.16(a), costs $2^{-(w+1)}g$. Order N against order N_0 for the exact coefficients costs $M2^{-N_0}$, by Lemmas 15.14 and 15.16(b). □

15.5 A fixed number of steps of growing order

Everything the solver does at precision m is fixed by the problem and m through a short schedule.

Definition 15.18 (Problem, schedule and trajectories). A *problem* consists of a quadratic field, a natural number $M \ge 1$ (the radius of a sup-norm ball), an initial point $y_0 \in \mathbb{Q}_\delta^d$ and a natural end time T. Its *schedule* is

$$R = \gamma + \alpha + \beta M + 1, \qquad \sigma = \mathrm{bl}(4R) + 1, \qquad S = T2^\sigma,$$
$$G = \left\lfloor \frac{(2^\sigma + 4R)^S}{2^{\sigma S}} \right\rfloor + 1, \qquad \kappa = \mathrm{bl}\big(G(1 + 2S(M+2))\big) + 2, \qquad N(n) = n + \kappa.$$

The step is $2^{-\sigma}$, the number of steps is S, and κ is the number of extra bits. The *trajectory at level n* is

$$y_0^{(n)} = [y_0]_{N(n)}, \qquad y_{k+1}^{(n)} = \Psi_{N(n),N(n)}\big(y_k^{(n)}\big) \ :$$

Taylor order and working precision both equal $N(n)$. The problem satisfies the *region certificate at level n_0* if

$$\big\|y_k^{(n_0)}\big\| \le M - 2^{-(n_0+2)} \qquad \text{for every } k \le S.$$

Since $4R < 2^{\mathrm{bl}(4R)}$, we have $8R \le 2^\sigma$, so the lemmas of Section 15.4 apply with $g = 1 + 4R/2^\sigma \le \frac{3}{2}$. The growth factor satisfies $g^S = (2^\sigma + 4R)^S/2^{\sigma S} < G$. None of these numbers depends on the precision. The region certificate is a finite list of comparisons of ratios: it concerns the $S + 1$ vectors of one computed trajectory and is checked by computing them. It is not an assumption about an exact solution.

For the oscillator with $M = 2$ and $T = 1$: $R = 2$, $\sigma = \mathrm{bl}(8)+1 = 5$, $S = 32$, $G = \lfloor (40/32)^{32} \rfloor + 1 = 1263$, and $\kappa = \mathrm{bl}(1263 \cdot 257) + 2 = 21$. The level-0 trajectory, with order and precision 21, passes the region certificate at level 0, so every level is covered by the results below. At $m = 40$ the solver runs level 40, with order and precision 61; these are the numbers of the opening.

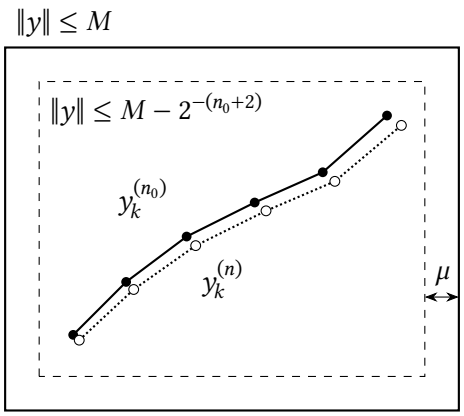

Figure 15.1. The region certificate in two dimensions, where the sup-norm balls are squares. The trajectory at level n_0 (solid, filled points) has been computed and stays in the inner square. A finer level $n \ge n_0$ (dotted, open points) stays within $E_k \le \mu = 2^{-(n_0+2)}$ of it, so it stays in the outer square, where the Taylor step is Lipschitz (Theorem 15.20).

Lemma 15.19 (The error budget)**.** *Let $n \le n'$. Let τ and ρ be the right-hand sides of Lemma 15.17(b) for a step at level n' and at level n, compared with $\Phi_{N(n)}$:*

$$\tau = 2^{-(N(n')+1)}(1+g) + M2^{-N(n)}, \qquad \rho = 2^{-(N(n)+1)}(1+g) + M2^{-N(n)},$$

and let $e_0 = 2^{-(N(n')+1)} + 2^{-(N(n)+1)}$. Then the bound E_k of Theorem 15.8 with these g, τ, ρ and e_0 satisfies $E_k \le 2^{-(n+2)}$ for every $k \le S$.

Proof. Because $g \le 2$, each of τ and ρ is at most $3 \cdot 2^{-(N(n)+1)} + M2^{-N(n)} \le (M+2)2^{-N(n)}$, and $e_0 \le 2^{-N(n)}$. By the second part of Theorem 15.8, with $g^k \le g^S < G$ and $k \le S$,

$$E_k \le G\,2^{-N(n)} + SG \cdot 2(M+2)\,2^{-N(n)} = G\big(1 + 2S(M+2)\big)2^{-(n+\kappa)}.$$

By the definition of κ, $G(1 + 2S(M+2)) < 2^{\kappa-2}$, so $E_k < 2^{-(n+2)}$. □

Theorem 15.20 (Every finer level stays in the region)**.** *If the region certificate holds at level n_0 and $n \ge n_0$, then $\|y_k^{(n)}\| \le M$ for every $k \le S$.*

Proof. The geometry is that of Figure 15.1. Apply Theorem 15.9 with D the ball of radius M, D_{in} the ball of radius $M - 2^{-(n_0+2)}$, margin $\mu = 2^{-(n_0+2)}$, and $\Phi = \Phi_{N(n_0)}$, which is g-Lipschitz on D by Lemma 15.17(a). The reference trajectory is $z = y^{(n_0)}$; it lies in D_{in} by the certificate and follows Φ up to ρ by Lemma 15.17(b). The other trajectory is $Y = y^{(n)}$; while $Y_k \in D$ it follows Φ up to τ by Lemma 15.17(b) with $N_0 = N(n_0) \le N(n)$. The two starting points are roundings of y_0, so they are within e_0. Lemma 15.19 with $n_0 \le n$ gives $E_k \le 2^{-(n_0+2)} = \mu$ for $k \le S$. □

Theorem 15.21 (Two levels agree at the end time)**.** *If the region certificate holds at level n_0 and $n_0 \le n \le n'$, then*

$$\big\| y_S^{(n')} - y_S^{(n)} \big\| \le 2^{-(n+2)}.$$

Proof. By Theorem 15.20 both trajectories stay in the ball of radius M for $k \le S$. The second form of Theorem 15.9, with $\Phi = \Phi_{N(n)}$, $Y = y^{(n')}$, $z = y^{(n)}$ and the defects of Lemma 15.17(b), bounds their distance at step S by E_S, and Lemma 15.19 bounds E_S by $2^{-(n+2)}$. □

The solution value is now a certified real, read off the trajectory at the right level.

Theorem 15.22 (The solution value as a certified real)**.** *Let the region certificate hold at level n_0, and let $i < d$. Put*

$$a_m = \operatorname{near}\Big(2^m \big(y_S^{(\max(m,n_0))}\big)_i\Big).$$

Then $|a_m/2^m - (y_S^{(\max(M',n_0))})_i| \le 2^{-m}$ whenever $m \le M'$, and (a_m) is a certified real x_i. We call x_i, and the point $\bar{x}_i$ of $\mathbb{R}_\delta$ that it names, coordinate i of the solution value at time T.

Proof. Rounding costs $2^{-(m+1)}$. Theorem 15.21 with $n = \max(m, n_0) \le n' = \max(M', n_0)$ costs at most $2^{-(\max(m,n_0)+2)} \le 2^{-(m+2)}$. The sum is at most $3 \cdot 2^{-(m+2)} < 2^{-m}$. The ideal-value lemma with $I(M') = (y_S^{(\max(M',n_0))})_i$, $T(m) = m$ and $C = 0$ gives the certified real. □

No exact solution, no Lipschitz constant and no completed real number is assumed. The modulus of x_i follows from the four bound laws and one finite check. Every proof in Sections 15.1, 15.2, 15.4 and 15.5 is a computation with ratios, an induction or the Archimedean step; none uses a choice principle or an omniscience principle. For the oscillator, the answer of x_0 at precision 40 is 925207132232. Section 15.8 shows that, under classical hypotheses that hold here, x_0 reads $\sin 1$.

15.6 Counting the work

The answer a_m is computed by an explicit finite procedure: round y_0, take S computed steps at level $\max(m, n_0)$, select coordinate i and round. Within a step the order of evaluation is fixed. Row $k+1$ of the table is formed from the vector Af_k, the Cauchy sum $\sum_{i \le k} B(f_i, f_{k-i})$, accumulated term by term from the zero vector, the sum $c\,[k=0] + Af_k$, to which the Cauchy sum is then added, the division by $k+1$ and the rounding. The Taylor sum is accumulated from f_0, adding $2^{-\sigma k} f_k$ for $k = 1, \dots, N$ in turn, and then rounded. We count the arithmetic of this procedure.

The *cost model* charges one unit for each arithmetic operation on ratios: a sum, a product, a quotient by a natural number, a rounding $[\cdot]_w$, and the final rounding to an integer. An operation on vectors of $\mathbb{Q}_\delta^d$ costs d; one evaluation of A costs c_A and one of B costs c_B. Storing and reading values is free, and the size of the operands is not counted here; it is the subject of Proposition 15.26.

Theorem 15.23 (The exact count)**.** *Let the region certificate hold at level n_0, and let $N = N(\max(m, n_0))$. The procedure above returns the answer a_m of Theorem 15.22, and its count is exactly*

$$\operatorname{cost}(m) = 1 + d + S \cdot \operatorname{step}(N), \qquad 2\operatorname{step}(N) = 2N(c_A + 6d) + 2d + (c_B + d)N(N + 1).$$

Moreover

$$\operatorname{cost}(m) \le \big(S(c_A + c_B + 8d) + d + 1\big)(m + n_0 + \kappa + 1)^2 \qquad \text{and} \qquad S \le 16RT.$$

Proof. The procedure follows the definitions of Section 15.5 step for step, so it returns a_m. Row $k + 1$ of a coefficient table costs one evaluation of A, $k + 1$ evaluations of B with $k + 1$ vector additions in the sum (together $(k + 1)(c_B + d)$), two vector additions and one division ($3d$), and the rounding of the row (d). So the rows up to k cost $\operatorname{rows}(k)$ with $\operatorname{rows}(0) = 0$ and $\operatorname{rows}(k + 1) = \operatorname{rows}(k) + c_A + (k + 1)(c_B + d) + 4d$, and induction gives $2\operatorname{rows}(k) = 2k(c_A + 4d) + (c_B + d)k(k + 1)$. The Taylor sum of order N costs N scalings and N additions ($2dN$), and its rounding d; so $\operatorname{step}(N) = \operatorname{rows}(N) + 2dN + d$, which is the displayed formula. The trajectory costs d for the initial rounding and $S\operatorname{step}(N)$ for the steps, and the answer one more rounding.

For the bound, comparing coefficients shows $2\operatorname{step}(N) \le 2(c_A + c_B + 8d)(N + 1)^2$. With $Q = m + n_0 + \kappa + 1 \ge N + 1 \ge 1$, $\operatorname{cost}(m) \le (1 + d)Q^2 + S(c_A + c_B + 8d)Q^2$. Finally $2^{\operatorname{bl}(n)} \le 2n$ for $n \ge 1$, so $2^\sigma = 2 \cdot 2^{\operatorname{bl}(4R)} \le 16R$ and $S = T2^\sigma \le 16RT$. □

The count is quadratic in m because one step of order N forms the Cauchy sums of every row, about $N^2/2$ evaluations of B, while the number of steps does not depend on m. The extra precision κ does not depend on m either. It grows at most linearly in RT: with $a = 4R/2^\sigma$ we have $aS = 4RT$ and $(1 + a)^S \le e^{aS} = e^{4RT}$, so G has at most about $5.8\,RT$ binary digits, and κ adds to these the digits of $1 + 2S(M + 2)$ and two more.

Fields met in practice are given by their coefficients.

Definition 15.24 (Coefficient field)**.** A *coefficient field* of dimension d consists of a vector $c \in \mathbb{Q}_\delta^d$ and, for each coordinate i, a finite list of terms (a, j) and a finite list of terms (b, j, k), with ratios a, b and indices $j, k < d$. It defines

$$(Au)_i = \sum_{(a,j)} a\,u_j, \qquad B(u, v)_i = \sum_{(b,j,k)} b\,u_j v_k,$$

with the bounds $\gamma = \max_i \lceil |c_i| \rceil$, $\alpha = \max_i \sum_{(a,j)} \lceil |a| \rceil$ and $\beta = \max_i \sum_{(b,j,k)} \lceil |b| \rceil$, the sums running over the terms of coordinate i.

Proposition 15.25 (Coefficient fields are quadratic fields)**.** *A coefficient field satisfies the four laws of Definition 15.12. One evaluation of A costs $c_A = 2 \cdot$ (number of A-terms) operations and one evaluation of B costs $c_B = 3 \cdot$ (number of B-terms). Hence, for a problem whose field is a coefficient field and which satisfies the region certificate at level n_0, the answer a_m costs at most*

$$\big(S(c_A + c_B + 8d) + d + 1\big)(m + n_0 + \kappa + 1)^2$$

operations, with $S \le 16RT$.

Proof. Each law is the triangle inequality over a finite sum. For instance, if $\|u - u'\| \le r$, $\|v - v'\| \le s$, $\|v\| \le P$ and $\|u'\| \le P'$, then $|bu_j v_k - bu'_j v'_k| \le |b|\big(|u_j - u'_j|\,|v_k| + |u'_j|\,|v_k - v'_k|\big) \le \lceil|b|\rceil(rP + P's)$, and summing over the terms of coordinate i gives at most $\beta(rP + P's)$. The bounds for c and A are the same argument with one factor. A term of A is evaluated with one product and one addition, a term of B with two products and one addition. Insert c_A and c_B into Theorem 15.23. □

Unit cost per operation is only half of a cost statement: the numbers could grow. They do not grow faster than the precision allows. A ratio is stored as an integer numerator over a positive integer denominator, without reduction, and we bound both.

Proposition 15.26 (Operand sizes)**.** *Let a problem have a coefficient field and satisfy the region certificate at level n_0, and let $N = N(\max(m, n_0))$. Let $\mathscr{B}(N)$ be the capacity* (H.1) *of Appendix H; it is a polynomial $q_P N^2 + l_P N + c_P$ whose natural coefficients depend only on the problem. Every ratio that the computation of a_m stores, uses as an operand or produces has numerator and denominator of absolute value at most $2^{\mathscr{B}(N)}$. Moreover*

$$\mathscr{B}(N) \le (q_P + l_P + c_P)\,(m + n_0 + \kappa + 1)^2,$$

so each of these ratios is written with at most $2\mathscr{B}(N) + 3$ binary digits.

The proof, a bookkeeping of numerators and denominators through every operation, is in Section H.1 of Appendix H. Together with Theorem 15.23 it says that m bits cost $O(m^2)$ operations on numbers of $O(m^2)$ digits, for a fixed problem. With any implementation of the four operations whose cost is bounded by a polynomial in the lengths of the operands, the answer a_m therefore costs a number of bit operations bounded by a polynomial in m. Section 15.9 makes this exact for one fixed machine.

15.7 Polynomial fields become quadratic

Reducing a polynomial system to a quadratic one by new variables goes back to Kerner [49]. We introduce one new variable for every monomial of bounded degree.

Definition 15.27 (Polynomial field and its quadratization)**.** A *polynomial field* p on $\mathbb{Q}_\delta^d$ gives each coordinate a finite list of terms (q, ξ), with a ratio q and an exponent vector $\xi \in \mathbb{N}^d$, and $p_i(x) = \sum q\, x^\xi$ over the terms of p_i. Let $D = \max(1, \deg p)$, where $\deg p$ is the largest total degree $|\xi| = \xi_0 + \cdots + \xi_{d-1}$ of a term. The *quadratized field* has one variable w_α for each exponent vector α with $|\alpha| \le D$, the constant monomial included. It is the coefficient field with $c = 0$, no A-terms, and, for the variable w_α, the B-terms

$$(\alpha_i q,\ \alpha - e_i,\ \xi) \qquad \text{for each } i \text{ with } \alpha_i > 0 \text{ and each term } (q, \xi) \text{ of } p_i,$$

where e_i is the ith unit vector. For an initial point x_0, a radius $M \ge 1$ and an end time T, the *quadratized problem* has the initial values $w_\alpha(0) = x_0^\alpha$, radius M and end time T. If it satisfies the region certificate at level n_0, the *polynomial solution* at time T is the certified real x_i of Theorem 15.22 for the variable w_{e_i}.

The construction mirrors the chain rule: for a solution x of $x' = p(x)$,

$$(x^\alpha)' = \sum_i \alpha_i x^{\alpha - e_i} p_i(x) = \sum_i \sum_{(q,\xi)\in p_i} (\alpha_i q)\, x^{\alpha - e_i} x^\xi.$$

Both $\alpha - e_i$, when $\alpha_i > 0$, and ξ have total degree at most D, so both are variables, and no monomial needs to be split. The certified computation uses only the quadratized field; the chain rule enters when the result is compared with a classical solution (Corollary 15.30). Conversely, a solution of the quadratized system that starts at the monomials of x_0 consists of the monomials of a solution of $x' = p(x)$ (Proposition H.11): the new variables add no solutions.

Theorem 15.28 (Dimension and cost of the quadratization)**.** *Let p be a polynomial field with $D = \max(1, \deg p)$ and t_p terms in all.*

(a) The variables are exactly the exponent vectors of total degree at most D; there are at most $(D+1)^d$ of them. Write d_Q for their number.

(b) The quadratized field has $c_A = 0$ and $c_B \le 3 d_Q t_p$.

(c) If the quadratized problem satisfies the region certificate at level n_0, the answer of the polynomial solution x_i at precision m costs at most

$$\big(S(3d_Q t_p + 8d_Q) + d_Q + 1\big)(m + n_0 + \kappa + 1)^2$$

operations, where $S \le 16RT$ and R and κ belong to the quadratized problem.

Proof. (a) List the vectors by recursion on d: for $d = 0$ there is the empty vector; for $d+1$ coordinates take, for each first entry $a \le D$, the vectors (a, ξ) with ξ in the list for d coordinates and degree $D - a$. Induction on d shows that (a, ξ) is listed exactly when $a + |\xi| \le D$, and that the list has at most $(D+1)\cdot(D+1)^d$ entries. (b) The field has no A-terms. The variable w_α receives at most one B-term for each term of each p_i, so at most t_p terms, and $c_B \le 3 d_Q t_p$. (c) Insert (a) and (b) into Proposition 15.25. □

Like the proofs of Sections 15.1, 15.2, 15.4 and 15.5, the proofs of Theorems 15.23 and 15.28 and of Proposition 15.25 are finite computations with ratios and inductions; they use no choice principle and no omniscience principle.

15.8 What the certified point is

Theorem 15.22 produced a point of $\mathbb{R}_\delta$ from finite data and one finite check. Classical analysis has its own object, the solution $y(T)$ of the initial value problem, whenever one exists. The two agree under the hypotheses of the following theorem. It is a classical statement about real numbers: its hypotheses and its proof use the real numbers of classical analysis, their completeness and the calculus of derivatives. None of the results of Sections 15.1 to 15.7 depends on it.

Theorem 15.29 (The certified point is the classical solution value)**.** *Let a problem satisfy the region certificate at level n_0. Suppose that A extends to a real linear map and B to a real bilinear map on $\mathbb{R}^d$, agreeing with A and B on rational vectors, with $\|Au\| \le \alpha\|u\|$ and $\|B(u,v)\| \le \beta\|u\|\,\|v\|$. Suppose that $y : [0,T] \to \mathbb{R}^d$ is continuous, $y(0) = y_0$, y has the right derivative $c + Ay(t) + B(y(t), y(t))$ at every $t \in [0,T)$, and $\|y(t)\| \le M$ on $[0,T]$. Then, for every level $n \ge n_0$,*

$$\left\| y(T) - y_S^{(n)} \right\| \le C_P\, 2^{-n}, \qquad C_P = e^{(\alpha+4\beta M)T}\Big(1 + S\big((\alpha M + \beta M^2)2^{-\sigma} + M + 2\big)\Big),$$

and the answers of the solution value satisfy $|a_m/2^m - y_i(T)| \le 2^{-m}$ for every m and every coordinate i.

The proof is in Section H.2. Its idea is to compare, on each step, the true solution with the Taylor polynomial of the computed point: that polynomial misses the equation by a residual of order 8^{-N}, the classical Gronwall inequality bounds the resulting distance, and the per-step errors are added up as in Section 15.2.

Corollary 15.30 (Polynomial fields)**.** *Let the quadratized problem of a polynomial field p, with initial point x_0, radius M and end time T, satisfy the region certificate at level n_0. Suppose that $x : [0,T] \to \mathbb{R}^d$ is continuous, $x(0) = x_0$, x has the right derivative $p(x(t))$ at every $t \in [0,T)$, and every monomial $x(t)^\alpha$ with $|\alpha| \le D$ has absolute value at most M on $[0,T]$. Then the answers of the polynomial solution x_i satisfy $|a_m/2^m - x_i(T)| \le 2^{-m}$ for every m. The monomial condition holds when $\|x(t)\| \le r$ on $[0,T]$ for some $r \ge 1$ with $r^D \le M$.*

For the oscillator, $y(t) = (\sin t, \cos t)$ satisfies the hypotheses with $M = 2$, so $925207132232/2^{40}$ lies within 2^{-40} of $\sin 1$. The hypotheses of the theorem are the ones the identification uses: a real realization of the field with the same bounds, and a classical solution that stays in the ball of the certificate. The theorem assumes that solution; it does not construct one. Where no classical solution is known to stay in that ball, Theorem 15.29 does not apply as stated, and the certified point is still defined and still computed to every precision.

15.9 One machine for every problem and every precision

Theorem 15.23 counts operations on ratios of unbounded size. The final step of the chapter replaces that count by machine steps on a tape of bits, with one machine for all problems at once. The machine is the plainest one available.

Definition 15.31 (One-tape binary machine)**.** A *control table* is a finite list $H = (h_0, \dots, h_{L-1})$ of instructions, each of one of the forms write(b, s'), left(s'), right(s'), branch(s_0, s_1) and halt, with a bit b and natural numbers s', s_0, s_1, the *control states*. A *configuration* consists of a control state, a head position in $\mathbb{Z}$ and a tape, a map from $\mathbb{Z}$ to $\{0,1\}$; the blank symbol is 0. One step executes h_s for the current state s: write(b, s') writes b in the scanned cell and goes to s'; left(s') and right(s') move the head by one cell and go to s'; branch(s_0, s_1) goes to s_0 if the scanned cell holds 0 and to s_1 if it holds 1. If h_s is halt, or if $s \ge L$, the configuration does not change. On an input word u the machine starts in state 0, with the head on cell 0, u written in cells $0, 1, \dots$ and 0 everywhere else. It *runs from u to v within t steps* if after exactly t steps the current instruction is halt and the whole tape is v written from cell 0, with 0 in every other cell.

Control states are positions in the table, never data, and there are no registers. Because a halted machine stands still, "within t steps" means that it halts at some time at most t, having erased everything it wrote except the output.

Numbers travel in binary. For a word u of bits, the *frame* of u is $1^{|u|}0u$: its length in unary, a separator and the bits. A natural number n is written with its $\mathrm{bl}(n)+1$ lowest binary digits, least significant first, and framed; an integer z is the bit $[z<0]$ followed by the digits of $|z|$, framed.

Definition 15.32 (Requests and answers)**.** Let a problem have a coefficient field of dimension d. The *request* for coordinate i at precision m, with certificate level n_0, is the concatenation of

(i) the *shape*: d; for each coordinate, the number of its A-terms and their indices j; for each coordinate, the number of its B-terms and their index pairs (j,k);

(ii) the *payload*: the number of integers that follow, then the numerator and the positive denominator of every coordinate of y_0, every coordinate of c, every A-coefficient and every B-coefficient, each as a framed integer;

(iii) the framed natural numbers M, T, n_0, i and m.

For a width W and an integer a with $|a|<2^{W+1}$, the *answer word* is the frame of the bit $[a<0]$ followed by exactly $W+1$ binary digits of $|a|$, least significant first. The width used at precision m is $W_m=4\mathscr{B}(N)+4$, with $N=N(\max(m,n_0))$ and $\mathscr{B}$ the capacity of Proposition 15.26.

The request contains the original rational data and nothing computed from them: no schedule, no Taylor order, no working precision, no width and no intermediate value. The machine must compute all of these itself. The answer word is a fixed-width sign-magnitude numeral; by Proposition 15.26 its width is at most a constant times $(m+n_0+\kappa+1)^2$, well above the roughly m significant bits of the answer.

Theorem 15.33 (One machine for every problem and every precision)**.** *There are one control table H and one natural number λ with the following property. Let a problem have a coefficient field, with rational initial point y_0, radius $M\geq 1$ and natural end time T, and let it satisfy the region certificate at level n_0. Then there is a constant K such that, for every coordinate $i<d$ and every precision m, the answer a_m at precision m of the certified real x_i of Theorem 15.22 satisfies $|a_m|<2^{W_m+1}$ (Lemma H.5), and the machine H runs from the request for coordinate i at precision m to the answer word of a_m within $K(m+1)^\lambda$ steps.*

The same H and λ serve every polynomial field. Let p be a polynomial field with rational initial point x_0, radius $M\geq 1$ and natural end time T, whose quadratized problem satisfies the region certificate at level n_0. Then there is a constant K such that, for every $i<d$ and every m, the answer at precision m of the polynomial solution x_i is less than 2^{W_m+1} in absolute value, with W_m the width of the quadratized problem, and H runs from the request of the quadratized problem for the variable w_{e_i} at precision m to the answer word of that answer within $K(m+1)^\lambda$ steps.

Conditions and scope.

Data
Rational coefficients, a rational initial point, a natural radius $M \geq 1$ and a natural end time T, all written in binary in the request.

Certificate
The region certificate at level n_0 is a hypothesis. It is a finite check of the computed trajectory at one level; the machine does not perform it, and the theorem says nothing about problems that fail it. For polynomial fields the machine reads the request of the quadratized problem; it does not quadratize.

Output
The fixed-width sign-magnitude numeral of the integer a_m. Because a_m is an answer of the certified real x_i, $|a_m/2^m - a_n/2^n| \leq 2^{-m} + 2^{-n}$ for every n, and in the order of $\mathbb{R}_\delta$ the point $\bar{x}_i$ and $\eta(a_m/2^m)$ are within 2^{-m}, as shown after Proposition 15.5.

Resources counted
Machine steps of H, including reading the request, all arithmetic, writing the answer and erasing the scratch tape. The bound $K(m+1)^\lambda$ is polynomial in the number m of requested bits, the usual measure for computing real numbers.

Constants
H and λ are fixed once for all problems. K depends on the whole problem (field, dimension, initial point, M, T and n_0) but not on i or m. The exponent λ is a numeral with 55 decimal digits (Theorem I.209): the construction composes the fixed exponents of the stages and makes no attempt to keep it small.

Not claimed
Any bound on how K depends on the size of the problem; any statement about hardware time; that the answer is a prefix of a binary expansion (it is a certified approximation at scale 2^{-m}); and any statement about the logical principles used in the construction.

Identification
The point $\bar{x}_i$ is the classical solution value $y_i(T)$ under the hypotheses of Theorem 15.29, or of Corollary 15.30 for polynomial fields.

The order of the quantifiers is the content of the theorem, in the sense of Chapter 10: there exist H and λ, for every problem with a certificate there exists K, for every i and m the bound holds. Only the constant is chosen after the problem.

Pouly and Graça [45] gave algorithms with guaranteed accuracy for polynomial differential equations, with running times polynomial in the end time, the accuracy and the length of the solution curve, and Bournez, Graça and Pouly [46] characterized polynomial-time computation by solutions of polynomial differential equations of polynomial length. In its dependence on the problem, Theorem 15.33 is weaker than their results: nothing is said about how K grows, the exponent is very large, and a finite region certificate takes the place of a bound on the solution. What it adds is one fixed one-tape binary machine with one exponent for the whole class. In the bit-complexity bound of Pouly and Graça the exponent grows with the

dimension of the system; here one exponent λ serves every problem of every dimension, and the dimension enters only the constant K. It also adds an answer that is a certified point of $\mathbb{R}_\delta$ with a proved modulus, and the exact count of the arithmetic behind it.

How the theorem is proved

The machine is $H = \mathrm{machine}(P)$ for one structured program P, and three lemmas carry the argument from the mathematics of the previous sections to steps of H. The first turns structured programs into control tables without changing the count.

Structured programs are built from skip, write b, left and right by sequencing $P;Q$, a branch $\mathrm{branch}(P_0, P_1)$ on the scanned bit, and a loop $\mathrm{loop}(P)$ that runs P while the scanned bit is 1. Their size is 1 for the four primitives, $|P;Q| = |P| + |Q|$, $|\mathrm{branch}(P_0, P_1)| = 1 + |P_0| + |P_1|$ and $|\mathrm{loop}(P)| = 1 + |P|$. A *counted execution* of P from a head position and tape to another, in t units, is defined by the rules: each primitive takes one unit (skip changes nothing); a sequence adds the units of its parts; a branch takes one unit plus those of the part selected by the scanned bit; a loop on a scanned 0 takes one unit and changes nothing, and on a scanned 1 takes one unit plus those of P and of the loop again. Every test is counted, including the final one of each loop. The compilation $\mathrm{comp}(P, s, x)$, a list of $|P|$ instructions meant for the addresses $s, \dots, s + |P| - 1$ with exit state x, is $[\mathrm{branch}(x, x)]$, $[\mathrm{write}(b, x)]$, $[\mathrm{left}(x)]$ and $[\mathrm{right}(x)]$ for the primitives; $\mathrm{comp}(P, s, s + |P|)$ followed by $\mathrm{comp}(Q, s + |P|, x)$ for $P;Q$; $\mathrm{branch}(s + 1, s + 1 + |P_0|)$ followed by $\mathrm{comp}(P_0, s + 1, x)$ and $\mathrm{comp}(P_1, s + 1 + |P_0|, x)$ for a branch; and $\mathrm{branch}(x, s + 1)$ followed by $\mathrm{comp}(P, s + 1, s)$ for a loop. Finally $\mathrm{machine}(P)$ is $\mathrm{comp}(P, 0, |P|)$ followed by halt.

Lemma 15.34 (The counted compiler)**.**

(a) If P has a counted execution in t units from head h and tape τ to head h' and tape τ', and a control table holds $\mathrm{comp}(P, s, x)$ *at the addresses $s, \dots, s + |P| - 1$, then t steps of that table from state s, head h and tape τ reach state x, head h' and tape τ'.*

(b) If P has a counted execution in t units from head 0 *and the input tape of u to a tape that is v written from cell* 0 *with* 0 *elsewhere, then* $\mathrm{machine}(P)$ *runs from u to v within t steps.*

Proof. (a) Induction on the derivation of the execution. A primitive is one instruction, executed in one step, with exit x (skip is a branch whose two targets are x). For $P;Q$ the table holds $\mathrm{comp}(P, s, s + |P|)$ at s and $\mathrm{comp}(Q, s + |P|, x)$ at $s + |P|$; the induction hypothesis for P and then for Q gives $t_P + t_Q$ steps from s to x. For a branch, the first instruction moves in one step to $s + 1$ or to $s + 1 + |P_0|$ according to the scanned bit, and the hypothesis for the selected part finishes at x. For a loop, the first instruction tests the scanned bit in one step: on 0 it goes to x with nothing changed; on 1 it goes to $s + 1$, the hypothesis for P returns the machine to s, and the hypothesis for the remaining execution of the loop finishes at x. In every case the number of steps is the number of units. (b) Apply (a) with $s = 0$ and $x = |P|$; the instruction at address $|P|$ is halt. □

The second lemma says that the trajectory needs only integers at one working precision, with exactly two roundings per row and step.

Stage	Contract, from its input tape to its output tape
Parse	Move the bits of every frame onto tracks 3 and 4 of the rows (the saved request), marking on track 15 the first row of every frame after the first, and erase the input cells as they are read, except for one mark on the last cell. At most $100000(\ell+1)^3$ steps for a request of length ℓ (Theorem I.42).
Decode	Erase that mark. Write every natural number of the request in unary on tracks 9 and 10: d, the term counts and indices, the payload length, M, T, n_0, i and m. Exponent 8 (Theorem I.58); with Parse, 11 in X (Corollary I.59).
Schedule	From the saved request compute in unary the magnitudes of the payload integers and, by row sums and maxima of the numbers $\lceil\lvert q\rvert\rceil$, the bounds γ, α, β and the capacities s, L, s_0 (Theorem I.62); then, by a fixed program of 51 unary operations, the sum $R=\gamma+\alpha+\beta M+1$, σ, S, G, κ, q_P, l_P and c_P; finally N, $\mathscr{B}(N)$ by Horner's rule and W_m. Exponent $g_q = 23040\cdot 6^{51}+12$ (Theorem I.88).
Initialize	Store the controls and reserve the rows; for each coordinate j compute $\operatorname{near}(2^N y_{0,j}) = \lfloor (2p\,2^N+q)/(2q)\rfloor$ from $y_{0,j}=p/q$ by one division and append its signed word to the binary stream. Exponent 190674 (Theorem I.102).
Coefficients	For order l and coordinate j compute the product D of the denominators of the coefficients of coordinate j and the integer U with $c_j[l=0]+(Af_l)_j+\sum_{i\le l} B(f_i,f_{l-i})_j = U/(Ds^2)$, $s=2^N$. The floor of $(2U+Ds(l+1))/(2Ds(l+1))$, computed in an area of $3W_m$ bits, is $r_{l+1,j}=\operatorname{near}(U/(Ds(l+1)))$; append its signed word to the buffer. Exponent 118 per entry, 120 per table (Theorems I.119, I.121).
Taylor sum	For each coordinate form $T=\sum_{l\le N} 2^{\sigma(N-l)} z_l$ by Horner's rule on the stored entries z_l, in a word of $W_m+\sigma N+N+4$ bits; halve T σN times, rounding down, and add the last bit dropped. This is $\operatorname{near}(\sum_{l\le N} 2^{-\sigma l} z_l)$, rounded once. Write the new vector to the binary stream. Exponent 8 in $d+\sigma+N+W_m+r+1$ (Theorem I.161); one step, 136 (Theorem I.162).
Step loop	Repeat the two previous stages, on the same rows, once for each of the S marks of the step count on track 14. Invariant: the stored vector is Z_k of Lemma 15.35, in the ball of radius M by Theorem 15.20; here the region certificate is used. Exponent 137 (Theorem I.184).
Select	Read i from the saved request; copy the signed word of coordinate i of Z_S to the front of the binary stream and end the stream there; empty the buffer. Exponent 3 (Theorem I.187); with Initialize and the loop, 105 252 600 (Theorem I.188).
Round and emit	Shift the magnitude of $z=(Z_S)_i$ right by $N-m$ places, keeping the last digit dropped and the OR of the earlier ones; add one if that digit is 1 and, for negative z, the OR is 1; add rows; write the sign. This is the signed word of $\operatorname{near}(2^m z/2^N)=a_m$ (Lemma 15.35). Exponent 7 in $m+N+W_m+r+1$ (Theorem I.198).
Frame and erase	Copy the word into the output buffer as marks, a 0 and its bits, which is the answer word; write the buffer into the cells $0,1,\dots$; erase every row found through the headers on track 0, and the root; stop on cell 0. At most $2000(r+1)^2$ steps on r rows, which doubles the exponent (Theorem I.204).

Table 15.1. The stages of the machine of Theorem 15.33 in the order in which they run, with the results of Appendix I that construct them. Unless stated otherwise a bound has the form $K(X+r+1)^g$ of Lemma 15.36: r rows are in use at the start, K depends only on the problem and n_0, and g is the stated exponent.

Lemma 15.35 (The trajectory in integers)**.** *Fix a level n and let $w = N(n)$. Define integer vectors Z_k by $Z_0 = \mathrm{near}(2^w y_0)$, coordinatewise, and let Z_{k+1} be obtained from Z_k as follows: the rows $r_0 = Z_k$ and $r_{l+1} = \mathrm{near}\big(2^w \,\mathrm{next}(f, l)\big)$ with $f_j = r_j/2^w$, for $l < N(n)$, and then $Z_{k+1} = \mathrm{near}\big(2^w S_{N(n)}(f)\big)$. Then $y_k^{(n)} = Z_k/2^w$ for every k, and*

$$a_m = \mathrm{near}\Big(2^m \,\frac{(Z_S)_i}{2^{N(\max(m,n_0))}}\Big)$$

with Z_S computed at level $\max(m, n_0)$.

Proof. For every ratio q, $[q]_w = \mathrm{near}(2^w q)/2^w$. Induction on the row index shows that $r_l/2^w$ is the coefficient $a_l^{(w)}$ of the table at $Z_k/2^w$ with rounding $[\cdot]_w$, and then $Z_{k+1}/2^w = \Psi_{w,w}(Z_k/2^w)$. Induction on k gives the first claim, and the formula for a_m is that of Theorem 15.22. □

The third lemma composes resource bounds. A stage of P starts with r rows of scratch tape in use and ends with r' rows after t units; its contract bounds $t + r' + 1$ by a constant times a power of $X + r + 1$, where $X = m + n_0 + \kappa + 1$ is the scale of the request.

Lemma 15.36 (Composing resource bounds)**.**

(a) Let $N \geq 1$ and $e \geq 1$. If $s + r + 1 \leq A\,N^e$ and $t + r' + 1 \leq K(N + r + 1)^g$, then

$$(s + t) + r' + 1 \leq \big(A + K(A + 1)^g\big) N^{e(g+1)}.$$

(b) If $c \geq 1$, then $(m + c)^\lambda \leq c^\lambda (m + 1)^\lambda$.

(c) Suppose a first stage, started with r rows in use, ends after t_1 units with r_1 rows and $t_1 + r_1 + 1 \leq K_1(X + r + 1)^{g_1}$, and a second stage, started from every tape the first can leave, ends after t_2 units with r_2 rows and $t_2 + r_2 + 1 \leq K_2(X + r_1 + 1)^{g_2}$. Then the two stages in sequence end after $t_1 + t_2$ units, and

$$t_1 + t_2 + r_2 + 1 \leq \big(K_1 + K_2(K_1 + 1)^{g_2}\big)(X + r + 1)^{(g_1+1)(g_2+1)}.$$

Proof. (a) Since $N \leq N^e$ and $r + 1 \leq AN^e$, we have $N + r + 1 \leq (A + 1)N^e$, so

$$t + r' + 1 \leq K(A + 1)^g N^{eg} \leq K(A + 1)^g N^{e(g+1)}.$$

Also $s \leq AN^e \leq AN^{e(g+1)}$. Add. (b) $m \leq mc$, so $m + c \leq c(m + 1)$; raise to the power λ. (c) Put $Y = X + r + 1 \geq 1$. Then $t_1 + r_1 + 1 \leq K_1 Y^{g_1} \leq K_1 Y^{g_1+1}$, and since $X \leq Y$, $t_2 + r_2 + 1 \leq K_2(Y + r_1 + 1)^{g_2}$. Apply (a) with $N = Y$, $s = t_1$, $e = g_1 + 1$, $A = K_1$, $r = r_1$ and $g = g_2$. □

The program P is a sequence of stages, each with a contract of this form. Table 15.1 lists them, and Appendix I constructs every stage program and proves its contract and its bound. The scratch area is the negative half of the tape, arranged in rows of sixteen tracks. The request does not stay where it was written. The first stage moves it into these rows, its bits onto two tracks and a mark at the start of every frame after the first onto a third, and erases the input cells as it reads them, except for one mark on the last cell; the second stage erases that mark,

so that the input cells stay blank until the answer is written there. Control numbers, such as the schedule and the loop counters, are kept in unary as runs of marked cells. Numerical data are kept as signed binary words of the width W_m, and the arithmetic of a step works in areas of $3W_m$ and of $W_m + \sigma N + N + 4$ bits (Proposition I.32).

Proof of Theorem 15.33. Let P be the program of Theorem I.209 in Appendix I, let H be the control table machine(P), and let

$$\lambda = 11\Big(2(g_q + 1)\big(8(762700 \cdot 138 + 2) + 1\big) + 1\Big), \qquad g_q = 23040 \cdot 6^{51} + 12,$$

be the exponent of that theorem. Both are fixed before any problem is given. Let a problem with a coefficient field satisfy the region certificate at level n_0, and let K be the constant of Theorem I.209; it depends on the problem and on n_0, not on i or m. Part (b) of that theorem is the first claim: for every coordinate $i < d$ and every precision m, $|a_m| < 2^{W_m+1}$, and H runs from the request for coordinate i at precision m to the answer word of a_m within $K(m+1)^\lambda$ steps. Its last part is the second claim, with the same H and λ, because the polynomial solution x_i is the certified real of the variable w_{e_i} of the quadratized problem (Definition 15.27).

Theorem I.209 is proved stage by stage along Table 15.1. The first two stages read the request, whose length is at most a constant depending on the problem times X, within a constant times X^{11} units (Corollary I.59). Every later stage meets a contract whose exponent does not depend on the problem, in X and the rows already in use, and Lemma 15.36(c) composes such contracts in sequence. The step loop adds one to the exponent of a step and puts the number S of steps into the constant (Lemma I.19). Its invariant is the vector Z_k of Lemma 15.35, which lies in the ball of radius M by Theorem 15.20, so every integer the machine stores fits the widths of Proposition I.32. Rounding and emitting leaves the signed word of $\mathrm{near}(2^m (Z_S)_i / 2^N)$, which is the answer a_m of Theorem 15.22 by Lemma 15.35 and fits W_m by Lemma H.5. Framing and erasing is quadratic in the rows and doubles the exponent (Lemma I.205). Lemma 15.36(a) then adds the reading of the request, and part (b) turns $X^\lambda = (m + c)^\lambda$, $c = n_0 + \kappa + 1$, into $c^\lambda (m+1)^\lambda$. Finally Lemma 15.34(b) turns the counted execution of P into a run of H with the same number of steps. □

This chapter proves the mathematics that the machine computes: the certified solution value and its modulus (Theorem 15.22), the count of the arithmetic of the ratio procedure (Theorem 15.23) and the size of its numbers (Proposition 15.26), together with the three lemmas above, which turn a structured program into the control table H, reduce the trajectory to integers and compose stage bounds. The machine does not run the ratio procedure of Section 15.6: it keeps integer numerators over the denominator 2^N and sums by Horner's rule, and Lemma 15.35 shows that it computes the same values. Appendix I constructs every stage program of Table 15.1 from a small set of tape routines, proves its contract and its step bound with a fixed exponent, bounds every integer the machine stores (Proposition I.32), and assembles the stages into the program P with its exponent λ and its constant K (Theorem I.209). With these results the proof of Theorem 15.33 is complete.

Questions to work through

1. An expression is built from certified reals by h nested sums. At what precision does Proposition 15.4 ask its leaves when the expression is requested at precision n? Compare with the request $2n + 1$ of the protocol sum of Chapter 11 after h nestings.

2. Write $y' = -y^2$, $y(0) = \frac{1}{2}$, as a coefficient field with $d = 1$, and take $T = 1$ and $M = 1$. Compute γ, α, β, R, σ, S, G and κ. What finite check does the region certificate at level 0 ask for?

3. Use Theorem 15.11 to find a lower bound for the number of Runge–Kutta steps that can give e to 40 bits. Compare with the 32 steps that the Taylor solver uses for the oscillator at every precision. Which feature of the two methods explains the difference?

4. Compute step(N) and cost(40) for the oscillator from Theorem 15.23, and compare with the bound of Proposition 15.25.

5. Quadratize $x' = x^3$. List the variables, the terms of the new field and the initial values, and check the identity behind Definition 15.27 for the variable x^3.

Chapter 16

A calculus of δ's own objects

Take the unit interval with its finite rational nets, and a sequence of rational open intervals that covers every point of it. Chapter 13 shows that finitely many of the intervals always suffice exactly when the decidable fan theorem FAN_Δ holds, with no choice principle in either direction. Can an omniscience principle pay for this? LPO decides, for each binary sequence, whether it has an entry 1, and once unique choice collects its answers for infinitely many sequences into one sequence, it gives the finite subcover (Corollary 13.10). Does LPO give the finite subcover without that collection?

To ask the question we have to say what a proof is allowed to do. The statement quantifies over compact sets of points of $\mathbb{R}_\delta$, over their nets, over covers and over points. Intuitionistic second-order arithmetic (Definition 7.14) quantifies over numbers and sets of numbers. The theories of Theorems 12.22 and 12.63 add sequences of numbers, and the proof of Theorem 12.63 writes a point as a formula with a sequence variable; a set of points or a function on points then becomes a formula, and a statement about all of them becomes a schema. What we want is a calculus whose variables range over δ's objects directly: points of the line as classes of regular sequences, functions on the line, sets of points, compact sets with their nets. In such a calculus the statement above is one sentence, and "LPO derives it" has a definite meaning once the terms of the calculus are fixed.

This chapter builds that calculus and answers the question for its computable form. Its objects live at two stages, an earlier one and a later one, as in the two-stage structures of Chapter 6. Every derivation is sound for this reading (Theorem 16.8), and every derivation of intuitionistic second-order arithmetic translates into a derivation of the calculus (Theorem 16.11). The calculus admits every map of ordinary mathematics as a term. For that reason it has no recursive model (Theorem 16.14), and it derives every true sentence built from equations over carriers that do not change from one stage to the next, LPO, $\mathrm{WLPO}_{\mathrm{seq}}$ and the compactness sentences among them (Proposition 16.15); there "LPO derives it" says only that the statement is classically true. Restricting the terms to maps computed by programs gives the *computable calculus*, which keeps every rule and has a model in which the objects are those with computable names. In the computable calculus we prove two kinds of separation, and both hold even when every instance of excluded middle is added as a base rule. LPO does not derive the sequential form $\mathrm{WLPO}_{\mathrm{seq}}$ of WLPO (Theorem 16.27). And none of the decidable fan theorem, its c-set form $\mathrm{FAN}_{\mathrm{c}}$, decidable weak König's lemma, Heine–Borel for presented compact sets, the positive lower bound, the positive infimum and presented Heine–Cantor is derivable from LPO (Theorems 16.32 to 16.36). These statements are written with equations between computed terms: an atom of an order or of a membership relation is governed by no rule (Remark 16.19), so a statement resting on one could fail to be derivable for that reason alone.

Every one of these failures has the same source. In the model, LPO is true and each question has its answer, but the answers are not collected into a computable function. With LPO the computable calculus decides each question; it cannot collect the answers. That is the dual of

Theorem 12.22, which shows that collecting decides nothing.

As in Chapters 7 and 12, the arguments about a model are carried out in ordinary classical mathematics: they say which statements are true in a model, and they ask nothing of the calculus under study. Where a proof below uses classical reasoning in that sense, we say so at the step.

16.1 Objects that exist at two stages

Chapter 6 read arithmetic at two stages: a structure M_0 at an earlier stage, a structure M_1 at a later stage, and a passage h from the first to the second. An equation or an existential statement was read at the earlier stage alone, while an implication or a universal statement had to hold at the later stage too. The calculus of this chapter uses the same reading for every kind of object, not only for numbers.

Definition 16.1 (Two-stage carriers and their maps)**.** A *carrier* X consists of a set X_0 of objects at the earlier stage, a set X_1 of objects at the later stage, and a map $h_X : X_0 \to X_1$, the *passage*, which says what each earlier object becomes later. A *map* $f : X \to Y$ of carriers is a pair of maps $f_0 : X_0 \to Y_0$ and $f_1 : X_1 \to Y_1$ that commutes with the passage:

$$f_1(h_X(x)) = h_Y(f_0(x)) \qquad \text{for every } x \in X_0.$$

Two maps are equal when both components are. Identities and composition are taken componentwise. A *predicate* P on X is a pair of subsets $P_0 \subseteq X_0$ and $P_1 \subseteq X_1$ that *persists*: $x \in P_0$ implies $h_X(x) \in P_1$.

We write h for every passage when the carrier is clear. The passage need not be injective or onto: two earlier objects may become one, and new objects may appear later. The following carriers are used throughout.

- The *constant carrier* of a set S has S at both stages and the identity as passage. We use it for the natural numbers $\mathbb{N}$, for the set $\mathbb{Q}$ of ratio records of Chapter 4, for finite binary strings and bits, and for the one-point set $\mathbf{1}$, whose carrier is the context of a closed sentence.
- The *product* $X \times Y$ has $X_0 \times Y_0$ and $X_1 \times Y_1$, with the passage $(x, y) \mapsto (h(x), h(y))$. The projections and the pairing $\langle f, g \rangle$ of two maps are maps of carriers.
- The *exponential* Y^X has, at the earlier stage, all maps of carriers $X \to Y$; at the later stage, all functions $X_1 \to Y_1$; and the passage sends a map (f_0, f_1) to f_1. *Evaluation* $\mathrm{ev} : Y^X \times X \to Y$ is $\mathrm{ev}_0((f_0, f_1), x) = f_0(x)$ and $\mathrm{ev}_1(f, x) = f(x)$. A map $k : Z \times X \to Y$ has a *curried* form $\lambda k : Z \to Y^X$: at the earlier stage z goes to the map $\big(x \mapsto k_0(z, x),\ x \mapsto k_1(h(z), x)\big)$, and at the later stage to $x \mapsto k_1(z, x)$.
- The *truth values* Ω have, at the earlier stage, the pairs (p, q) of propositions with p implying q ("true now" implies "true later"); at the later stage, all propositions; and the passage $(p, q) \mapsto q$.

- A predicate P on X cuts out the *subcarrier* with P_0 and P_1 and the restricted passage. Equivalence relations $\sim_0$ on X_0 and $\sim_1$ on X_1 with $x \sim_0 y$ implying $h(x) \sim_1 h(y)$ give the *quotient* carrier $(X_0/\sim_0, X_1/\sim_1)$ with the induced passage, and the quotient map $X \to X/\sim$.

For constant carriers S and T, a map $(f_0, f_1) : S \to T$ has $f_1 = f_0$, because the passages are identities; so both stages of T^S consist of the functions from S to T, and the exponential is again constant. Predicates on X and maps $X \to \Omega$ correspond: P gives its *characteristic map*, which sends $x \in X_0$ to the pair $(x \in P_0,\ h(x) \in P_1)$ and $x \in X_1$ to the proposition $x \in P_1$; persistence is exactly the condition that the pair lies in Ω_0. So the earlier-stage objects of Ω^X, the *classifiers* on X, are the predicates on X, and the later-stage objects are all properties of later objects. A classifier can grow: an object outside it at the earlier stage can be inside it later.

Definition 16.2 (The carriers of δ's objects)**.** The *displays* are the exponential $\mathbb{Q}^{\mathbb{N}}$ of constant carriers, so both stages consist of the sequences of ratio records. The *regular carrier* $\mathscr{R}$ is the subcarrier of the regular sequences of Definition 12.14, at both stages. The *line* $\mathscr{L}$ is the quotient of $\mathscr{R}$ by the relation $\approx$ of naming the same point, at both stages. The carriers of *functions on the line* and of *sets of points* are the exponentials $\mathscr{L}^{\mathscr{L}}$ and $\Omega^{\mathscr{L}}$.

Regularity is one condition on a sequence, so it persists. Both stages of $\mathscr{L}$ are $\mathbb{R}_\delta$ itself, read through representatives at each stage, with no choice of a representative for a family of points. The function carrier contains every function on $\mathbb{R}_\delta$ at the later stage, and the subset carrier every set of points; at the earlier stage a set of points is a pair of sets with the earlier one contained in the later one.

The structure just described is the Kripke semantics of intuitionistic logic on the frame with two worlds, an earlier one below a later one, with domains that may change from one world to the next [53, 4]. In the language of categories it is the category of presheaves on the two-element chain; products, exponentials and Ω are its products, exponentials and object of truth values. We use none of that theory. Every fact needed below is checked directly from the definitions.

16.2 Terms, formulas and their reading

A formula of the calculus lives in a *context*, a carrier G whose points are the values of its free variables. A closed sentence has the one-point context $\mathbf{1}$. A context $G \times X$ has one more variable, of type X, than G.

Definition 16.3 (Terms)**.** For carriers G and X, the *terms* $t : G \vdash X$ are generated by four constructions:

- $\mathrm{map}(f)$, for every map of carriers $f : G \to X$;
- the pair $\langle t, u \rangle : G \vdash X \times Y$ of $t : G \vdash X$ and $u : G \vdash Y$;
- the application $t\,u : G \vdash Y$ of $t : G \vdash Y^X$ to $u : G \vdash X$;

- the abstraction $\lambda t \,:\, G \vdash Y^X$ of $t \,:\, G \times X \vdash Y$.

Each term is read as a map $[\![t]\!] \,:\, G \to X$:

$$[\![\mathrm{map}(f)]\!] = f, \quad [\![\langle t, u\rangle]\!] = \langle [\![t]\!], [\![u]\!]\rangle, \quad [\![t\,u]\!] = \mathrm{ev} \circ \langle [\![t]\!], [\![u]\!]\rangle, \quad [\![\lambda t]\!] = \lambda [\![t]\!].$$

The *graph* of t is the map $\mathrm{gr}(t) = \langle \mathrm{id}, [\![t]\!]\rangle \,:\, G \to G \times X$.

Variables are not a separate kind of term. The newest variable of the context $G \times X$ is the term $\mathrm{map}(\pi_2)$, and an older variable is reached through the first projection $\pi_1 \,:\, G \times X \to G$. Substituting a term t for the newest variable is reindexing along $\mathrm{gr}(t)$.

Definition 16.4 (Formulas)**.** The *formulas* in context G are generated by ten constructions:

- the atom $R(t)$, for every predicate R on a carrier X and every term $t \,:\, G \vdash X$;
- $\top$ and $\bot$;
- the equation $t = u$, for terms $t, u \,:\, G \vdash X$;
- $A \wedge B$, $A \vee B$ and $A \to B$;
- the quantifiers $\forall_X A$ and $\exists_X A$, for a carrier X and a formula A in context $G \times X$;
- the *reindexing* $f^* A$ in context D, for a map $f \,:\, D \to G$ and a formula A in context G.

We write $\neg A$ for $A \to \bot$.

The quantifiers range over any carrier: numbers, sequences, points of the line, functions on it, its subsets, truth values. Each formula is read as a predicate on its context. Write $g \Vdash_0 A$ when the earlier object $g \in G_0$ belongs to the reading of A, and $g \Vdash_1 A$ when the later object $g \in G_1$ does. The clauses are those of Table 16.1. For a pair (g, x) in a product context we write $(g, x) \Vdash_i A$.

Lemma 16.5 (Readings persist)**.** *For every formula A in context G and every $g \in G_0$: if $g \Vdash_0 A$, then $h(g) \Vdash_1 A$. So the reading of every formula is a predicate on its context.*

Proof. By induction on A, for all contexts at once. For an atom, $[\![t]\!]_0(g) \in R_0$ gives $h([\![t]\!]_0(g)) \in R_1$ by persistence of R, and this point is $[\![t]\!]_1(h(g))$ because $[\![t]\!]$ commutes with the passage. For an equation apply h to both sides and use the same commutation. The cases $\top$, $\bot$, $\wedge$ and $\vee$ follow from the induction hypotheses. For $A \to B$ and $\forall_X A$ the second half of the earlier clause is the later clause at $h(g)$. For $\exists_X A$, a witness $x \in X_0$ with $(g, x) \Vdash_0 A$ gives $(h(g), h(x)) \Vdash_1 A$ by the induction hypothesis, so $h(x)$ is a later witness. For $f^* A$, $f_0(g) \Vdash_0 A$ gives $h(f_0(g)) \Vdash_1 A$, and $h(f_0(g)) = f_1(h(g))$. □

For formulas P and Q in context G we say that P *entails* Q, written $P \vDash Q$, when every $g \in G_0$ with $g \Vdash_0 P$ has $g \Vdash_0 Q$ and every $g \in G_1$ with $g \Vdash_1 P$ has $g \Vdash_1 Q$. A *two-stage truth value* is a pair of propositions A_0 and A_1 with A_0 implying A_1, that is an element of Ω_0; it is the atom $\underline{A}$ of the closed context whose reading is A_0 at the earlier stage and A_1 at the later one.

Formula	earlier stage, $g \in G_0$	later stage, $g \in G_1$
$R(t)$	$[\![t]\!]_0(g) \in R_0$	$[\![t]\!]_1(g) \in R_1$
$\top$, $\bot$	always, never	always, never
$t = u$	$[\![t]\!]_0(g) = [\![u]\!]_0(g)$	$[\![t]\!]_1(g) = [\![u]\!]_1(g)$
$A \wedge B$, $A \vee B$	both, at least one of $g \Vdash_0 A$, $g \Vdash_0 B$	both, at least one at stage 1
$A \to B$	$g \Vdash_0 A$ implies $g \Vdash_0 B$, and $h(g) \Vdash_1 A$ implies $h(g) \Vdash_1 B$	$g \Vdash_1 A$ implies $g \Vdash_1 B$
$\forall_X A$	$(g, x) \Vdash_0 A$ for every $x \in X_0$, and $(h(g), x) \Vdash_1 A$ for every $x \in X_1$	$(g, x) \Vdash_1 A$ for every $x \in X_1$
$\exists_X A$	$(g, x) \Vdash_0 A$ for some $x \in X_0$	$(g, x) \Vdash_1 A$ for some $x \in X_1$
$f^* A$	$f_0(g) \Vdash_0 A$	$f_1(g) \Vdash_1 A$

Table 16.1. The two-stage reading of formulas. An implication and a universal statement at the earlier stage also look ahead to the later stage; the other constructions are read at one stage.

An example. Let $q : \mathscr{R} \to \mathscr{L}$ be the quotient map. The sentence

$$\forall_{\mathscr{L}} \exists_{\mathscr{R}} \big(\mathrm{map}(q \circ \pi_2) = \mathrm{map}(\pi_2 \circ \pi_1) \big)$$

says that every point of the line is the class of a regular sequence. At the later stage it says this of the points of $\mathbb{R}_\delta$. At the earlier stage it says the same of the earlier points and also, through the second half of the universal clause, of the later ones. Its existential is read at one stage at a time: one representative for one point, never a choice of representatives for a family. The sentence is derived from rule 9 of Table 16.2 by one universal introduction.

16.3 Derivations and the twenty-nine base rules

A judgment of the calculus has one hypothesis formula: $P \vdash Q$, with P and Q in the same context. A list of hypotheses is their conjunction. The judgment $\top \vdash Q$ in the one-point context derives the sentence Q.

Definition 16.6 (Derivations)**.** Given a family of *base rules*, each a judgment $P \vdash Q$, a *derivation* is a finite tree built by the following twenty constructions, in which $\pi = \pi_1 : G \times X \to G$ and A, B, C, P, Q are formulas of the appropriate contexts. A *derivation in the calculus* is a derivation from the base rules of Table 16.2.

(1) a base rule $P \vdash Q$;

(2) $P \vdash P$;

(3) $P \vdash \top$;

(4) from $P \vdash \bot$ infer $P \vdash Q$;

(5) from $P \vdash Q$ and $Q \vdash C$ infer $P \vdash C$;

(6) from $P \vdash A$ and $P \vdash B$ infer $P \vdash A \wedge B$;

(7–8) from $P \vdash A \wedge B$ infer $P \vdash A$, and infer $P \vdash B$;

(9–10) from $P \vdash A$ infer $P \vdash A \vee B$; from $P \vdash B$ infer $P \vdash A \vee B$;

(11) from $P \vdash A \vee B$, $P \wedge A \vdash C$ and $P \wedge B \vdash C$ infer $P \vdash C$;

(12) from $P \wedge A \vdash B$ infer $P \vdash A \to B$;

(13) from $P \vdash A \to B$ and $P \vdash A$ infer $P \vdash B$;

(14) from $\pi^* P \vdash A$, with A in context $G \times X$, infer $P \vdash \forall_X A$;

(15) from $P \vdash \forall_X A$ infer $P \vdash \mathrm{gr}(t)^* A$, for a term $t : G \vdash X$;

(16) from $P \vdash \mathrm{gr}(t)^* A$ infer $P \vdash \exists_X A$, for a term $t : G \vdash X$;

(17) from $P \vdash \exists_X A$ and $\pi^* P \wedge A \vdash \pi^* C$ infer $P \vdash C$;

(18) from $P \vdash Q$ infer $f^* P \vdash f^* Q$, for a map $f : D \to G$;

(19) $P \vdash t = t$;

(20) from $P \vdash t = u$ and $P \vdash \mathrm{gr}(t)^* A$ infer $P \vdash \mathrm{gr}(u)^* A$, for A in context $G \times X$.

No construction admits a formula because it is true, and none carries a proof of its own soundness. The base rules need a few abbreviations. Over any context G, 0 is the term of the constant map with value 0, and $S(t)$, $t + u$ and $t \cdot u$ are the terms of the maps that compute the successor, the sum and the product of the values of t and u at each stage. The map $\mathrm{succ} : G \times \mathbb{N} \to G \times \mathbb{N}$ sends (g, n) to $(g, n + 1)$. For a formula A in context $G \times \mathbb{N}$,

$$\mathrm{Ind}(A) := \mathrm{gr}(0)^* A \wedge \forall_{\mathbb{N}}\big(A \to \mathrm{succ}^* A\big).$$

The membership predicate $\in$ on Ω is $\{(p, q) : p\}$ at the earlier stage and $\{q : q\}$ at the later stage. In the context $G \times \Omega^X \times X$, let c be the classifier variable and x the newest variable, let Mem be the atom $\in(c\,x)$, and let $\mathrm{fg} : G \times \Omega^X \times X \to G \times X$ forget the classifier. For a formula A in context $G \times X$,

$$\mathrm{Comp}(A) := \exists_{\Omega^X} \forall_X \big((\mathrm{Mem} \to \mathrm{fg}^* A) \wedge (\mathrm{fg}^* A \to \mathrm{Mem})\big).$$

For $s : G \vdash \mathscr{R}$ write $[s]$ for the term of $q \circ [\![s]\!]$, and $s \approx t$ for the atom of the predicate "names the same point" at the pair $\langle s, t \rangle$. For terms $r : G \vdash \mathscr{L}$ and $s, t : G \vdash \mathscr{R}$ let

$$\mathrm{Surj}(r) := \exists_{\mathscr{R}}\big([\mathrm{map}(\pi_2)] = \mathrm{map}([\![r]\!] \circ \pi_1)\big),$$
$$\mathrm{Eff}(s, t) := ([s] = [t] \to s \approx t) \wedge (s \approx t \to [s] = [t]).$$

Finally, a map $f : D \to G$ *lifts* to $f \times \mathrm{id} : D \times X \to G \times X$.

The eighteen reindexing rules take the place of a syntactic substitution lemma. Reindexing of $\top$ and of $\bot$ needs no rule of its own. For a map $f : D \to G$, $f^* \top \vdash \top$ is construction (3). For the converse, derive $\top \vdash 0 = 0$ in context D by (19), pass to $f^*(0 = 0)$ by rule 19, and cut with the reindexing of $0 = 0 \vdash \top$. In the same way $f^* \bot$ gives $f^*(S(0) = 0)$, rule 18 turns it into the equation $S(0) = 0$ in context D, and rule 1 with (13) gives $\bot$; the converse is (4). Here and below we use that $\mathrm{map}([\![t]\!] \circ f)$ is the same term as the corresponding term over D whenever the two maps are equal, as they are for 0 and $S(0)$.

	Rule	Judgment (P any formula of the context)
1	successor	$P \vdash S(t) = 0 \to \bot$
2	injectivity	$P \vdash S(t) = S(u) \to t = u$
3–4	addition	$P \vdash t + 0 = t$; $\quad P \vdash t + S(u) = S(t + u)$
5–6	multiplication	$P \vdash t \cdot 0 = 0$; $\quad P \vdash t \cdot S(u) = t \cdot u + t$
7	induction	$\mathrm{Ind}(A) \vdash \forall_{\mathbb{N}} A$, for every formula A in every context $G \times \mathbb{N}$
8	comprehension	$P \vdash \mathrm{Comp}(A)$, for every carrier X and formula A in context $G \times X$
9	representatives	$P \vdash \mathrm{Surj}(r)$, for $r : G \vdash \mathscr{L}$
10	effectiveness	$P \vdash \mathrm{Eff}(s, t)$, for $s, t : G \vdash \mathscr{R}$
11	computation	$P \vdash (\lambda t)\, u = \mathrm{map}(\llbracket t \rrbracket \circ \mathrm{gr}(u))$, for $t : G \times X \vdash Y$ and $u : G \vdash X$
12–13	identity	$\mathrm{id}^* A \vdash A$; $\quad A \vdash \mathrm{id}^* A$
14–15	composition	$g^* f^* A \vdash (f \circ g)^* A$, and back
16–17	atoms	$f^* R(t) \vdash R(\mathrm{map}(\llbracket t \rrbracket \circ f))$, and back
18–19	equations	$f^*(t = u) \vdash \mathrm{map}(\llbracket t \rrbracket \circ f) = \mathrm{map}(\llbracket u \rrbracket \circ f)$, and back
20–25	connectives	$f^*(A \circ B) \vdash f^* A \circ f^* B$, and back, for $\circ$ each of $\wedge$, $\vee$, $\to$
26–29	quantifiers	$f^* \forall_X A \vdash \forall_X (f \times \mathrm{id})^* A$, and back; the same for $\exists_X$

Table 16.2. The base rules of the calculus. Rules 1–7 are the arithmetic rules and induction of Chapter 5, in every context and for formulas of every type. Rule 8 is comprehension at every type. Rules 9 and 10 say that the line is the quotient of the regular sequences. Rule 11 computes an application of an abstraction. Rules 12–29 say that reindexing commutes with every construction of formulas.

Remark 16.7 (What a term may be)**.** A term $\mathrm{map}(f)$ may carry *any* map of carriers, and an atom $R(t)$ any predicate. The calculus is therefore an interpreted language: its symbols are the objects of ordinary mathematics themselves, and two terms $\mathrm{map}(f)$ and $\mathrm{map}(g)$ are the same term exactly when $f = g$. A derivation is still a finite tree, and every step is one of the twenty constructions or one of the twenty-nine rules; no formula is admitted because it is true. But terms are identified by their maps, so every true identity of maps is derivable by reflexivity. If $\llbracket t \rrbracket = \llbracket u \rrbracket$, then $\mathrm{map}(\llbracket t \rrbracket \circ \mathrm{id})$ and $\mathrm{map}(\llbracket u \rrbracket \circ \mathrm{id})$ are the same term, so construction (19) derives their equation from any hypothesis P; rule 19 at the identity map turns it into $P \vdash \mathrm{id}^*(t = u)$, and rule 12 gives $P \vdash t = u$. What is *not* the case is that the derivable sentences form a list produced by a program. Three consequences shape the rest of the chapter. An identity between maps proved in ordinary mathematics makes two terms literally equal, which the translation of Section 16.5 uses at its atoms. A term may carry a map that no program computes, which is why the calculus has no recursive model (Section 16.6). And since a term may carry any map, every sentence built from equations over constant carriers that is true in ordinary mathematics is derivable (Proposition 16.15).

16.4 Every derivation holds at both stages

Theorem 16.8 (Soundness of the calculus)**.** *If the calculus derives $P \vdash Q$, then $P \vDash Q$: every earlier object of the context that satisfies P at the earlier stage satisfies Q there, and every later object that satisfies P at the later stage satisfies Q there. More generally, every derivation from a*

family of base rules each of which is an entailment is an entailment. The proof uses no omniscience or choice principle.

Proof. The proof has two steps. Step 1 shows that each of the twenty constructions turns entailments into an entailment, whatever the base rules, provided each base rule is an entailment. Step 2 shows that each of the twenty-nine base rules is an entailment. Induction on the derivation then gives the theorem. Throughout, $\pi = \pi_1 : G \times X \to G$, i is a stage, and we assume $g \Vdash_i P$.

Step 1. Hypothesis, truth, cut, the conjunction rules, the disjunction introductions and reflexivity are immediate from the clauses of Table 16.1. Falsehood is never satisfied, so construction (4) holds vacuously. For disjunction elimination, $g \Vdash_i A \vee B$; if $g \Vdash_i A$, then $g \Vdash_i P \wedge A$ and the second premise gives $g \Vdash_i C$, and the case of B is the same.

Implication introduction, from $P \wedge A \vdash B$. At the later stage, if $g \Vdash_1 A$, then $g \Vdash_1 P \wedge A$, so $g \Vdash_1 B$. At the earlier stage the clause has two halves. If $g \Vdash_0 A$, then $g \Vdash_0 P \wedge A$ and $g \Vdash_0 B$. If $h(g) \Vdash_1 A$, then $h(g) \Vdash_1 P$ by Lemma 16.5, so $h(g) \Vdash_1 P \wedge A$ and $h(g) \Vdash_1 B$. *Implication elimination* uses the first half of the clause at the earlier stage, and the clause itself at the later stage.

Universal introduction, from $\pi^* P \vdash A$. Since $\pi_i(g, x) = g$, every (g, x) satisfies $\pi^* P$ at stage i. At the later stage this gives $(g, x) \Vdash_1 A$ for every $x \in X_1$. At the earlier stage it gives $(g, x) \Vdash_0 A$ for every $x \in X_0$, and persistence gives $h(g) \Vdash_1 P$, hence $(h(g), x) \Vdash_1 A$ for every $x \in X_1$: both halves of the clause. *Universal elimination* at a term t: the clause at the object $x = [\![t]\!]_i(g)$, which lies in X_i, says $(g, [\![t]\!]_i(g)) \Vdash_i A$, and that is $g \Vdash_i \mathrm{gr}(t)^* A$. *Existential introduction* at t uses the same object as witness. *Existential elimination*: the first premise gives $x \in X_i$ with $(g, x) \Vdash_i A$; then $(g, x) \Vdash_i \pi^* P \wedge A$, so $(g, x) \Vdash_i \pi^* C$, which says $g \Vdash_i C$.

Reindexing along f: $g \Vdash_i f^* P$ means $f_i(g) \Vdash_i P$, so $f_i(g) \Vdash_i Q$, which is $g \Vdash_i f^* Q$. *Substitution of equals*: the first premise says $[\![t]\!]_i(g) = [\![u]\!]_i(g)$, and replacing one by the other in $(g, [\![t]\!]_i(g)) \Vdash_i A$ gives $(g, [\![u]\!]_i(g)) \Vdash_i A$.

In Step 1, persistence is used at implication introduction and universal introduction, and nowhere else.

Step 2. Fix g and a stage. In rules 1–6 and 8–11 the hypothesis P plays no role. In rule 7 the hypothesis is $\mathrm{Ind}(A)$, and in rules 12–29 it is one side of an identity of readings.

Rules 1–6. Their conclusions are equations, or implications between equations, of natural numbers that hold at every point: $n + 1 \neq 0$; $m + 1 = n + 1$ gives $m = n$; $m + 0 = m$; $m + (n + 1) = (m + n) + 1$; $m \cdot 0 = 0$; $m \cdot (n + 1) = m \cdot n + m$. At the earlier stage an implication has two halves, and both are the same arithmetic fact.

Rule 7, induction. Let $g \Vdash_0 \mathrm{Ind}(A)$. Then $(g, 0) \Vdash_0 A$. The earlier half of the universal clause and the first half of the implication clause give, for every n, that $(g, n) \Vdash_0 A$ implies $(g, n + 1) \Vdash_0 A$; ordinary induction on n gives $(g, n) \Vdash_0 A$ for every n. For the later half of the conclusion, $(h(g), 0) \Vdash_1 A$ by persistence (the passage of $\mathbb{N}$ is the identity), and the later half of the universal clause gives the step $(h(g), n) \Vdash_1 A \Rightarrow (h(g), n + 1) \Vdash_1 A$; induction again gives every n. At the later stage the rule is ordinary induction.

Rule 8, comprehension. Let A be in context $G \times X$, and let $\chi : G \times X \to \Omega$ be the characteristic

map of the reading of A. At the earlier stage take the classifier $c = (\lambda\chi)_0(g)$. For $x \in X_0$ it gives the pair $\big((g,x) \Vdash_0 A,\ (h(g),h(x)) \Vdash_1 A\big)$, so the atom Mem holds at (g,c,x) exactly when $(g,x) \Vdash_0 A$. After the passage it is the property $x \mapsto \big((h(g),x) \Vdash_1 A\big)$ of later objects, so Mem holds at $(h(g),h(c),x)$ exactly when $(h(g),x) \Vdash_1 A$. Both implications in $\mathrm{Comp}(A)$ are therefore identities, in both halves of every earlier clause. At the later stage take the property $x \mapsto \big((g,x) \Vdash_1 A\big)$.

Rule 9, representatives. At each stage every element of a quotient is the class of some element, so $\mathrm{Surj}(r)$ holds: it is one existential statement about one point.

Rule 10, effectiveness. At each stage two regular sequences have the same class exactly when they name the same point, since the quotient is taken by that equivalence relation.

Rule 11, computation. By the definitions of evaluation and currying, $\mathrm{ev} \circ \langle \lambda[\![t]\!], [\![u]\!] \rangle$ and $[\![t]\!] \circ \langle \mathrm{id}, [\![u]\!] \rangle$ are the same map at both stages, so the equation holds everywhere.

Rules 12–29. Each side is read as the same predicate, by unfolding the clauses of Table 16.1. The only cases that need a remark are $f^*(A \to B)$ and $f^*\forall_X A$, whose earlier clauses mention $h(f_0(g))$ on one side and $f_1(h(g))$ on the other. These are equal because f commutes with the passage.

No step decides a proposition or chooses an object for a family. □

Corollary 16.9 (Derived sentences hold at both stages)**.** *If the calculus derives $\top \vdash \underline{A}$ for a two-stage truth value $A = (A_0, A_1)$, then A_0 and A_1 both hold.*

Proof. The one point of $\mathbf{1}$ satisfies $\top$ at both stages, so it satisfies $\underline{A}$ at both stages by Theorem 16.8. □

16.5 Intuitionistic second-order arithmetic inside the calculus

Intuitionistic second-order arithmetic, HAS, is a calculus about numbers and sets of numbers (Definition 7.14). Its sets become classifiers on $\mathbb{N}$, which may grow from one stage to the next. We write HAS with positions for variables, as Chapter 5 does for its language: $x_0, x_1, \ldots$ are the number variables and $X_0, X_1, \ldots$ the set variables, each counted from the innermost binder of its own kind, and the eigenvariable conditions of Definition 7.14 become liftings.

Definition 16.10 (The translation of HAS)**.** Let $\mathbb{S} = \Omega^{\mathbb{N}}$ be the carrier of sets of numbers and $E = \mathbb{N}^{\mathbb{N}} \times \mathbb{S}^{\mathbb{N}}$ the carrier of *environments*. An environment is a number valuation ρ, giving the value $\rho(k)$ of x_k, and a set valuation σ, giving the classifier $\sigma(j)$ of X_j. A number term t of HAS becomes the term $\ulcorner t \urcorner : E \vdash \mathbb{N}$ of the map that evaluates t at ρ, at each stage; X_j becomes the term $\ulcorner X_j \urcorner : E \vdash \mathbb{S}$ of $(\rho,\sigma) \mapsto \sigma(j)$. Let $\mathrm{push}_{\mathbb{N}} : E \times \mathbb{N} \to E$ put a new number at position

0 of ρ and move the others up, and $\mathrm{push}_{\mathbb{S}} : E \times \mathbb{S} \to E$ do the same for σ. The translation A°, a formula in context E, is

$$(t = u)^\circ = \big(\ulcorner t \urcorner = \ulcorner u \urcorner\big), \qquad (t \in X_j)^\circ = \in\big(\ulcorner X_j \urcorner \ulcorner t \urcorner\big), \qquad \bot^\circ = \bot,$$
$$(A \wedge B)^\circ = A^\circ \wedge B^\circ, \quad (A \vee B)^\circ = A^\circ \vee B^\circ, \quad (A \to B)^\circ = A^\circ \to B^\circ,$$
$$(\forall x\, A)^\circ = \forall_{\mathbb{N}}\, \mathrm{push}^*_{\mathbb{N}} A^\circ, \quad (\exists x\, A)^\circ = \exists_{\mathbb{N}}\, \mathrm{push}^*_{\mathbb{N}} A^\circ,$$
$$(\forall X\, A)^\circ = \forall_{\mathbb{S}}\, \mathrm{push}^*_{\mathbb{S}} A^\circ, \quad (\exists X\, A)^\circ = \exists_{\mathbb{S}}\, \mathrm{push}^*_{\mathbb{S}} A^\circ.$$

A list of hypotheses becomes the conjunction of its translations: $[\,]^\circ = \top$ and $(A, \Gamma)^\circ = A^\circ \wedge \Gamma^\circ$.

The translation is a construction on syntax. It asks nothing about the truth of any formula, and it contains no negative translation: HAS is already intuitionistic.

Theorem 16.11 (HAS compiles into the calculus)**.** *For every list Γ of formulas and every formula A of HAS, if HAS derives $\Gamma \vdash A$, then the calculus derives $\Gamma^\circ \vdash A^\circ$.*

The derivation is built from the HAS derivation, node by node. It uses no soundness and no truth: the only facts of ordinary mathematics it uses are equalities of maps, the substitution lemma for number terms, which make two terms of the calculus the same term. Two tools carry the bookkeeping.

Write $A \equiv B$ when the calculus derives both $A \vdash B$ and $B \vdash A$. This relation is an equivalence, and it is a congruence for $\wedge$, $\vee$, $\to$, the quantifiers and reindexing, by the introduction and elimination constructions (Appendix J.1). Rules 12–29, together with the derived rules for $\top$ and $\bot$, push a reindexing through every construction up to $\equiv$, and $g^* f^* A \equiv (f \circ g)^* A$.

The second tool says that reindexing a translation along two maps of environments that agree on what a formula reads gives equivalent formulas. Call the following *operations* on HAS formulas: substituting a number term s at number position k; lifting the number positions by d at cutoff c (Definition 5.2); and renaming the set positions by a map r of indices, which under a set binder fixes 0 and moves $j + 1$ to $r(j) + 1$. Each has a counterpart on environments: insert the value of s at position k of ρ; delete the d positions starting at c; replace σ by $j \mapsto \sigma(r(j))$. The substitution lemma for number terms, proved by induction on the term, says that evaluating $O(t)$ at ρ is evaluating t at the counterpart of ρ, for each operation O.

Lemma 16.12 (Coherence of reindexing and syntax)**.** *Let O be one of these operations and let $f, g : D \to E$ be maps of carriers such that, at both stages and at every object, the environment given by g is the counterpart of O applied to the environment given by f. Then $f^*(OA)^\circ \equiv g^* A^\circ$ for every formula A of HAS.*

Proof. By induction on A, for all operations O and all D, f and g at once, since under a binder the operation changes. For an equation, rule 18 turns $f^*(\ulcorner Ot \urcorner = \ulcorner Ou \urcorner)$ into the equation of the terms $\mathrm{map}(\ulcorner Ot \urcorner \circ f)$ and $\mathrm{map}(\ulcorner Ou \urcorner \circ f)$. By the substitution lemma, $\ulcorner Ot \urcorner \circ f$ and $\ulcorner t \urcorner \circ g$ are the same map, so these are literally the terms $\mathrm{map}(\ulcorner t \urcorner \circ g)$ and $\mathrm{map}(\ulcorner u \urcorner \circ g)$, and rule 19 gives $g^*(\ulcorner t \urcorner = \ulcorner u \urcorner)$. Both directions are these two rules in the other order. A membership is the same with rules 16 and 17, the set position read through the renaming. For $\bot$ use the derived rules for $\bot$; for $\wedge$, $\vee$ and $\to$ push f^* and g^* inside by rules 20–25 and apply the induction hypotheses with the congruence.

For a number quantifier, rules 26–29 and the composition rules give $f^*(\forall_{\mathbb{N}}\mathrm{push}_{\mathbb{N}}^*(O'A)^\circ) \equiv \forall_{\mathbb{N}}(\mathrm{push}_{\mathbb{N}} \circ (f \times \mathrm{id}))^*(O'A)^\circ$, where O' is O moved under the binder: substitute at $k+1$ the lifted s, or lift at cutoff $c+1$; a renaming of set positions is unchanged. The maps $\mathrm{push}_{\mathbb{N}} \circ (f \times \mathrm{id})$ and $\mathrm{push}_{\mathbb{N}} \circ (g \times \mathrm{id})$ satisfy the hypothesis for O': the new number sits at position 0 on both sides and the old positions move up by one on both sides. The induction hypothesis and the congruence give $\equiv \forall_{\mathbb{N}}(\mathrm{push}_{\mathbb{N}} \circ (g \times \mathrm{id}))^* A^\circ$, which is $\equiv g^*(\forall x\, A)^\circ$ by the same rules backwards. A set quantifier is the same with $\mathrm{push}_{\mathbb{S}}$: a number operation passes the binder unchanged, and a renaming passes it in the lifted form described above. The existential quantifiers are identical with rules 28 and 29. □

Four instances are used. With $f = \mathrm{id}$ and $g = \mathrm{push}_{\mathbb{N}} \circ \mathrm{gr}(\ulcorner t \urcorner)$, substitution at 0 gives

$$A(t)^\circ \equiv \mathrm{gr}(\ulcorner t \urcorner)^* \mathrm{push}_{\mathbb{N}}^* A^\circ, \tag{16.1}$$

after rules 12–15. With $f = \mathrm{push}_{\mathbb{N}}$ and $g = \pi_1$, the lifting by one at cutoff 0 gives $\mathrm{push}_{\mathbb{N}}^*(A\uparrow)^\circ \equiv \pi_1^* A^\circ$, and conjunct by conjunct the same for a list Γ. With $f = \mathrm{push}_{\mathbb{S}}$ and $g = \pi_1$, the renaming $j \mapsto j+1$ gives $\mathrm{push}_{\mathbb{S}}^*(A^+)^\circ \equiv \pi_1^* A^\circ$, where A^+ moves every free set position up by one. And the renaming that sends 0 to j and $k+1$ to k, with $f = \mathrm{id}$ and $g = \mathrm{push}_{\mathbb{S}} \circ \mathrm{gr}(\ulcorner X_j \urcorner)$, gives the instance of a set variable, $A(X_j)^\circ \equiv \mathrm{gr}(\ulcorner X_j \urcorner)^* \mathrm{push}_{\mathbb{S}}^* A^\circ$.

Proof of Theorem 16.11. By induction on the HAS derivation. We give the cases that carry the argument; the others are in Appendix J.2.

Hypotheses. If A occurs in Γ, then A° is a conjunct of Γ°, reached by conjunction eliminations and cuts.

Implication introduction. The HAS premise is $A, \Gamma \vdash B$, so the induction hypothesis derives $A^\circ \wedge \Gamma^\circ \vdash B^\circ$, while construction (12) wants $\Gamma^\circ \wedge A^\circ \vdash B^\circ$. Cut with the derivation of $\Gamma^\circ \wedge A^\circ \vdash A^\circ \wedge \Gamma^\circ$ by the conjunction rules, then apply (12). Disjunction elimination is repaired in the same way.

Universal introduction. The premise is $\Gamma\uparrow \vdash A$, whose translation is derived. Reindexing along $\mathrm{push}_{\mathbb{N}}$ gives $\mathrm{push}_{\mathbb{N}}^*(\Gamma\uparrow)^\circ \vdash \mathrm{push}_{\mathbb{N}}^* A^\circ$, and the second instance above replaces the left side by $\pi_1^*\Gamma^\circ$. Construction (14) gives $\Gamma^\circ \vdash \forall_{\mathbb{N}}\mathrm{push}_{\mathbb{N}}^* A^\circ$, which is $\Gamma^\circ \vdash (\forall x\, A)^\circ$.

Universal elimination at a term t. Construction (15) with the term $\ulcorner t \urcorner$ gives

$$\Gamma^\circ \vdash \mathrm{gr}(\ulcorner t \urcorner)^* \mathrm{push}_{\mathbb{N}}^* A^\circ,$$

and (16.1) turns it into $\Gamma^\circ \vdash A(t)^\circ$.

Substitution of equals. The premises translate to $\Gamma^\circ \vdash \ulcorner t \urcorner = \ulcorner s \urcorner$ and $\Gamma^\circ \vdash A(t)^\circ$. By (16.1) the second is $\Gamma^\circ \vdash \mathrm{gr}(\ulcorner t \urcorner)^* \mathrm{push}_{\mathbb{N}}^* A^\circ$; construction (20) with the formula $\mathrm{push}_{\mathbb{N}}^* A^\circ$ gives the same with s, and (16.1) again gives $\Gamma^\circ \vdash A(s)^\circ$.

The six arithmetic axioms. The translation of $S(t)$ is the term $S(\ulcorner t \urcorner)$, of $t + s$ the term $\ulcorner t \urcorner + \ulcorner s \urcorner$, and so on, as maps. So each axiom translates to an instance of rules 1–6.

The induction axiom $\forall X(0 \in X \to \forall x(x \in X \to S(x) \in X) \to \forall x(x \in X))$. Let B be the atom "the newest number belongs to the newest set" in context $E \times \mathbb{S} \times \mathbb{N}$. By the coherence lemma at the atoms, the three parts of the matrix translate, up to $\equiv$, into $\mathrm{gr}(0)^* B$, $\forall_{\mathbb{N}}(B \to \mathrm{succ}^* B)$

and $\forall_{\mathbb{N}} B$. Rule 7 at B gives $\mathrm{Ind}(B) \vdash \forall_{\mathbb{N}} B$, and two conjunction steps and two implication introductions turn it into $P \vdash \mathrm{gr}(0)^* B \to \forall_{\mathbb{N}}(B \to \mathrm{succ}^* B) \to \forall_{\mathbb{N}} B$, for every hypothesis P; construction (14) over $\mathbb{S}$ and the equivalences just named finish the case.

Comprehension $\exists X \forall x (x \in X \leftrightarrow A^+)$, where A^+ is A with its set positions moved up so that X does not occur in it. The outer quantifier is a quantifier over $\mathbb{S} = \Omega^{\mathbb{N}}$, the classifier quantifier of Comp with $X = \mathbb{N}$. Under the two binders, $(x \in X)^\circ$ is the atom Mem, because the two maps that read the classifier at the number are equal; and $(A^+)^\circ$ is $\equiv \mathrm{fg}^* \mathrm{push}^*_{\mathbb{N}} A^\circ$, by the coherence lemma for the shift of set positions composed with forgetting the classifier. So the translation is $\equiv \mathrm{Comp}(\mathrm{push}^*_{\mathbb{N}} A^\circ)$, an instance of rule 8. □

Remark 16.13 (Arithmetic proofs inside the calculus)**.** Lemma 7.16 makes every posit-free derivation of Chapter 6, with induction on every formula, a derivation in HAS of the same judgment, and Theorem 16.11 then compiles it into the calculus. So every theorem of Heyting arithmetic, read as above, is derivable in the calculus. For a theorem φ of Peano arithmetic, Theorem 20.39(1) gives a closed term of type $\mathrm{Ty}(\varphi^N)$, and Theorems 20.36 and 20.32 turn it into a posit-free derivation of the negative translation φ^N, exactly as in the proof of the second part of Theorem 20.39; the two steps above then make $(\varphi^N)^\circ$ derivable in the calculus. Each composition is immediate from the results cited.

Composed with Theorem 16.8, the compiler shows that the translation of every theorem of HAS holds at both stages. The main use of the compiler is the other direction: the calculus contains HAS, so whatever the calculus fails to derive, HAS fails to derive in translation.

16.6 The full calculus has no recursive model

The separations of Chapter 12 were proved in a model whose sequences are the computable ones. The same cannot be done for the calculus as it stands, because its terms include every map, and some maps are not computed by any program. One such map, placed in one instance of the rule of computation, already rules out every reading of the right kind.

Let $r : \mathbb{N} \to \mathbb{N}$ be the function with $r(i) = 1$ when program i halts on input 0 and $r(i) = 0$ otherwise. It is defined in ordinary mathematics by a case distinction; no program computes it [21]. The map $((), n) \mapsto r(n)$ from $\mathbf{1} \times \mathbb{N}$ to $\mathbb{N}$ is a map of constant carriers, so

$$h_r = \lambda\, \mathrm{map}\big(((), n) \mapsto r(n)\big)$$

is a closed term of type $\mathbb{N}^{\mathbb{N}}$. For each n let $\bar{n}$ be the closed term $\mathrm{map}(() \mapsto n)$, the numeral. Rule 11 at $\bar{n}$ derives

$$h_r\, \bar{n} = \mathrm{map}\big(() \mapsto r(n)\big),$$

and the right side is the numeral $\overline{r(n)}$: the two terms carry the same map, so they are the same term.

Theorem 16.14 (No recursive reading of the full calculus)**.** *There is no pair of assignments V, giving a natural number $V(t)$ to every closed term t of type $\mathbb{N}$, and J, giving a computable function $J(t) : \mathbb{N} \to \mathbb{N}$ to every closed term t of type $\mathbb{N}^{\mathbb{N}}$, such that*

(1) $V(\bar{n}) = n$ for every numeral;

(2) $V(t\,\bar{n}) = J(t)(n)$ for every closed t of type $\mathbb{N}^{\mathbb{N}}$ and every n;

(3) V gives the two sides of every closed instance of rule 11 of type $\mathbb{N}$ the same value.

The proof reasons in a classical metatheory.

Proof. Suppose V and J exist. For every n, by (2), (3) at the instance above, and (1),

$$J(h_r)(n) = V(h_r\,\bar{n}) = V\big(\overline{r(n)}\big) = r(n).$$

So r is the computable function $J(h_r)$. Then program i halts on input 0 exactly when the computable function $J(h_r)$ is 1 at i, which would decide the halting problem [21]. This is impossible. □

The same freedom of terms makes the full calculus derive every true statement of a common kind. Call a formula *equational over constant carriers* when it contains no atom, every equation in it compares two terms whose carrier is constant, and every quantifier in it ranges over a constant carrier. Numbers, sequences of numbers, binary strings, bits, binary sequences, decidable sets of strings, points of the line, functions on the line, ratio covers, presented sets and presented maps all live on constant carriers; truth values and sets of points do not.

Proposition 16.15 (The full calculus derives every true equational sentence)**.** *Reason in a classical metatheory. Let A be a formula of the calculus in a context G that is equational over constant carriers, and suppose that $g \Vdash_1 A$ for every later object $g \in G_1$. Then the calculus derives $P \vdash A$ for every formula P in context G. In particular it derives, from $\top$, the sentences LPO, $\mathsf{WLPO_{seq}}$, SPD and $\mathsf{AR} = \mathsf{SPD} \to \mathsf{WLPO_{seq}}$ of Section 16.8, the seven compactness sentences $\mathsf{FAN}_\Delta^=$, $\mathsf{FAN}_c^=$, $\mathsf{WKL}^=$, $\mathsf{HB}^=$, $\mathsf{PLB}^=$, $\mathsf{PINF}^=$ and $\mathsf{HC}^=$ of Section 16.10, and the implication from each of $\mathsf{HB}^=$, $\mathsf{PLB}^=$, $\mathsf{PINF}^=$ and $\mathsf{HC}^=$ to $\mathsf{FAN}_\Delta^=$, all with their presentations erased.*

Proof. The derivation is built in Appendix J.3; here is its plan. The *indicator* of a formula A in context G is the map $\chi_A : G \to \mathbb{N}$ whose later component sends g to 1 when $g \Vdash_1 A$ and to 0 otherwise, and whose earlier component is the later one composed with the passage. It is defined by a case distinction in the metatheory, and it is a map of carriers because the passage of $\mathbb{N}$ is the identity. Write 1 for the term $S(0)$. By induction on A, the calculus derives $\chi_A = 1 \vdash A$ and $A \vdash \chi_A = 1$ for every formula equational over constant carriers. Five facts carry the induction:

(i) two terms of a constant carrier with the same later values carry the same map, so their equation is derivable from any hypothesis (Remark 16.7);

(ii) substitution of equals, construction (20), turns a derived equation $a = b$ and a true identity between two maps evaluated at a into the same identity evaluated at b;

(iii) rule 1 refutes an equation between two terms whose values are 0 and 1;

(iv) rule 7 derives $\forall_{\mathbb{N}} x\big(x = 0 \vee \exists_{\mathbb{N}} y(x = S(y))\big)$, which splits an indicator into the cases 0 and 1;

(v) at a quantifier over a constant carrier X, a witness or a counterexample chosen in the metatheory for each later object of the context is a map into X, and so a term.

If A holds at every later object, then χ_A and 1 have the same later values, so $P \vdash \chi_A = 1$ is derivable by (i), and a cut with $\chi_A = 1 \vdash A$ gives $P \vdash A$.

The sentences named are equational over constant carriers, as their definitions show, and each holds at the later stage of the one-point context, where after erasure every quantifier ranges over all objects of ordinary mathematics. LPO is excluded middle applied to each sequence. $\mathsf{WLPO}_{\mathsf{seq}}$ holds because the function that marks the vanishing rows is now in the range of its sequence quantifier. SPD holds because excluded middle decides whether $a = 0$, and a point $a \neq 0$ has an inverse (Lemma F.11, with the stage N found as in the proof of Theorem 16.27); AR then holds because its conclusion does. The later readings of the compactness sentences are the statements of Chapter 13 for all presented sets, covers and maps (Section 16.10). In the metatheory the full fan theorem holds by König's lemma. Proposition 13.4 gives FAN_c and FAN_Δ from it, Theorem 12.72 gives weak König's lemma from LLPO and countable choice, Theorems 13.25 and 13.28 and Corollary 13.30 give Heine–Borel, the positive lower bound and the positive infimum from FAN_Δ, and Theorem 13.32 gives Heine–Cantor for presented sets from the full fan theorem. An implication with a true conclusion is true. □

So in the full calculus, for sentences of this kind, "A derives B" says only that $A \to B$ is true in ordinary classical mathematics: a derivation of $A \vdash B$ makes $A \to B$ true at the later stage by Theorem 16.8, and conversely the proposition supplies one. LPO derives $\mathsf{WLPO}_{\mathsf{seq}}$ and every compactness sentence of Section 16.10 there, because all of them are classically true. The question of the chapter's opening therefore has its answer in the computable calculus.

The obstruction to a recursive reading is not a missing rule but a term that is present. Two facts show exactly where it lies.

Remark 16.16 (What a recursive reading can and cannot keep)**.** A closed term of type $\mathbb{N}^{\mathbb{N}}$ agrees with some computable function exactly when the function it carries is computable. And rule 11 has a recursive reading at every computable body: if $t : \mathbf{1}\times\mathbb{N} \vdash \mathbb{N}$ carries a computable function, one computable function gives the values of the right sides $\mathrm{map}([\![t]\!] \circ \mathrm{gr}(\bar{n}))$ of all its instances at numerals. A second obstruction comes from the existential rule. For every closed term t of type $\mathbb{N}^{\mathbb{N}}$ the calculus derives $\exists_{\mathbb{N}^{\mathbb{N}}}(\mathrm{map}(\pi_2) = \mathrm{map}([\![t]\!] \circ \pi_1))$, by existential introduction at t, reflexivity and rule 19. A reading in which this quantifier ranges over computable sequences and equality means equality would make the sequence of t computable, and $t = \mathrm{map}(() \mapsto r)$ is a closed sequence term whose sequence is not.

So a model in which functions are computable must restrict the terms. The next section does this by a property of each term, not by a list of forbidden ones.

16.7 The computable calculus and its model

The restriction keeps the carriers, the readings, the twenty constructions and the twenty-nine rules, and asks one more thing of each term and each map: that a program compute it on names.

Definition 16.17 (Names and tracked maps)**.** A *presentation* of a carrier X is a relation "e names x" between natural numbers e and later objects $x \in X_1$; a later object is *named* when some number names it. Only the later stage carries names. We use the following presentations, with $\{e\}(a)$ the output of program e on input a and $(e)_0, (e)_1$ the components of the pair numbered e, as in the proof of Theorem 12.22.

- On $\mathbb{N}$, e names n when $e = n$. On binary strings, bits and ratio records, e names an object when e is its standard code.
- On Ω and on $\mathbf{1}$, every number names every object.
- On $X \times Y$, e names (x, y) when $(e)_0$ names x and $(e)_1$ names y.
- On Y^X, e names a function $f : X_1 \to Y_1$ when, for every name a of every $x \in X_1$, the run $\{e\}(a)$ halts with a name of $f(x)$.
- On $\mathscr{R}$, e names a regular sequence s when $\{e\}(n)$ halts with the code of the ratio record s_n for every n. On $\mathscr{L}$, e names a point when it names a regular sequence of which the point is the class.

A map $f : X \to Y$ of presented carriers is *tracked* when one program c sends every name of every later object to a name of its image: for every $x \in X_1$ and every name a of x, $\{c\}(a)$ halts with a name of $f_1(x)$.

Every presentation of a truth value carries no information about it: the number 0 names both the true and the false proposition. This is deliberate. A name of a classifier is then a program that halts on every name of its argument, and nothing more.

The identity, composition, projections, pairing, evaluation, currying, the arithmetic operations of $\mathbb{N}$, constant maps with a named value, the quotient map $\mathscr{R} \to \mathscr{L}$ and every map into Ω are tracked: evaluation by a universal program, currying by computing a program for a function of the second argument from the first, and a map into Ω by the program that returns 0 (Appendix J.4).

Definition 16.18 (The computable calculus)**.** Its contexts and quantifier domains are presented carriers, with products presented by pairs. Its terms are the terms of Definition 16.3 whose readings are tracked, and its reindexing maps are tracked maps. Its formulas are built by the ten constructions of Definition 16.4 from these terms and maps, with every predicate allowed as an atom. Its derivations are built by the twenty constructions of Definition 16.6 from the twenty-nine base rules of Table 16.2, with tracked terms and maps as their parameters; in rule 11, the map $[\![t]\!] \circ \mathrm{gr}(u)$ is tracked by composing the trackers of t and u. *Erasing* the presentations and the trackers sends each formula and each derivation of the computable calculus to a formula and a derivation of the calculus.

The atoms are not restricted, and every rule is kept. What changes is that a term must come with a program. The term h_r of the previous section is not a term of the computable calculus (Proposition 16.21(d)).

Remark 16.19 (Atoms that no rule governs)**.** Only three kinds of base rule act on atoms: rule 8, through the membership predicate $\in$ on Ω; rule 10, through the predicate $\approx$ on $\mathscr{R} \times \mathscr{R}$; and the reindexing rules 16 and 17, which move any atom along a map. An atom of a predicate other than $\in$ and $\approx$ is therefore governed by no rule. Choose, for some of these predicates R, a formula φ_R in the context X of R, and replace every atom $R(t)$ by the reindexing $[\![t]\!]^*\varphi_R$. This replacement maps derivations of the computable calculus to derivations: the constructions and the other rules are schematic in formulas, and an instance of rule 16 or 17 becomes an instance of the composition rules 14 and 15. Take $\varphi_R = \bot$ for every predicate R, other than $\in$ and $\approx$, that holds at every later object. A derivation of $\top \vdash R(t)$ for such a predicate would become a derivation of $\top \vdash [\![t]\!]^*\bot$, which Theorem 16.22 below excludes. So even the closed atom of the true relation $0 \leq 0$ is not derivable from $\top$. Sentences whose content rests on such relations, such as the order of the numbers or of the line, the length of a string or membership in a presented set, are therefore written with equations between terms of tracked maps (Section 16.10). The sentences of Section 16.8 already contain no atom.

Definition 16.20 (The model of named objects)**.** For a formula A of the computable calculus in context G and a later object $g \in G_1$, define $g \Vdash A$ by recursion on A:

- $g \Vdash R(t)$ when $[\![t]\!]_1(g) \in R_1$, and $g \Vdash t = u$ when $[\![t]\!]_1(g) = [\![u]\!]_1(g)$;
- $\top$, $\bot$, $\wedge$, $\vee$ and $\to$ are read classically;
- $g \Vdash \forall_X A$ when $(g, x) \Vdash A$ for every *named* $x \in X_1$, and $g \Vdash \exists_X A$ when $(g, x) \Vdash A$ for some named $x \in X_1$;
- $g \Vdash f^*A$ when $f_1(g) \Vdash A$.

P entails Q in the model when every named $g \in G_1$ with $g \Vdash P$ has $g \Vdash Q$.

This is a Tarskian model in the spirit of Henkin's general models of higher types [52]: truth is classical, and the quantifiers at each type range over a chosen part of the domain, here the named objects. In it, sequences of numbers range over the computable functions and points of the line over the points with computable names, as in the model of Theorem 12.63; truth values range over all propositions and sets of points over all sets of points, since every one of them is named.

The countermodels below assemble standard ingredients of recursive analysis. On the constant carriers of numbers, sequences, strings and decidable sets, the model of named objects is the ω-model REC of the computable sets, read with classical logic, and that weak König's lemma fails there is standard [76, Chapter VIII]. The dead cover of Section 16.10 covers the computable points of $[0, 1]$ by rational intervals with no finite subcover, as the singular coverings of Zaslavskiĭ and Ceĭtin do [77], and the tent function of that section, continuous at the computable points of $[0, 1]$ and not uniformly continuous there, is the corresponding example for Heine–Cantor in recursive constructive mathematics [40, Chapter 3].

Proposition 16.21 (The named objects)**.** *In the presentations of Definition 16.17:*

(a) a function $f : \mathbb{N} \to \mathbb{N}$ is named in $\mathbb{N}^{\mathbb{N}}$ exactly when it is computable, and the same holds for binary sequences and for maps from binary strings to bits;

(b) a point of $\mathscr{L}$ is named exactly when it is the class of a regular sequence whose entries are computed by a program; in particular the point $\eta(q)$ of every ratio record q is named;

(c) every tracked map from Ω to $\mathbb{N}$ takes the same value at every proposition;

(d) the map $((), n) \mapsto r(n)$ of Section 16.6 is not tracked.

Proof. (a) If e names f, then $\{e\}(n)$ halts with $f(n)$ for every n, so a program computes f; conversely a program for f names f, since the name of a number is the number. For strings and bits compose with the computable coding. (b) is the definition; the constant sequence of q is computed by a program that ignores its input. (c) Let c track $f : \Omega \to \mathbb{N}$. The number 0 names every proposition p, so $\{c\}(0)$ halts with a name of $f_1(p)$, which is $f_1(p)$ itself; the run has one output, so $f_1(p) = \{c\}(0)$ for every p. (d) A tracker c would send the name of $((), n)$ with components 0 and n to $r(n)$, so r would be computable. □

Theorem 16.22 (Soundness of the computable calculus)**.** *If the computable calculus derives $P \vdash Q$, then P entails Q in the model of named objects.*

Proof. Two facts about names are used. (N1) If g is named and t is a term of the computable calculus, then $[\![t]\!]_1(g)$ is named: run the tracker on a name of g; the same holds for tracked maps. (N2) A pair (g, x) is named exactly when g and x are, by pairing and unpairing names.

The twenty constructions are handled as in Step 1 of the proof of Theorem 16.8, at the later stage only, with the following changes. Universal introduction uses (N2): if g is named and x is named, then (g, x) is named and satisfies $\pi^* P$, so it satisfies A. Universal elimination and existential introduction use the object $[\![t]\!]_1(g)$, which is named by (N1). Existential elimination uses (N2), and reindexing uses (N1) for the map. Since implication is read at one stage, persistence is not needed.

For the base rules: rules 1–6 are arithmetic truths. For rule 7, every number is named, so a quantifier over named numbers is a quantifier over all numbers, and the rule is ordinary induction. For rule 8, the property $x \mapsto \big((g, x) \Vdash A\big)$ is a later object of Ω^X, and it is named, by any program that halts with 0 on every input, because 0 names every proposition; with it as the classifier, both implications of $\mathrm{Comp}(A)$ are identities. For rule 9, a name of a point names a regular sequence whose class is that point, and that sequence is named. Rules 10, 11 and 12–29 are identities at the later stage, as in Theorem 16.8. □

Corollary 16.23 (The computable calculus is consistent)**.** *The computable calculus does not derive $\top \vdash \bot$ in the one-point context.*

Proof. The point of $\mathbf{1}$ is named and satisfies $\top$, and nothing satisfies $\bot$. □

Theorem 16.22 is the tool for every separation below. To show that a sentence B is not derivable from a sentence A, it is enough to find that A is true and B false at the point of **1**. Implication introduction and elimination show that $A \vdash B$ is derivable exactly when $\top \vdash A \to B$ is, so the two forms of a separation stand or fall together (Question 3); and a derivation of $\top \vdash B$ gives one of $A \vdash B$ by a cut with $A \vdash \top$. Each separation below is stated in all three forms, $\top \vdash B$, $\mathsf{LPO} \vdash B$ and $\top \vdash \mathsf{LPO} \to B$.

The connectives of this model are read classically. So $A \vee \neg A$ is true at every point for every formula A, and every omniscience principle stated for one sequence at a time, such as the sentence LPO of Section 16.8, is true. The decision is made for each instance separately, by the classical mathematics in which the model is described, and no program makes it. A principle that asks for infinitely many decisions collected into one sequence, such as $\mathsf{WLPO}_{\mathsf{seq}}$, can be false there (Theorem 16.27). The separations below therefore do not come from a missing decision. They come from the quantifiers: a sequence, a path or a point exists in the model only if a program names it. Comprehension always produces a classifier on $\mathbb{N}$, but no tracked map reads a number off a classifier: composed with the tracked map $p \mapsto (n \mapsto p)$ from Ω to $\Omega^{\mathbb{N}}$, a tracked map from $\Omega^{\mathbb{N}}$ to $\mathbb{N}$ becomes a tracked map from Ω to $\mathbb{N}$, which takes one value at every proposition by Proposition 16.21(c); so it takes the same value at the empty classifier and at the full one (Question 4).

Remark 16.24 (Excluded middle as a base rule)**.** Every instance $A \vee \neg A$ is true at every point of the model of named objects, because the model reads the connectives classically. So Theorem 16.22 holds for the computable calculus with every judgment $P \vdash A \vee \neg A$, in every context and for all formulas P and A, added as a base rule: the proof needs one more case, and this observation is that case. Every separation below therefore holds in that extension too. A sentence that is false in the model is not derivable there from $\top$, nor from LPO, nor in the form $\top \vdash \mathsf{LPO} \to B$. In the computable calculus itself, the same argument shows that such a sentence is not derivable from LPO together with any finite list of universal closures $\forall_{X_1} \cdots \forall_{X_k}(A \vee \neg A)$ of instances of excluded middle.

Theorem 16.25 (HAS compiles into the computable calculus)**.** *Present the environment carrier E of Definition 16.10 as a product of exponentials; its named environments are those with a computable number valuation, and every set valuation. Then all the terms and maps of the translation are tracked, and every derivation of $\Gamma \vdash A$ in HAS gives a derivation of $\Gamma^\circ \vdash A^\circ$ in the computable calculus. Erasing it gives a derivation, in the calculus, of the translated judgment of Theorem 16.11.*

Proof. The construction is that of the proof of Theorem 16.11, with the same cases and the same coherence lemma; the reindexing maps it uses are $\mathrm{push}_{\mathbb{N}}$, $\mathrm{push}_{\mathbb{S}}$, the successor, projections, graphs of the terms $\ulcorner t \urcorner$ and $\ulcorner X_j \urcorner$, and the maps that forget a classifier. Each is tracked: evaluating a number term at a valuation named by a program is computed from that program, and putting a new entry in front of a valuation is computed from the programs of the entry and of the valuation (Appendix J.4). A set valuation is named by any program that halts on every input with the number of a program that halts on every input, because every number names every truth value. Erasing the presentations sends A° to the translation of Definition 16.10, formula by formula. □

For a translated HAS formula, the model of named objects reads every set variable as an arbitrary set of numbers and every number variable as a number; so it gives each HAS formula its ordinary classical truth, and every principle of Definition 7.18, excluded middle included, is true there. So the model separates none of these principles from one another inside HAS. Its separations concern sentences with quantifiers over sequences, paths, trees and points, which lie outside the image of the translation.

Proposition 16.26 (The model is not a realizability model)**.** *Read the formulas of the computable calculus by Kleene's realizability [50] over the same presentations: e realizes $A \wedge B$ when $(e)_0$ realizes A and $(e)_1$ realizes B; $A \vee B$ when $(e)_0 = 0$ and $(e)_1$ realizes A, or $(e)_0 \neq 0$ and $(e)_1$ realizes B; $A \to B$ when $\{e\}(a)$ halts with a realizer of B for every realizer a of A; $\forall_X A$ at g when $\{e\}(a)$ halts with a realizer of A at (g, x) for every name a of every $x \in X_1$; $\exists_X A$ when $(e)_0$ names some x and $(e)_1$ realizes A at (g, x); f^*A at g when e realizes A at $f_1(g)$; $\top$ always and $\bot$ never; and an atom or an equation by evidence, given by a relation* $\mathrm{Ev}(p, e)$ *between truth values and numbers that is* sound, $\mathrm{Ev}(p, e)$ *implying p, and has evidence for the true proposition. Let θ be the formula $\in(\mathrm{map}(\pi_2)) \vee \neg\in(\mathrm{map}(\pi_2))$ in context $\mathbf{1} \times \Omega$, which says $p \vee \neg p$ of the newest truth value p. Then no number realizes the instance* $\mathrm{Comp}(\theta)$ *of rule 8, whatever the evidence relation, while* $\mathrm{Comp}(\theta)$ *is true in the model of named objects.*

Proof. The second statement is Theorem 16.22 applied to the rule. For the first, first look at θ itself, and call $(e)_0$ the *tag* of a number e. At p true, a realizer of θ must have tag 0: a tag $\neq 0$ would need a realizer of $\neg p$, which would turn evidence for the true proposition into a realizer of $\bot$. At p false, a realizer must have tag $\neq 0$, since tag 0 needs evidence for a false proposition, and soundness excludes it. So no number realizes θ at both values. Both values have tag-correct realizers: the number of the pair $(0, a)$, with a evidence for truth, and the number of the pair $(1, 0)$.

Now suppose e realizes $\mathrm{Comp}(\theta)$. Then $(e)_0$ names a classifier χ on Ω, and $d = (e)_1$ realizes $\forall_\Omega\big((\mathrm{Mem} \to \theta) \wedge (\theta \to \mathrm{Mem})\big)$ at χ. The number 0 names both truth values, so the one run $\{d\}(0)$ yields one number b that realizes the matrix at p true and at p false. Its second component turns the realizers of θ just described into evidence for $\chi(\mathrm{true})$ and for $\chi(\mathrm{false})$; by soundness both propositions hold, so both are the true proposition, and the evidence a for truth is evidence for each. Its first component then sends this one number a, in one run, to one number that realizes θ at p true and at p false. That is impossible. □

The model of named objects decides each instance of a disjunction on its own, which is why it validates the instance; a realizer must make the decision uniformly in the names, and over a presentation in which a name says nothing about a truth value it cannot. Kleene's reading in the proof of Theorem 12.22 was defined for arithmetic with sequences, whose atoms are decided equations. Over these presentations it does not extend to the computable calculus: one instance of rule 8 has no realizer.

16.8 LPO decides each row but cannot collect the rows

Scalar pair division says that for every two points a and b of the line, either both are 0, or $a \neq 0$ and b is a multiple ac of a, or $b \neq 0$ and a is a multiple bc of b; here $x \neq 0$ means $\neg(x = 0)$. Chapter 14 shows that it is equivalent to basis selection and to rank–nullity

(Theorems 14.13 and 14.14), that it implies WLPO (Theorem 14.16), and that it follows from $\mathrm{WLPO}_{\mathrm{seq}}$ (Proposition 14.17): for every binary double sequence there is a binary sequence that records, for every row, whether the row vanishes. Does scalar pair division give back $\mathrm{WLPO}_{\mathrm{seq}}$? With unique choice it does, since WLPO with unique choice gives $\mathrm{WLPO}_{\mathrm{seq}}$ (Corollary 13.10, item 3). Without it the question is about collection: scalar pair division settles one pair of points at a time, while $\mathrm{WLPO}_{\mathrm{seq}}$ asks for one sequence that settles infinitely many rows at once. We answer it in the computable calculus, even with LPO added and with excluded middle as a base rule.

Let Seq be $\mathbb{N}^{\mathbb{N}}$ with its presentation, so that its named objects are the computable functions, and write αn for the application of a sequence term to a number term. Let $\mathrm{Bin}(\alpha)$ be $\forall_{\mathbb{N}}(\alpha n = 0 \vee \alpha n = 1)$, and write $\langle i, n\rangle = (i+n)\cdot(i+n)+n$, the pairing of the proof of Theorem 12.22, a term built from $+$ and $\cdot$. The following are closed sentences of the computable calculus:

$$
\begin{aligned}
\mathsf{LPO} &:= \forall_{\mathsf{Seq}}\alpha\big(\mathrm{Bin}(\alpha) \to \forall_{\mathbb{N}} n\,(\alpha n = 0) \vee \exists_{\mathbb{N}} n\,(\alpha n = 1)\big),\\
\mathsf{WLPO}_{\mathsf{seq}} &:= \forall_{\mathsf{Seq}} A\,\Big(\mathrm{Bin}(A) \to \exists_{\mathsf{Seq}} f\big(\mathrm{Bin}(f) \wedge \forall_{\mathbb{N}} i\,(fi = 0 \leftrightarrow \forall_{\mathbb{N}} n\, A\langle i, n\rangle = 0)\big)\Big),\\
\mathsf{SPD} &:= \forall_{\mathscr{L}} a\,\forall_{\mathscr{L}} b\,\Big((a = 0 \wedge b = 0) \vee \big(\neg(a = 0) \wedge \exists_{\mathscr{L}} c\,(a\cdot c = b)\big)\\
&\qquad\qquad \vee \big(\neg(b = 0) \wedge \exists_{\mathscr{L}} c\,(b\cdot c = a)\big)\Big),\\
\mathsf{AR} &:= \mathsf{SPD} \to \mathsf{WLPO}_{\mathsf{seq}}.
\end{aligned}
$$

The point 0 and multiplication on the line are tracked maps (Appendix J.4). The second sentence is $\mathrm{WLPO}_{\mathrm{seq}}$ of Definition 13.8 with the two bits of f exchanged: here $f(i) = 0$ marks a vanishing row. All four sentences are built from application, arithmetic, equations and the connectives. No atom of them asserts a principle.

Theorem 16.27 (LPO does not collect)**.** *In the computable calculus none of the following is derivable:* $\top \vdash \mathsf{WLPO}_{\mathsf{seq}}$*;* $\mathsf{LPO} \vdash \mathsf{WLPO}_{\mathsf{seq}}$*;* $\top \vdash \mathsf{LPO} \to \mathsf{WLPO}_{\mathsf{seq}}$*;* $\top \vdash \mathsf{AR}$*;* $\mathsf{LPO} \vdash \mathsf{AR}$*;* $\top \vdash \mathsf{LPO} \to \mathsf{AR}$*. The same holds when every instance of excluded middle is added as a base rule. The proof reasons in a classical metatheory.*

Proof. By Theorem 16.22, and by Remark 16.24 when excluded middle is added, it is enough to evaluate the sentences at the point of **1** in the model of named objects; Lemma J.2 unfolds each of them there.

LPO *is true.* Its sequences range over the computable functions (Proposition 16.21(a)). For a binary α, either some $\alpha(n)$ is 1, or none is, and then every $\alpha(n)$ is 0. This is excluded middle for the statement "some $\alpha(n)$ is 1", applied in the metatheory to each α separately; no program decides it uniformly in α.

$\mathsf{WLPO}_{\mathsf{seq}}$ *is false.* By Proposition 16.21(a), the sentence is true exactly when every computable binary A has a computable binary f with $f(i) = 0$ exactly when $A\langle i, n\rangle = 0$ for every n. Let $A\langle i, n\rangle$ be 1 when program i halts on input 0 within n steps, and let A be 0 at the numbers that are not values of the pairing. This is the bounded-halting function h of the proof of Theorem 12.22, read through the pairing: A is computable, since n steps of a run can be simulated and the pairing is inverted by a bounded search. Row i vanishes exactly when

program i never halts on input 0. A computable f as required would decide, for every i, whether program i halts on input 0, which no program does [21].

SPD *is true.* Let a and b be named points. If $a = 0$ and $b = 0$, the first alternative holds. Suppose $a \neq 0$; whether $a = 0$ is decided here by excluded middle in the metatheory. Let s be a regular sequence named by a program, of which a is the class. Some stage N has $|s_N| > 2/(N+1)$: otherwise every stage satisfies $|s_n| \leq 2/(n+1)$ and $a = \eta(0)$ by Lemma 12.15. This existence is again classical. For this N, Lemma F.11 gives the regular sequence $n \mapsto 1/s_{4(N+1)^2(n+1)-1}$, whose point y has $ay = \eta(1)$. A program computes it from the program of s, with N fixed, so y is named. Multiplication is tracked, so $c = y \cdot b$ is named, and $a \cdot c = b$: the second alternative holds. If $a = 0$ and $b \neq 0$, the third alternative holds in the same way. The stage N depends on a, so the inverse is named for each a separately; no program computes it from a name of a.

Conclusion. LPO is true and $\mathsf{WLPO}_{\mathsf{seq}}$ false, so no derivation of $\top \vdash \mathsf{WLPO}_{\mathsf{seq}}$ or of $\mathsf{LPO} \vdash \mathsf{WLPO}_{\mathsf{seq}}$ exists, nor of $\top \vdash \mathsf{LPO} \to \mathsf{WLPO}_{\mathsf{seq}}$, whose conclusion is false at the point. Since SPD is true and $\mathsf{WLPO}_{\mathsf{seq}}$ false, AR is false, and the same argument excludes the last three judgments. □

Proposition 16.28 (The sentence asks the reversal question)**.** *Erase the presentations of* AR*. The resulting sentence of the calculus has, at each of the two stages, the reading: scalar pair division for all points of* $\mathbb{R}_\delta$ *implies* $\mathrm{WLPO}_{\mathrm{seq}}$ *for all binary double sequences.*

Proof. After erasure every quantifier ranges over a constant carrier, so the earlier and the later halves of each clause of Table 16.1 say the same thing, and unfolding the clauses gives the statement. □

So the computable calculus does not derive, even from LPO and with excluded middle as a base rule, the implication from scalar pair division to $\mathrm{WLPO}_{\mathrm{seq}}$; in particular it does not derive that implication outright. In the full calculus the same sentences are derivable outright (Proposition 16.15), so the separation is a fact about computed terms. What fails is collection. In the model, LPO is true and settles each row: for every i there is exactly one bit that records whether row i vanishes. What the model lacks is a computable function with these values, and the calculus has no rule that produces a number function from such a relation. Its comprehension rule produces classifiers, and no tracked map reads a number off a classifier (Proposition 16.21(c), composed with the tracked map $p \mapsto (n \mapsto p)$ from Ω to $\Omega^{\mathbb{N}}$, as in Question 4). Scalar pair division is true in the model for the same reason that LPO is: it is settled pair by pair, without a program.

The result is the dual of Theorem 12.22. There, countable choice collects witnesses and decides nothing. Here, omniscience decides and collects nothing.

16.9 Kleene's tree

The compactness statements fail in the model for one reason, found by Kleene [51, 4]: there is a computable infinite binary tree with no computable path. The proof of Theorem 13.11 uses the same tree to show that excluded middle does not give the fan theorem; we collect its properties in one lemma. We use the trees and paths of Definition 12.71.

Say that program e *has halted by n with output o* when its run on input 0 halts within n steps with output o. *Kleene's tree* T_K consists of the binary strings l such that, for every $e < |l|$ that has halted by $|l|$ with some output o, the digit l_e is 1 if $o = 0$ and 0 if $o \neq 0$. A digit is constrained once its program has halted, and the constraint contradicts the output.

Lemma 16.29 (Kleene's tree)**.**

(a) Membership in T_K is decided by a program.

(b) T_K is a decidable binary tree: it contains the empty string and every initial segment of each of its members.

(c) T_K has a member of every length.

(d) Every computable binary sequence p leaves T_K: $\bar{p}(n) \notin T_K$ for some n.

Proof. (a) Deciding $l \in T_K$ runs each program $e < |l|$ for $|l|$ steps and compares outputs with digits.

(b) The empty string has no constraint. Let $lb \in T_K$ and $e < |l|$. If e has halted by $|l|$ with output o, it has halted by $|l| + 1$ with the same output, so the constraint on digit e holds in lb, and digit e of l is digit e of lb. So $l \in T_K$.

(c) For a length N, let g_N have digit e equal to 1 exactly when program e has halted by N with output 0. Each constraint at length N is met: output 0 gives digit 1, and any other output gives digit 0.

(d) The function $(c, x) \mapsto p(c)$ is computable, so by Kleene's recursion theorem [19, Chapter XII] there is a program e with $\{e\}(x) = p(e)$ for every x. Its run on input 0 halts with output $p(e)$, say within k steps. Let $n = k + e + 1$. Then $e < n$ and e has halted by n with output $p(e)$. If $p(e) = 0$, the constraint demands digit 1 at e; if $p(e) = 1$, it demands digit 0. Either way $\bar{p}(n)$, whose digit at e is $p(e)$, violates it, so $\bar{p}(n) \notin T_K$. □

The tree and its path in ordinary mathematics are a different matter. By Theorem 12.72, LLPO with countable choice gives a path through T_K, and classically one exists. The lemma says only that no program computes one. In the model of named objects, paths are computable functions, so there T_K is an infinite decidable tree without a path.

16.10 Compactness is not derivable in the computable calculus

We now return to the question of the chapter's opening. The statements studied in Chapter 13 become sentences of the computable calculus, and none of them is derivable, even from LPO and with excluded middle as a base rule. Every relation they use, among numbers, strings and points, is written as an equation between terms of tracked maps, so that the rules of the calculus act on it. An atom of the order or of membership would be governed by no rule (Remark 16.19), and a sentence that rested on one would fail to be derivable for that reason alone.

Carriers and tracked maps. Let W be the carrier of binary strings and B that of bits, both constant and presented by codes; $\mathsf{P} = \mathsf{B}^{\mathbb{N}}$ the carrier of binary sequences; and $\mathsf{D} = \mathsf{B}^{\mathsf{W}}$ the carrier of decidable sets of strings, given by their maps to $\{0,1\}$ as in Definition 13.1. By Proposition 16.21(a), the named sequences and the named decidable sets are the computable ones. The carriers of presented sets (Definition 13.22), of ratio covers (Definition 13.5) and of presented uniform maps (Definition 13.27) are constant; each object is the set, cover or map together with its data. A presented set is *named* by a program that computes, from n, the list of programs of the regular sequences of its n-th net. A cover is named by a program that computes the two ratios of its k-th interval from k. A presented uniform map is named when programs name its set, its function on the line, its transformer, read on programs, and its modulus. For Heine–Cantor a *map package* is a presented set with a function on the line, named when both are. The sentences below use the terms of the following tracked maps, whose programs are described in Appendix J.4:

- on numbers, the successor S and the sum $+$;
- on strings, the length $|w|$, the digit w_i at position i (with the value 0 when $i \geq |w|$), the concatenation wt, the string wb with one more digit b, the empty string $\emptyset$ and the bit 1; and the applications $p(i)$ of a binary sequence and $D(w)$ of a decidable set;
- on the line, $\max(x,y)$, $x+y$, $-x$, the points 0 and 1, and the point $\eta(1/(k+1))$ of a number k;
- for a ratio cover c, the endpoints $a_c(k)$ and $b_c(k)$ of its k-th interval, as points of the line;
- for a presented set K, the number $\ell_K(n)$ of entries of its n-th net and the point $y_K(n,i)$ named by the i-th entry, which is 0 when $i \geq \ell_K(n)$; and on numbers $r(n) = 2^n - 1$, so that $1/(r(n)+1) = 2^{-n}$;
- for a presented uniform map or a map package M, its set K_M and the value $f_M(x)$ of its function at a point x; and for a function f on the line, the application $f(x)$.

Definition 16.30 (The relations as equations)**.** In the computable calculus the formulas on the right abbreviate the relations on the left. Each is built from equations, the connectives and quantifiers over $\mathbb{N}$ and W; it contains no atom.

$$
\begin{aligned}
n \leq N &:\equiv \exists_{\mathbb{N}} k\,(n+k=N), \qquad i < n :\equiv \exists_{\mathbb{N}} k\,\big(i + S(k) = n\big),\\
\mathrm{Hit}(D,p,n) &:\equiv \exists_{\mathsf{W}} w\big(|w| = n \wedge \forall_{\mathbb{N}} i\,(i<n \to p(i) = w_i) \wedge D(w) = 1\big),\\
\mathrm{CHit}(D,p,n) &:\equiv \exists_{\mathsf{W}} w\big(|w| = n \wedge \forall_{\mathbb{N}} i\,(i<n \to p(i) = w_i) \wedge \forall_{\mathsf{W}} t\, D(wt) = 1\big),\\
a \leq b &:\equiv \max(a,b) = b, \qquad 0 < y :\equiv \exists_{\mathbb{N}} k\,\big(\eta(1/(k+1)) \leq y\big),\\
a < b &:\equiv \exists_{\mathbb{N}} k\,\big(\eta(1/(k+1)) \leq b + (-a)\big),\\
x \approx_j y &:\equiv x \leq y + \eta(1/(j+1)) \wedge y \leq x + \eta(1/(j+1)),\\
x \in I_k(c) &:\equiv a_c(k) < x \wedge x < b_c(k), \qquad x \in [0,1] :\equiv 0 \leq x \wedge x \leq 1,\\
x \in K &:\equiv \forall_{\mathbb{N}} n\, \exists_{\mathbb{N}} i\,\big(i < \ell_K(n) \wedge x \approx_{r(n)} y_K(n,i)\big).
\end{aligned}
$$

So $\mathrm{Hit}(D,p,n)$ says $D(\bar{p}(n)) = 1$ through its one witness, the initial segment $\bar{p}(n)$, and $\mathrm{CHit}(D,p,n)$ says that $D(\bar{p}(n)t) = 1$ for every string t. A point lies in a presented set when every net has an entry within 2^{-n} of it; since presented sets are closed (Proposition 13.23), this is membership.

Lemma 16.31 (The equations read as the relations)**.** *In the model of named objects, at every named object of the context, each formula of Definition 16.30 holds exactly when the relation it abbreviates holds: $n \le N$; $i < n$; $D(\bar{p}(n)) = 1$; $D(\bar{p}(n)t) = 1$ for every string t; $a \le b$, $0 < y$ and $a < b$ in the order of the line; x and y lie within $1/(j+1)$; x lies in the k-th interval of c; $0 \le x \le 1$; and x is a member of K.*

The proof is in Appendix J.5. With these abbreviations the decidable fan theorem and its c-set form (Definition 13.2) and decidable weak König's lemma (Definition 12.71) are the sentences

$$\begin{aligned}
\mathsf{FAN}_{\Delta}^{=} &:= \forall_{\mathsf{D}} D\Big(\forall_{\mathsf{P}} p\, \exists_{\mathbb{N}} n\, \mathrm{Hit}(D,p,n) \to \exists_{\mathbb{N}} N \forall_{\mathsf{P}} p\, \exists_{\mathbb{N}} n\, \big(n \le N \wedge \mathrm{Hit}(D,p,n)\big)\Big),\\
\mathsf{FAN}_{c}^{=} &:= \text{the same with CHit in place of Hit},\\
\mathsf{WKL}^{=} &:= \forall_{\mathsf{D}} T\big(\mathrm{Tree}(T) \to \mathrm{Inf}(T) \to \exists_{\mathsf{P}} p\, \forall_{\mathbb{N}} n\, \mathrm{Hit}(T,p,n)\big),
\end{aligned}$$

where

$$\begin{aligned}
\mathrm{Tree}(T) &:\equiv T(\varnothing) = 1 \wedge \forall_{\mathsf{W}} w \forall_{\mathsf{B}} b\, \big(T(wb) = 1 \to T(w) = 1\big),\\
\mathrm{Inf}(T) &:\equiv \forall_{\mathbb{N}} n\, \exists_{\mathsf{W}} w\big(|w| = n \wedge T(w) = 1\big).
\end{aligned}$$

The four compactness sentences for presented sets are

$$\begin{aligned}
\mathsf{HB}^{=} &:= \forall K \forall c\Big(\forall_{\mathscr{L}} x\big(x \in K \to \exists_{\mathbb{N}} k\, x \in I_k(c)\big)\\
&\qquad \to \exists_{\mathbb{N}} N \forall_{\mathscr{L}} x\big(x \in K \to \exists_{\mathbb{N}} k\,(k < N \wedge x \in I_k(c))\big)\Big),\\
\mathsf{PLB}^{=} &:= \forall M\Big(\forall_{\mathscr{L}} x\big(x \in K_M \to 0 < f_M(x)\big)\\
&\qquad \to \exists_{\mathbb{N}} k \forall_{\mathscr{L}} x\big(x \in K_M \to \eta(1/(k+1)) \le f_M(x)\big)\Big),\\
\mathsf{PINF}^{=} &:= \forall M\Big(\exists_{\mathscr{L}} x(x \in K_M) \to \forall_{\mathscr{L}} x\big(x \in K_M \to 0 < f_M(x)\big) \to \exists_{\mathscr{L}} m\,\big(\mathrm{Inf}_M(m) \wedge 0 < m\big)\Big),\\
\mathsf{HC}^{=} &:= \forall M\Big(\forall_{\mathscr{L}} x\big(x \in K_M \to \forall_{\mathbb{N}} k \exists_{\mathbb{N}} j\, \mathrm{Ctl}_M(x,j,k)\big)\\
&\qquad \to \forall_{\mathbb{N}} k \exists_{\mathbb{N}} j \forall_{\mathscr{L}} x\big(x \in K_M \to \mathrm{Ctl}_M(x,j,k)\big)\Big).
\end{aligned}$$

Here K ranges over presented sets and c over ratio covers, and M over presented uniform maps in $\mathsf{PLB}^{=}$ and $\mathsf{PINF}^{=}$ and over map packages in $\mathsf{HC}^{=}$. The formula $\mathrm{Inf}_M(m)$ is

$$\forall_{\mathscr{L}} x\big(x \in K_M \to m \le f_M(x)\big) \wedge \forall_{\mathscr{L}} a\Big(\forall_{\mathscr{L}} x\big(x \in K_M \to a \le f_M(x)\big) \to a \le m\Big),$$

which says that m is the infimum of f_M on K_M, and

$$\mathrm{Ctl}_M(x,j,k) :\equiv \forall_{\mathscr{L}} y\big(y \in K_M \to x \approx_j y \to f_M(x) \approx_k f_M(y)\big),$$

so that the premise and the conclusion of $\mathsf{HC}^{=}$ are pointwise and uniform continuity on K_M (Definition 13.12). The forms for $[0,1]$ alone take c over ratio covers and f over the functions

on the line, $\mathscr{L}^{\mathscr{L}}$:

$$\begin{aligned}
\mathsf{HB}^{=}_{[0,1]} &:= \forall c\Big(\forall_{\mathscr{L}} x\big(x \in [0,1] \to \exists_{\mathbb{N}} k\, x \in I_k(c)\big) \\
&\qquad \to \exists_{\mathbb{N}} N \forall_{\mathscr{L}} x\big(x \in [0,1] \to \exists_{\mathbb{N}} k (k < N \wedge x \in I_k(c))\big)\Big), \\
\mathsf{PLB}^{=}_{[0,1]} &:= \forall f\Big(\mathrm{U}(f) \to \forall_{\mathscr{L}} x\big(x \in [0,1] \to 0 < f(x)\big) \\
&\qquad \to \exists_{\mathbb{N}} k \forall_{\mathscr{L}} x\big(x \in [0,1] \to \eta(1/(k+1)) \le f(x)\big)\Big), \\
\mathsf{PINF}^{=}_{[0,1]} &:= \forall f\Big(\mathrm{U}(f) \to \forall_{\mathscr{L}} x\big(x \in [0,1] \to 0 < f(x)\big) \to \exists_{\mathscr{L}} m\,\big(\mathrm{Inf}_f(m) \wedge 0 < m\big)\Big), \\
\mathsf{HC}^{=}_{[0,1]} &:= \forall f\big(\mathrm{C}(f) \to \mathrm{U}(f)\big),
\end{aligned}$$

where $\mathrm{Inf}_f(m)$ is $\mathrm{Inf}_M(m)$ with $x \in [0,1]$ in place of $x \in K_M$ and f in place of f_M, and the uniform and the pointwise continuity of f on $[0,1]$ are

$$\begin{aligned}
\mathrm{U}(f) &:\equiv \forall_{\mathbb{N}} k \exists_{\mathbb{N}} j \forall_{\mathscr{L}} x\Big(x \in [0,1] \to \forall_{\mathscr{L}} y\big(y \in [0,1] \to x \approx_j y \to f(x) \approx_k f(y)\big)\Big), \\
\mathrm{C}(f) &:\equiv \forall_{\mathscr{L}} x\Big(x \in [0,1] \to \forall_{\mathbb{N}} k \exists_{\mathbb{N}} j \forall_{\mathscr{L}} y\big(y \in [0,1] \to x \approx_j y \to f(x) \approx_k f(y)\big)\Big).
\end{aligned}$$

None of these sentences contains an atom. By Lemma 16.31, each of them has in the model of named objects the reading of Lemma J.2: the statement of Chapter 13 with every quantifier restricted to the named objects. Erasing the presentations, the later reading of each of the seven sentences $\mathsf{FAN}^{=}_{\Delta}$, $\mathsf{FAN}^{=}_{c}$, $\mathsf{WKL}^{=}$, $\mathsf{HB}^{=}$, $\mathsf{PLB}^{=}$, $\mathsf{PINF}^{=}$ and $\mathsf{HC}^{=}$ is the corresponding statement of Chapter 13 for all presented sets, covers and maps of ordinary mathematics.

Theorem 16.32 (Fan theorems and weak König's lemma)**.** *Let X be one of $\mathsf{FAN}^{=}_{\Delta}$, $\mathsf{FAN}^{=}_{c}$ and $\mathsf{WKL}^{=}$. In the computable calculus none of $\top \vdash X$, $\mathsf{LPO} \vdash X$ and $\top \vdash \mathsf{LPO} \to X$ is derivable, and the same holds when every instance of excluded middle is added as a base rule. The proof reasons in a classical metatheory.*

Proof. LPO is true in the model of named objects (proof of Theorem 16.27), so by Theorem 16.22, and by Remark 16.24 when excluded middle is added, it is enough to show that each sentence is false there. In the model, quantifiers over binary sequences and over decidable sets of strings range over the computable ones, and Hit, CHit, Tree and Inf read as the relations they abbreviate (Lemmas 16.31 and J.2).

$\mathsf{FAN}^{=}_{\Delta}$. Let $D(l) = 1$ exactly when $l \notin T_K$. By Lemma 16.29(a) D is computable, and by (d) every computable sequence has an initial segment with $D = 1$. Fix N. By (c) some string g of length N lies in T_K; let p be g followed by zeros, a computable sequence. Then $\bar{p}(N) = g \in T_K$, and by (b) every $\bar{p}(n)$ with $n \le N$ lies in T_K. So no N bounds the bar on the computable sequences, and the sentence is false.

$\mathsf{FAN}^{=}_{c}$. With the same D, the c-set of D contains every string with $D = 1$: a string outside T_K has all its extensions outside T_K, by (b). So every computable sequence meets the c-set. A uniform bound for the c-set would, at the empty extension, be a uniform bound for D, which was just refuted.

$\mathsf{WKL}^{=}$. T_K is a named decidable set of strings, a tree by (b), with a member of every length by (c). A path in the model is computable and leaves T_K by (d). □

Proposition 16.33 (The reading of weak König's lemma)**.** *Erasing the presentations of* $\mathsf{WKL}^{=}$ *gives a sentence whose later reading is weak König's lemma for decidable binary trees. That statement is equivalent to* $\mathrm{LLPO}_{\mathrm{seq}}$ *(Definition 13.8), and neither direction uses a choice principle.*

Proof. The first assertion is the unfolding of the clauses, all carriers being constant after erasure; at the later stage the abbreviations Hit, Tree and Inf read as the relations they abbreviate, with every string and every sequence in the range of the quantifiers. The equivalence is Proposition 13.9. □

So weak König's lemma, written with equations, is not derivable in the computable calculus even from LPO and with excluded middle as a base rule, while its later reading is exactly $\mathrm{LLPO}_{\mathrm{seq}}$: LLPO for infinitely many rows at once, with the answers collected into one sequence. With LPO the computable calculus has the decisions and lacks the collection.

The compactness sentences fail on the unit interval, presented as in Chapter 13; its package is named (Appendix J.6). We use the base-four geometry of the proof of Theorem 13.6: for a string s of length n, the number $\kappa(s)$ with base-four digits $3s_0, \dots, 3s_{n-1}$, the Cantor point $c(s) = \kappa(s)/4^n$ in $[0,1]$, the Cantor interval $J(s)$, whose left end is $c(s)$, and the open cells $C(s)$ with ratio endpoints. Three of the facts proved there are used:

(C1) if $|t| \geq |s|$ and $c(t) \in C(s)$, then s is an initial segment of t (fact (b));

(C2) for every regular sequence r naming a point x of $[0,1]$, the *address* a_r, whose digit at each depth compares one stage of r with a ratio, has $x \in C(\bar{a}_r(n))$ for every n (fact (c));

(C3) if r is computed by a program, so is a_r (Appendix J.6).

Fix an enumeration $w_0, w_1, \dots$ of the binary strings. The *dead cover* of T_K has as its k-th interval the empty interval $(0,0)$ if $w_k \in T_K$, and the cell $C(w_k)$ if $w_k \notin T_K$. Its endpoints are ratios computed from k, so the cover is named.

Theorem 16.34 (Heine–Borel for presented sets)**.** *Let X be* $\mathsf{HB}^{=}$ *or* $\mathsf{HB}^{=}_{[0,1]}$*. In the computable calculus none of $\top \vdash X$,* $\mathsf{LPO} \vdash X$ *and* $\top \vdash \mathsf{LPO} \to X$ *is derivable, and the same holds when every instance of excluded middle is added as a base rule. The proof reasons in a classical metatheory.*

Proof. As before, it is enough to show that both sentences are false in the model, at the dead cover and, for $\mathsf{HB}^{=}$, at the named presented set $[0,1]$. By Lemma 16.31, a named point is a member of the presented set $[0,1]$ exactly when $0 \leq x \leq 1$, and it lies in the k-th interval of the cover exactly when it lies between the two ends; so at this cover both sentences say that finitely many of its intervals cover the named points of $[0,1]$.

The dead cover covers every named point of $[0,1]$. Let $x \in [0,1]$ be named, by a program for a regular sequence r. By (C3) the address a_r is computable, so by Lemma 16.29(d) some initial segment $u = \bar{a}_r(n)$ lies outside T_K. By (C2), $x \in C(u)$, and $C(u)$ is the interval of the index of u, a number and so named.

No initial part of the cover suffices. Fix N and put $L = \sum_{k<N}(|w_k| + 1)$, which exceeds $|w_k|$ for every $k < N$. By Lemma 16.29(c) some string t of length L lies in T_K. Its Cantor point $c(t)$ is

a ratio in $[0,1]$, so it is named (Proposition 16.21(b)). Suppose $c(t)$ lay in the interval $k < N$. That interval is not empty, so $w_k \notin T_K$ and $c(t) \in C(w_k)$. Since $|w_k| < L = |t|$, (C1) makes w_k an initial segment of t, and $t \in T_K$ gives $w_k \in T_K$ by Lemma 16.29(b). This contradiction shows that $c(t)$ lies in none of the first N intervals. □

The two positivity statements reduce to Heine–Borel inside the model, through the cover series f_c of Lemma 13.26. That lemma shows that f_c is positive at every point that lies in an interval of c; that $f_c \geq 1/(k+1)$ on a set of points makes the first N intervals cover that set for some N; and that f_c, with the transformer of names it describes and a modulus, is a presented uniform map on every set of points. When the cover and the presented set are named, so is this presented uniform map, with a modulus computed by a program (Appendix J.7).

Theorem 16.35 (Positive lower bounds and positive infima)**.** *Let X be one of $\mathsf{PLB}^{=}$, $\mathsf{PINF}^{=}$, $\mathsf{PLB}^{=}_{[0,1]}$ and $\mathsf{PINF}^{=}_{[0,1]}$. In the computable calculus none of $\top \vdash X$, $\mathsf{LPO} \vdash X$ and $\top \vdash \mathsf{LPO} \to X$ is derivable, and the same holds when every instance of excluded middle is added as a base rule. The proof reasons in a classical metatheory.*

Proof. It is enough to show that the four sentences are false in the model. By Lemma 16.31, $0 < y$, $a \leq b$ and membership read as the relations they abbreviate.

$\mathsf{PLB}^{=}$. Suppose it were true. Let c be the dead cover of T_K and consider the named presented uniform map f_c on the presented set $[0,1]$. By the first part of the proof of Theorem 16.34, every named point of $[0,1]$ lies in an interval of c, so f_c is positive there. The sentence gives k with $1/(k+1) \leq f_c(x)$ for every named $x \in [0,1]$. Applied to the set of named points of $[0,1]$, the lemma gives an N such that the first N intervals cover every named point of $[0,1]$, which the second part of that proof refutes.

$\mathsf{PLB}^{=}_{[0,1]}$. The same argument applies to f_c as a function on the line. It is named, and its modulus $\mu(k) = 2k+1$ (Appendix J.7) makes $\mathrm{U}(f_c)$ true in the model.

$\mathsf{PINF}^{=}$. Suppose it were true; we show that $\mathsf{PLB}^{=}$ would be true. Let M be a named presented uniform map, positive at the named points of K_M. If K_M has no named point, every k is a lower bound on its named points. Otherwise $\mathsf{PINF}^{=}$ gives a named m that is the infimum of f_M on the named points of K_M, with $0 < m$, which gives k with $1/(k+1) \leq m$; so $1/(k+1) \leq m \leq f_M(x)$ there. The case distinction on whether K_M has a named point is made in the metatheory. So $\mathsf{PLB}^{=}$ would hold, which was just refuted.

$\mathsf{PINF}^{=}_{[0,1]}$. In the same way it would give $\mathsf{PLB}^{=}_{[0,1]}$, with no case distinction, since $[0,1]$ has named points. □

Heine–Cantor needs a function rather than a cover. We use the tents of the proof of Theorem 13.13: for a string s of length n, the centre $g(s)$ of its gap, at distance $2^{-(2n+1)}$ from $c(s)$, and the tent $\tau_s(x) = \max(0, 1 - 8 \cdot 4^n |x - g(s)|)$, which vanishes outside the overlap $O(s)$ of the cells of the children of s. The *finite heads* of T_K are $H_N = \sum\{\tau_s : s \in T_K,\ |s| < N\}$. The *tent function* τ of T_K takes at a point x the common value of the heads $H_N(x)$ from some N on, when they become constant, and the value 0 when they do not; this definition by cases is made in the metatheory.

Theorem 16.36 (Heine–Cantor for presented sets)**.** *Let X be $\mathsf{HC}^{=}$ or $\mathsf{HC}^{=}_{[0,1]}$. In the computable calculus none of $\top \vdash X$, $\mathsf{LPO} \vdash X$ and $\top \vdash \mathsf{LPO} \to X$ is derivable, and the same holds when every instance of excluded middle is added as a base rule. The proof reasons in a classical metatheory.*

Proof. We show that $\mathsf{HC}^{=}$ is false in the model at the map package of $[0,1]$ and τ, and $\mathsf{HC}^{=}_{[0,1]}$ at the function τ on the line. By Lemma 16.31, $\approx_j$ reads as closeness within $1/(j+1)$ and membership as membership. Three facts are proved in Appendix J.8.

τ is named. A program computes a name of $\tau(x)$ from every name of every point x of the line: it runs the address digits of the given regular sequence and searches for the first depth n at which the address string lies outside T_K. The search ends on every name, because the address of a computable regular sequence is computable and leaves T_K by Lemma 16.29(d). At that depth all heads from n on agree at x, so $\tau(x) = H_n(x)$, and a name of $H_n(x)$ is computed from n and the name of x by finite arithmetic.

τ is continuous at every named point of $[0,1]$. Such a point lies in the open cell of a string outside T_K, and on that cell τ equals one finite head, a finite sum of tents, which changes by a bounded multiple of the change of its argument.

τ is not uniformly continuous on the named points of $[0,1]$. For every j, a string $s \in T_K$ of length $j+1$ gives the two ratios $c(s)$ and $g(s)$ of $[0,1]$, which are named and lie within $2^{-(2j+3)} \le 1/(j+1)$ of each other, while $\tau(c(s)) = 0$ and $\tau(g(s)) = 1$. These values are not within $1/2$, so at $k = 1$ no j serves.

So the premise of each sentence holds at τ and its conclusion fails. LPO and every instance of excluded middle are true, and Theorem 16.22 with Remark 16.24 finishes the proof. □

These results say that the computable calculus does not derive compactness, written with equations, even with LPO and with excluded middle as a base rule. They do not say that compactness fails. In ordinary mathematics with excluded middle and countable choice, weak König's lemma holds (Theorem 12.72), and with it the decidable fan theorem and Heine–Borel for presented sets (Theorems 13.7 and 13.25); LPO with unique choice already gives the decidable fan theorem (Corollary 13.10); and the full calculus derives all seven sentences for presented sets outright (Proposition 16.15). What the model shows is what a derivation in the computable calculus would need and that calculus lacks: a way to gather, along infinitely many strings or points, answers that LPO supplies one at a time.

16.11 What remains open

A model with two later stages. Every separation of this chapter uses one model, in which truth is classical and the quantifiers range over named objects. A separation of a different kind, such as one that keeps a compactness statement while refuting weak excluded middle, $\neg p \vee \neg\neg p$, needs a model in which a truth value can be undecided. The natural candidate is a finite Kripke structure with a root and two incomparable later stages. To use it for the computable calculus one needs an interpretation of the calculus in that structure that commutes with the ten constructions of formulas, is coherent with the binders, makes every instance of the twenty-nine rules an entailment, and reads the two sentences to be separated as their

counterparts in the structure. Whether such an interpretation exists is open. Two natural attempts fail. The model of named objects, copied to all three stages, meets the first three requirements, but it makes weak excluded middle true. And a classifier at the root built from one truth value at each branch can describe only the sets $\{(p, q) : L(p) \text{ and } R(q)\}$, while excluded middle at the root, true at (true, true) and at (false, false) and false at (true, false), is not of that form: L and R would have to hold at both truth values.

Derivations of the compactness implications. Chapter 13 proves in ordinary mathematics that Heine–Borel for presented sets, the positive lower bound, the positive infimum and presented Heine–Cantor each imply the decidable fan theorem. In the full calculus the erased implications from $\mathsf{HB}^{=}$, $\mathsf{PLB}^{=}$, $\mathsf{PINF}^{=}$ and $\mathsf{HC}^{=}$ to $\mathsf{FAN}_{\Delta}^{=}$ are derivable (Proposition 16.15), as is $\mathsf{FAN}_{\Delta}^{=}$ itself. Whether the computable calculus derives $\top \vdash X \to \mathsf{FAN}_{\Delta}^{=}$ for each X among $\mathsf{HB}^{=}$, $\mathsf{PLB}^{=}$, $\mathsf{PINF}^{=}$ and $\mathsf{HC}^{=}$ is open. The model of named objects cannot settle it: both sides are false there, so each implication is true there.

The full calculus. Proposition 16.15 settles the full calculus for every sentence that is equational over constant carriers: it derives each one that is true in ordinary classical mathematics, so between two such sentences it proves no separation that classical mathematics does not already give. A separation of another kind in the full calculus would have to concern sentences outside this class: sentences with atoms, or with quantifiers over carriers that change between the stages, such as Ω and the sets of points.

Realizability. Proposition 16.26 rules out uniform realizability over presentations in which a name says nothing about a truth value. Whether presentations whose names of truth values carry evidence give a realizability model of the computable calculus is open.

Native prices. $\mathrm{LLPO}_{\mathrm{seq}}$ is not written here as a sentence of the calculus, and the equivalence of Proposition 16.33 is proved in ordinary mathematics, not as a derivation.

Questions to work through

1. In Table 16.1, drop the second half of the earlier clause for implication. Find a formula in the context Ω whose reading is then no longer a predicate, and point to the step of Lemma 16.5 that fails.

2. Show that conditions (1) and (2) of Theorem 16.14 can be met together. Which instance of condition (3) does your assignment violate?

3. Show that a judgment $A \vdash B$ between sentences is derivable exactly when $\top \vdash A \to B$ is, in the calculus and in the computable calculus.

4. Use Proposition 16.21(c) to show that no tracked map from $\Omega^{\mathbb{N}}$ to $\mathbb{N}^{\mathbb{N}}$ sends every classifier on $\mathbb{N}$ to its 0–1 function, the function with value 1 exactly where the classifier holds. Where does the proof of Theorem 16.27 meet the same obstacle?

5. In the proof of Theorem 16.32, the path p made of a member g of T_K of length N followed by zeros has no initial segment of length at most N outside T_K. Explain why p nevertheless leaves T_K, and bound the length of its first initial segment outside T_K in terms of the program given by the recursion theorem.

Part V

Mathematics and finite physical records

Part V connects finite mathematical descriptions with finite physical records. Its theorems concern stated mathematical models of an apparatus: a record space and a reader (Chapter 17); finite operations with a supplied preparation, externally selected controls and a complete reader (Chapter 18); and an interaction that conserves two stated charges, read by a neutral sharp pointer (Chapter 19). Every physical reading of these results is relative to those listed hypotheses. A theorem says what follows when an apparatus satisfies them; that a particular device satisfies them is an identification, which the theorem does not supply. These chapters reason in classical mathematics, about worlds and recorders as about finite operations and conserved charges.

Two results should be read at exactly this scope. Theorem 18.11 approximates every finite instrument, within any tolerance on every retained reference, with externally switched positive-energy pulses; it is not a claim that an autonomous apparatus with bounded controls exists. Theorem 19.5 is a lower bound on the error of every recorder that meets its four conditions; it is not a claim that the bound is attained. Each theorem of Chapters 17 to 19 is followed by a remark that lists its conditions, preparation, controls, resources and identifications, as they apply, and what it does not claim.

Chapter 17

What a finite record can establish

An instrument returns one of two marks. The experimenter wants to know which of three preparations was supplied. If that mark is the whole available record, a reader cannot always give the right answer: two preparations must leave the same mark, and the reader then receives the same information in two cases requiring different answers.

The conclusion changes if the question changes. Perhaps the experimenter only needs to separate one preparation from the other two. Or perhaps the apparatus can perform another test. A limit on recognition must therefore name both the question and the record. Counting possible preparations alone does not tell us which of their differences an observer must recover.

This chapter gives that distinction a precise form. We first prove the collision argument for an arbitrary record. We then construct the record of an adaptive testing procedure and count its possible outcomes. Finally, we replace exact answers by answers with a stated error, and Section 17.7 asks which questions a growing record can confirm, refute or settle, and what deciding them costs. Each argument concerns the information supplied to the reader, except the cost results of that section, which concern the logical principles that a decision requires; physical preparation, retention and readout enter as separate requirements on the apparatus.

17.1 The target, the record and the reader

Let W be the allowed preparations or worlds. A member $w \in W$ contains whatever distinctions the experiment can depend on. We need not reconstruct all of w. Instead, fix a target map

$$\tau : W \longrightarrow Y.$$

The value $\tau(w)$ is the answer the task requires. Two worlds may differ while having the same target value.

Let R be the possible retained records and let $r : W \to R$ give the record actually obtained in each world for the procedure under consideration. A reader d takes a record and either returns an element of Y or reports failure. We write its answer as $d(r)$ when it succeeds.

Definition 17.1 (Exact readout)**.** The procedure gives an exact readout of τ if the reader succeeds on every actual record and

$$d(r(w)) = \tau(w) \qquad \text{for every } w \in W. \tag{17.1}$$

Records that never occur may be rejected.

The order of these maps matters. The apparatus acts on the world to produce a record; the reader acts on the record to return the target. An arbitrary assignment of a different code to every answer does not establish that the apparatus can obtain the assigned code from an unknown preparation. Equation (17.1) is the required connection.

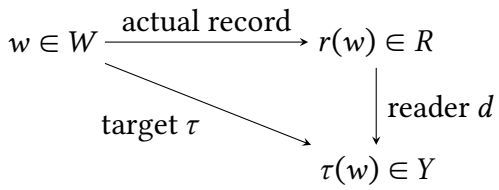

Figure 17.1. Exact readout requires the two routes to agree for every allowed world. A mathematical code supplies the upper route only when the apparatus actually produces it.

Lemma 17.2 (A record cannot separate its own collisions)**.** *If the readout is exact and $r(w) = r(v)$, then $\tau(w) = \tau(v)$.*

Proof. Apply the same reader to the equal records. Exactness identifies its answer on one side with $\tau(w)$ and on the other with $\tau(v)$. Thus

$$\tau(w) = d(r(w)) = d(r(v)) = \tau(v).$$ □

Only distinctions relevant to the target must survive. If the target itself separates all worlds, the lemma says that the record map must be injective. Otherwise, several worlds can share a record without causing an error, provided their required answers agree.

17.2 Several worlds can remain compatible with one record

The map r describes one determined record per world. Some experiments have several possible outcomes, and some records leave several preparations possible. We can state the essential condition without choosing a probability distribution or a deterministic outcome map.

Write $C(s, w)$ when record s is compatible with world w under the stated experimental model. The condition includes the experiment that was performed and every relevant control or calibration assumption. A reader is sound on this relation if, whenever $C(s, w)$ holds, it succeeds and returns $\tau(w)$.

Proposition 17.3 (A sound answer is constant on compatible worlds)**.** *Suppose the reader is sound. If $C(s, w)$ and $C(s, v)$, then $\tau(w) = \tau(v)$. Moreover, if an actual record map satisfies $C(r(w), w)$ for every w, soundness gives exact readout for that map.*

Proof. Soundness says that the single answer $d(s)$ equals both target values, which proves the first assertion. For the second, apply soundness to $s = r(w)$ and the stated actual-world compatibility condition. □

This formulation separates two possible failures. A proposed record may be compatible with worlds requiring different answers. Or the compatibility model may omit the world that actually produced the record. The first failure concerns discrimination; the second concerns the model's relation to the experiment. A proof of the first condition does not repair the second.

The proposition is a necessary condition on a sound reader. It does not construct an effective reader from an arbitrary compatibility relation. Finding the compatible worlds, deciding their common target and making the record readable can each require further work.

17.3 A finite capacity bound

Choose a finite family of allowed worlds w_i, indexed by a finite set I, whose target values are pairwise different. The family need not include every allowed world. Suppose the whole retained record has only M possible values.

Theorem 17.4 (Capacity required by exact recognition)**.** *If the readout is exact on the allowed worlds, then*

$$|I| \leq M.$$

Conditions and scope.

Preparation and record
A finite family of allowed worlds with pairwise different targets, and a record map r giving the actual record in each. The record space must contain everything the reader uses: timing, channel, control settings and the printed mark.

Resources counted
The number M of possible values of the whole retained record.

Identification
Applying the theorem to an apparatus identifies its complete output with r. The theorem itself concerns the map r.

Not claimed
That any apparatus reaches the records, or that M distinct records suffice for a construction.

Proof. Associate i with its actual record $r(w_i)$. If two indices have the same record, Lemma 17.2 gives the same target value. The choice of the family then gives the same index. We have constructed an injection from I into the set of possible records, so the finite cardinal inequality follows. □

The bound concerns distinguishable records, including everything the reader may use. If timing, position, the choice of output channel or a separate control register supplies additional information, it belongs in R. Counting only the printed mark would then count an incomplete record.

No optimality claim is built into the theorem. An injection into a large record space is necessary for exact recovery; it does not show how a particular apparatus reaches the needed records. The construction of a working procedure is a separate positive task.

17.4 Adaptive tests still produce a bounded transcript

An experimenter may choose the next test after seeing the previous result. To count this procedure correctly, we must preserve that dependence. Fix a set A of available tests and an alphabet of $B \geq 1$ possible outcomes. For this section, a test a has a determined outcome

$$o(a, w) \in \{0, \dots, B-1\}$$

in each world w. Fix the procedure in advance. It may adapt to the outcomes, but it receives no information about w other than through those outcomes.

Definition 17.5 (A bounded adaptive test tree)**.** A tree with budget m has one of two forms:

1. Stop and return a specified answer, using none of the remaining tests.
2. If $m > 0$, choose a test $a \in A$ and, for each of its B outcomes, supply a continuation tree with budget $m - 1$.

Execution follows the continuation selected by the observed outcome. Write $\mathrm{run}(T, w)$ for the answer eventually returned by tree T.

The budget decreases at every test, so every execution stops. Different branches can choose different tests and stop at different depths. This is a finite inductive description of the whole policy, rather than a list of independent tests to which adaptation is added afterward.

Choose one padding symbol p from the outcome alphabet. We now construct a transcript $c_T(w)$ with exactly m slots. At a stop node, fill all remaining slots with p. At a test node, write the observed outcome in the first slot and follow it with the continuation's transcript.

The corresponding reader already knows T. At a stop node it returns that node's answer and ignores the remaining slots. At a test node it reads the first symbol, chooses the corresponding continuation, and reads the tail there. Denote this reader by D_T.

Lemma 17.6 (The transcript retains the answer of the procedure)**.** *For every bounded tree and every allowed world,*

$$D_T(c_T(w)) = \mathrm{run}(T, w).$$

Proof. Induct on the tree. At a stop node, both sides are its specified answer. At a test node, the first transcript symbol is $o(a, w)$. The reader therefore chooses exactly the continuation chosen in execution. The remaining transcript is the transcript of that continuation. Apply the induction hypothesis to its smaller tree. □

Padding loses no information needed for this answer. The fixed tree tells the reader when a stop node has been reached. Even if a padding symbol is also a genuine test outcome, the reader knows which slots it is supposed to read from the branch it has followed.

Theorem 17.7 (Capacity of a bounded adaptive procedure)**.** *Suppose a tree performs at most m tests with B possible outcomes per test and returns the correct target for every world in a finite family of N distinct target values. Then*

$$N \le B^m. \tag{17.2}$$

Conditions and scope.

Preparation and control
Each test has a determined outcome in each world, and the adaptive policy is fixed in advance; it learns about the world only through the outcomes.

Resources counted
At most m tests, each with B possible outcomes.

Not claimed
Tests that change the system are covered only after their changing state and the available controls are modelled. The bound B^m is a necessary capacity, not a construction.

Proof. There are B^m strings of length m over the outcome alphabet: each of the m slots has B choices. Lemma 17.6 and correctness of the tree give exact readout from its constructed transcript. Distinct target values therefore give distinct transcripts; apply Theorem 17.4. □

In particular, no such procedure with one binary test can always identify one of three distinct targets: the conclusion would require $3 \le 2$. Adaptation helps choose useful questions, but it cannot make a transcript carry more distinct answers than it has distinguishable values.

This tree model assumes determined outcomes $o(a, w)$ for the supplied world. When a test changes the system, its changing state and the available controls must be represented before applying this construction. The earlier collision and record-capacity theorems apply to any supplied actual record map with exact recovery; the tree theorem adds the particular structure that justifies the bound B^m.

17.5 An error tolerance gives a separation bound

Many tasks ask for an approximation. Let target values lie in a space with a distance dist satisfying symmetry and the triangle inequality. Let the reader return a reconstructed value $d(s)$, and fix an error allowance $\varepsilon \ge 0$. Suppose

$$\operatorname{dist}(\tau(w), d(r(w))) \le \varepsilon \qquad \text{for every allowed } w. \tag{17.3}$$

Lemma 17.8 (A shared record bounds target separation)**.** *If $r(w) = r(v)$, then*

$$\operatorname{dist}(\tau(w), \tau(v)) \le 2\varepsilon.$$

Proof. Both worlds are reconstructed as the same value $y = d(r(w)) = d(r(v))$. The triangle inequality and the two error guarantees give

$$\operatorname{dist}(\tau(w), \tau(v)) \le \operatorname{dist}(\tau(w), y) + \operatorname{dist}(y, \tau(v)) \le 2\varepsilon. \qquad \square$$

Theorem 17.9 (Capacity for separated approximate targets)**.** *Suppose a finite family has N target values, every distinct pair separated by more than 2ε. A readout satisfying* (17.3) *on this family requires at least N distinguishable records. For a bounded adaptive tree as above, it requires $N \le B^m$.*

Conditions and scope.

Conditions
A distance with symmetry and the triangle inequality, an error allowance ε met in every allowed world, and a family whose targets are separated by more than 2ε.

Not claimed
An optimal code, or a geometry beyond the stated distance.

Proof. If two members had the same record, Lemma 17.8 would contradict their strict separation. The record map is therefore injective on the selected family, giving the first bound. For the tree, use its padded transcript and reader. Lemma 17.6 transfers the procedure's error guarantee to this reader, and there are B^m possible transcripts. □

The strict inequality is the relevant margin. An approximation is permitted to merge sufficiently nearby targets. The theorem counts a family whose members are far enough apart that the specified error cannot hide their differences. It supplies a necessary capacity, without assuming a geometry or an optimal code beyond the stated distance and separation.

17.6 Finite length without a common budget

A different question arises when every individual record is finite but there is no single length bound for all records. Such a record family need not be finite. Its binary strings can still be encoded by natural numbers. Define

$$c(\varnothing) = 0, \qquad c(0s) = 2c(s) + 1, \qquad c(1s) = 2c(s) + 2. \tag{17.4}$$

Here $0s$ and $1s$ prepend a symbol to the finite string s.

Lemma 17.10 (Finite binary records have distinct natural-number codes)**.** *If $c(s) = c(t)$, then $s = t$.*

Proof. Induct on s. The empty string has code zero; every nonempty string has positive code, so equality with the empty string forces the other string to be empty. For two nonempty strings, a leading zero gives an odd code and a leading one gives an even code. Equal codes therefore have the same leading symbol. Subtract its offset and cancel the factor two to obtain equal tail codes. The induction hypothesis gives equal tails, hence equal strings. □

Theorem 17.11 (Exact finite-record identification is countable)**.** *Suppose every world yields a finite binary record, a reader exactly recovers its target, and different worlds have different target values. Then the world family injects into the natural numbers and is, classically, countable.*

Conditions and scope.

Conditions
Every world yields a finite binary record; a reader recovers the target exactly; different worlds have different targets.

Not claimed
A uniform length or time bound, or an apparatus that acquires the records. The identification of the physically real collections with those whose members leave exact finite records is not assumed here; the theorem says what follows for a collection that satisfies the conditions.

Proof. Lemma 17.2 makes the record map injective under the target-distinctness assumption. Compose that map with the injective code of Lemma 17.10. The result is an injection $w \mapsto c(r(w))$ into the natural numbers. □

No uniform length bound was used. Conversely, countability alone does not give a uniform record length, a time bound or an apparatus that can acquire the record. This is why the fixed-budget theorem and the countability theorem answer different questions.

The hypothesis is exact identification of the stated target family. A finite record can support a universal mathematical statement when it contains a proof whose rules justify that statement. The record-capacity argument does not count the objects mentioned in a proposition as though the reader had to identify each of them separately. It concerns a task whose different required answers must be distinguished by actual records.

17.7 What a record can confirm, refute or settle

A detector is examined once a second and reports 1 when it has fired and 0 otherwise. Two questions can be put to it. Has it ever fired? A record that ends in a 1 confirms this at once, but no record of zeros refutes it, since the next examination may fire. Will it never fire? Now a single 1 refutes the claim, and no finite record confirms it. Deciding the first question for every binary sequence is LPO and deciding the second is WLPO (Definition 7.8). That the two decisions are two of the omniscience principles is no accident. This section shows which questions finite records can confirm, refute or settle, and what deciding them costs, for any system that is examined again and again.

Worlds, records and recorders

Let W be a set of worlds, and let each world w yield a sequence of examination results $w(0), w(1), \ldots$ in a set A. The *record* of length n is $w{\restriction}n = (w(0), \ldots, w(n-1))$; two worlds *agree up to* n when their records of length n are equal. A *question* is a property Q of worlds. In the detector example W is the set of binary sequences, each read by itself; we call these worlds *binary runs*.

Definition 17.12 (Recorders)**.** A *recorder* is a rule R that assigns to every finite record either an answer, *yes* or *no*, or the mark $\circ$, meaning "read on". Its *answer on* w is $R(w{\restriction}n)$ for the least n at which this is not $\circ$, if there is one. R *confirms* Q when, for every world, $Q(w)$ holds exactly when the answer on w is *yes*; it *refutes* Q when $\neg Q(w)$ holds exactly when the answer on w is *no*; it *settles* Q when it does both. Q is *confirmable*, *refutable* or *settled* when some recorder confirms, refutes or settles it.

Q is Σ_1 when there is a set S of records with $Q(w) \Leftrightarrow \exists n\,(w{\restriction}n \in S)$, Π_1 when there is one with $Q(w) \Leftrightarrow \forall n\,(w{\restriction}n \in S)$, and Δ_1 when it is both. Q is *open* when every world w with $Q(w)$ has an n such that every world agreeing with w up to n satisfies Q, and *closed* when $\neg Q$ is open.

A recorder is any rule. It need not be computable, so the negative results below hold against unlimited computing power. We reason classically about worlds and recorders, as Section 7.12 reasons about its models; the cost theorems further on are proved without excluded middle or choice and say so.

Theorem 17.13 (Records confirm the open questions)**.** *For every set of worlds with its examinations and every question Q: Q is confirmable if and only if it is Σ_1, if and only if it is open; Q is refutable if and only if it is Π_1, if and only if it is closed; and Q is settled if and only if it is Δ_1, if and only if it is both open and closed.*

Conditions and scope.

Conditions
Any worlds and any question; recorders are arbitrary rules on finite records. The proof is classical: excluded middle decides whether a record forces Q. Applied to an experiment, the examinations are its successive outcomes and a recorder is its stopping rule.

Not claimed
That the constructed recorder can be carried out by a device, or any bound on the number of examinations it needs.

Proof. Say that a record r of length n *forces* Q when every world w with $w{\restriction}n = r$ satisfies Q. The *forcing recorder* answers *yes* at a record that forces Q, *no* at one that forces $\neg Q$, and $\circ$ otherwise; a record of an actual world cannot force both.

Let R confirm Q, and let $Q(w)$ hold, so that R answers *yes* first at $w{\restriction}n$. A world agreeing with w up to n has the same records up to that length, so R answers *yes* on it as well, and it satisfies Q. So Q is open. Conversely, let Q be open. If $Q(w)$, some record of w forces Q, so the forcing recorder answers on w, and its answer is *yes*, since no record of w forces $\neg Q$. If its answer on w is *yes*, a record of w forces Q, so $Q(w)$. Hence the forcing recorder confirms Q. If Q is Σ_1 with the set S, it is open, because agreeing worlds share their records; if Q is open, it is Σ_1 with S the set of records that force Q.

The three statements about refutation follow by applying these to $\neg Q$, with the answers exchanged and S replaced by its complement. A recorder that settles Q confirms and refutes it, so Q is open and closed; if Q is open and closed, the forcing recorder, which is the same rule for Q and $\neg Q$, confirms and refutes it. □

The theorem is the characterization, in formal learning theory, of the hypotheses that a method can verify, refute or decide with certainty [64, Chapter 4].

On binary runs, "ever fires" is Σ_1 and open, and "never fires" is Π_1 and closed. Neither is settled: the run of zeros agrees up to n with the run whose only 1 is at place n.

The zero test and the event test

The two detector questions are the model cases: the zero test reduces to every question that no recorder confirms, and the event test to every question that no recorder refutes, in the following sense.

Definition 17.14 (Finite-information maps and reductions)**.** A map Φ from worlds W' to worlds W has *finite information* when each examination of $\Phi(w')$ is fixed by finitely many examinations of w': for every w' and k there is an n such that $\Phi(v')(k) = \Phi(w')(k)$ for every v' agreeing with w' up to n. The *zero test reduces to* Q when a finite-information map Φ from binary runs has $Q(\Phi(\alpha)) \Leftrightarrow \forall n\, \alpha(n) = 0$; the *event test reduces to* Q when one has $Q(\Phi(\alpha)) \Leftrightarrow \exists n\, \alpha(n) = 1$. LLPO *reduces to* Q when one has, for every α with at most one entry 1, that $Q(\Phi(\alpha))$ gives $\alpha(2k) = 0$ for every k and $\neg Q(\Phi(\alpha))$ gives $\alpha(2k+1) = 0$ for every k.

The price proofs of Chapter 12 have this form: the jump construction of Theorem 12.6 turns a binary sequence into a point whose stages depend on finitely many entries.

Theorem 17.15 (What a record cannot settle)**.** *For every set of worlds and every question Q: Q is confirmable exactly when the zero test does not reduce to it; Q is refutable exactly when the event test does not reduce to it; and Q is settled exactly when neither test reduces to it.*

Conditions and scope.

Conditions
Any worlds and any question; the reductions are arbitrary finite-information maps and need not be effective. The proof is classical and chooses, for each n, a world witnessing the failure of openness at n.

Not claimed
That a reduction can be computed from a description of Q.

Proof. First, openness pulls back along a finite-information map Φ: if Q is open and $Q(\Phi(w'))$, choose n with every world agreeing with $\Phi(w')$ up to n in Q, and then, by finite information for $k < n$, an m such that every v' agreeing with w' up to m has $\Phi(v')$ agreeing with $\Phi(w')$ up to n. On binary runs "all zero" is not open, as noted above. So if the zero test reduces to Q, then Q is not open, and not confirmable, by Theorem 17.13.

Conversely, suppose Q is not open. Then some w_0 with $Q(w_0)$ has, for every n, a world y_n that agrees with w_0 up to n and fails Q. Let $\Phi(\alpha) = w_0$ when α is all zero, and $\Phi(\alpha) = y_N$ when the first entry 1 of α is at place N. Then $Q(\Phi(\alpha)) \Leftrightarrow \forall n\, \alpha(n) = 0$. For finite information at examination k: if α has its first 1 at N, every run agreeing with α up to $N+1$ has the same image; if α is all zero, every run agreeing with it up to $k+1$ is all zero or has its first 1 at some $N' > k$, and then $y_{N'}(k) = w_0(k)$.

The event test reduces to Q exactly when the zero test reduces to $\neg Q$, with the same map; this gives the statement about refutation. By Theorem 17.13, a question is settled exactly when it is confirmable and refutable. □

These reductions correspond to those of formal learning theory [64, Chapter 5].

On binary runs, questions that a record settles are as simple as they can be.

Theorem 17.16 (Settled questions about binary runs are finite)**.** *A question Q about binary runs is settled if and only if there is a number N such that any two runs that agree up to N have the same answer.*

Conditions and scope.

Conditions
All binary runs as worlds, and any question about them. The passage from a settling recorder to the number N is the one place in this section where compactness enters, through Kőnig's lemma for the binary tree [15] in its classical form.

Not claimed
A computable bound N, or a bound for other sets of worlds: on the promised runs of Theorem 17.17 no bound exists.

Proof. If N exists, every record of length N forces Q or forces $\neg Q$, so Q is open and closed. Conversely, let R settle Q. Call a finite binary string *undecided* when R gives $\circ$ at it and at every initial piece of it. The undecided strings form a tree: every initial piece of an undecided string is undecided. If there were undecided strings of every length, the tree would be infinite, and Kőnig's lemma would give a run α all of whose records are undecided. Then R would have no answer on α, whereas a recorder that settles Q answers *yes* on α if $Q(\alpha)$ and *no* otherwise. So for some N no string of length N is undecided: R answers on every run by the record of length N, and runs agreeing up to N receive the same answer. □

What deciding a question costs

The cost statements below are implications between decisions and principles, proved without excluded middle or choice, like the prices of Chapter 12; the statements about recorders beside them are classical, as before, except the hypothesis of Theorem 17.17(1), which must be proved without excluded middle.

Theorem 17.17 (The binary Markov principle costs time, not information)**.**

1. *If a recorder R is given, and it is proved without excluded middle that R settles Q, then* $\mathrm{MP}_{\mathrm{bin}}$ *implies that $Q(w)$ or $\neg Q(w)$ holds for every world w.*

2. *That cost is attained. On the promised runs, the binary runs that are not all zero, the question "the first entry* 1 *is at an even place" is settled, and its decision for every promised run is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$.

3. *No recorder settles that question within a bound fixed in advance: there are no recorder R and number N such that R settles it and answers on every promised run by the record of length N.*

Conditions and scope.

Logic

Part 1 and the equivalence in part 2 use no excluded middle, no choice principle and no omniscience principle besides $\mathrm{MP}_{\mathrm{bin}}$: whether a recorder answers at a given record is decided. The hypothesis of part 1 must be constructive; a question that is open and closed only classically can cost more: for a binary sequence β, the constant question "β is all zero" is classically open and closed on any set of worlds, yet deciding it at a world for every β is equivalent to WLPO (Definition 7.8), which intuitionistic second-order arithmetic does not derive from $\mathrm{MP}_{\mathrm{bin}}$ (Table 7.2). Part 3 and the settledness in part 2 are proved classically.

Not claimed

That every settled question costs exactly $\mathrm{MP}_{\mathrm{bin}}$; a question whose truth value is decided outright costs nothing.

Proof. (1) Fix w, and let $a(n) = 1$ when R answers at $w{\restriction}n$ and $a(n) = 0$ otherwise. The sequence a is not all zero: if it were, R would have no answer on w, so $Q(w)$ would fail, since R confirms Q, and $\neg Q(w)$ would fail, since R refutes Q. $\mathrm{MP}_{\mathrm{bin}}$ gives n with $a(n) = 1$, and a search through $a(0), \dots, a(n)$ finds the first answer. If it is *yes*, then $Q(w)$; if it is *no*, then $\neg Q(w)$.

(2) The recorder that reads on until the first 1 and then answers with its parity settles the question, since a promised run has a first 1. Given $\mathrm{MP}_{\mathrm{bin}}$, a promised run has an entry 1, a search finds the first one, and its parity decides the question. Conversely, suppose the question is decided on every promised run, and let α be not all zero. Decide it for α and for the shifted run α' with $\alpha'(0) = 0$ and $\alpha'(n + 1) = \alpha(n)$, which is also promised. If either first 1 is at an even place, α has an entry 1. If neither is, then every $\alpha(k)$ is 0: if $\alpha(k) = 1$, a search finds the first 1 of α at some $N \leq k$, and N even contradicts the first decision while N odd puts the first 1 of α' at the even place $N + 1$. This contradicts the promise, so absurdity gives an entry 1 in this case too.

(3) Suppose R and N exist. The runs whose only 1 is at $N + 1$ and at $N + 2$ agree up to $N + 1$, so R answers on both by the record of length N, and with the same answer. Their first entries 1 have different parities. □

So a question settled by a given recorder, constructively, costs at most the binary Markov principle, the guarantee that a search which cannot fail succeeds, and a settled question can cost exactly that. A recorder enacts that search by waiting, and what the waiting costs is time without a bound. The stronger principles cannot be bought this way. The principle paid here is $\mathrm{MP}_{\mathrm{bin}}$; the restricted schema of Theorem 6.9 costs nothing under induction on every formula, because a quantifier-free body comes with a bound.

Proposition 17.18 (The other prices are not paid by records)**.**

1. *Deciding "all zero" for every binary run is WLPO, and deciding "some entry is* 1*" for every binary run is LPO.*
2. *No recorder has an answer on every binary run with at most one entry* 1 *such that the answer is* yes *only when every even place is* 0*, and* no *only when every odd place is* 0*.*
3. *If the zero test, the event test or LLPO reduces to Q, then deciding Q for every world implies WLPO, LPO or LLPO respectively, and Q is not settled.*

The implications between decisions and principles in parts 1 and 3 use no choice principle.

Proof. (1) The first is the definition of WLPO. For the second, LPO gives a decision of "some entry is 1"; conversely, if it is decided for α, its failure gives $\alpha(n) = 0$ for each n, since $\alpha(n)$ is 0 or 1. (2) On the run of zeros such a recorder must answer, at some record of length n. If the answer is *yes*, the run whose only 1 is at $2n$ has the same record of length n, receives the same answer, and has a 1 at an even place; if it is *no*, use the place $2n + 1$. (3) A decision of Q at $\Phi(\alpha)$ is a decision of the reduced question at α. Theorem 17.15 covers the first two cases. If R settled Q and LLPO reduced to Q through Φ, then, because openness pulls back along Φ, the question $Q \circ \Phi$ about binary runs would be settled, and a recorder settling it would contradict part 2. □

Verdicts that may be revised

An experiment may also report a verdict after every examination and revise it. Such experiments reach further, and their reach is again exact.

Definition 17.19 (Guessing rules)**.** A *guessing rule* g assigns a verdict, *yes* or *no*, to every finite record. Its verdicts *settle on* b along w when $g(w{\restriction}n) = b$ for all large n. The rule *confirms Q in the limit* when $Q(w)$ holds exactly when its verdicts settle on *yes*, and *decides Q in the limit* when its verdicts settle on *yes* along every w with $Q(w)$ and on *no* along every other w. Q is Σ_2 when there are sets $S_0, S_1, \ldots$ of records with $Q(w) \Leftrightarrow \exists m\, \forall n\, (w{\restriction}n \in S_m)$, Π_2 when there are sets with $Q(w) \Leftrightarrow \forall m\, \exists n\, (w{\restriction}n \in S_m)$, and Δ_2 when it is both.

Theorem 17.20 (Revisable verdicts confirm exactly the Σ_2 questions)**.** *For every set of worlds and every question Q:*

1. *some guessing rule confirms Q in the limit if and only if Q is Σ_2, and some guessing rule decides Q in the limit if and only if Q is Δ_2;*
2. *every settled question is decided in the limit, and on binary runs the question "some entry is* 1*" is decided in the limit but not settled;*
3. *on binary runs, read as a census in which $\alpha(n) = 1$ records a region not recorded before, finiteness, $\exists N \forall n \geq N \alpha(n) = 0$, is Σ_2 and not Π_2, and no guessing rule decides it in the limit;*
4. *for observed orbits $x : \mathbb{N} \to \mathbb{Z}$, each read by itself, boundedness, $\exists B\, \forall t\, |x(t)| \leq B$, is Σ_2 and not Π_2, and no guessing rule decides it in the limit.*

Conditions and scope.

Conditions
Any worlds and any question; guessing rules are arbitrary rules on finite records, and the proof is classical.

Identification
That a cosmological census is a stream of new-region events, or an observed orbit a stream of recorded integers, and that every binary run is a possible census (every integer sequence a possible orbit), is a modelling assumption that the theorem does not supply.

Not claimed
A computable guessing rule, or a bound on when its verdicts settle.

Proof. (1) If g confirms Q in the limit, Q is Σ_2 with S_m the set of records that have verdict *yes* or length less than m. Conversely, let Q be Σ_2. Say that a candidate m *survives* a record r of length n when $m \le n$ and every initial piece of r, of every length up to n, lies in S_m. A candidate $m \le n$ that does not survive a record of length n survives none of its extensions. Let g answer *yes* at a nonempty record when it has a least surviving candidate and that candidate is also the least survivor of the record with its last entry removed, and *no* otherwise. If $Q(w)$, let c be the least m with every record of w in S_m. Each smaller candidate fails at some record, so from some length on the least survivor along w is always c, and the verdicts settle on *yes*. If the verdicts settle on *yes*, the least survivor is eventually constant, say a; then a survives every record of w, and $Q(w)$.

If g decides Q in the limit, it confirms Q in the limit, and with the verdicts exchanged it confirms $\neg Q$; and Q is Π_2 exactly when $\neg Q$ is Σ_2, with the complementary sets. Conversely, let Q and $\neg Q$ be Σ_2 with sets S_m and T_m. Run the candidates S_m at the even numbers $2m$ and T_m at the odd numbers $2m + 1$, and let the verdict be *yes* when the least survivor is even, or when there is none. The least candidate that survives every record of w exists and is even exactly when $Q(w)$, and the least survivor is eventually that candidate.

(2) If R settles Q, the rule that repeats the answer of R so far, and says *yes* before it has one, decides Q in the limit. The rule "*yes* once a 1 has appeared" decides "some entry is 1" in the limit; it is not settled, as noted after Theorem 17.13.

(3) Finiteness is Σ_2 with S_N the records whose entries at places $\ge N$ are 0. Suppose g decides it in the limit. Build strings $\sigma_0 \subseteq \sigma_1 \subseteq \cdots$: σ_0 is empty, and since σ_k followed by zeros is finite, g eventually says *yes* along it, at some record $\sigma_k 0^t$; put $\sigma_{k+1} = \sigma_k 0^t 1$. The run that extends every σ_k has infinitely many entries 1, yet g says *yes* at each of its records $\sigma_k 0^t$, so its verdicts do not settle on *no*. If finiteness were Π_2, it would be Δ_2 and decided in the limit by part 1.

(4) Boundedness is Σ_2 with S_B the records whose entries have absolute value at most B. For a census α let $x_\alpha(0) = 0$, and $x_\alpha(t + 1) = t + 1$ if $\alpha(t + 1) = 1$ and $x_\alpha(t)$ otherwise. This orbit is bounded exactly when the census is finite, and its record of length n is computed from that of α; so a rule deciding boundedness in the limit would decide finiteness, against part 3. As there, boundedness is not Π_2. □

These classes go back to the limiting recursion of Gold and Putnam [61, 62] and underlie formal learning theory [63, 64], where the topological reading of verifiable and refutable

hypotheses is standard. Here the rules are arbitrary, so the theorems concern information, not computation.

The exact value of a measured constant

A measured constant reaches us as a stream of readings at increasing precision. We take this as the measurement model: a *measured world* is a classical real number v, its value, together with rational readings $r_0, r_1, \ldots$ satisfying $|v - r_n| < 2^{-n}$ for every n; the n-th examination yields r_n. A real number y is *consistent* with a record $(r_0, \ldots, r_{n-1})$ when $|y - r_k| < 2^{-k}$ for every $k < n$.

Theorem 17.21 (An exact value can be refuted, never confirmed)**.** *In the measurement model, let c be a real number.*

1. *The question "the value is exactly c" is refutable, not confirmable and not settled, and the zero test reduces to it.*
2. *A record of a measured world establishes exactly that the value is consistent with it. The values of the measured worlds with a given record are exactly the values consistent with it; and if c is consistent with the record of length n of a measured world, then for some $\delta > 0$ every y with $|y - c| < \delta$ is the value of a measured world with the same record.*
3. *Every record consistent with the golden ratio φ is consistent with $\varphi + \varphi^{-K}$ for all large K, and these are pairwise different values, all different from φ.*

Conditions and scope.

Conditions
The measurement model, with strict tolerances; they make the consistent values an open set.

Identification
That a laboratory constant reaches experiment as such a world is the measurement model itself, which the theorem does not supply. An exact value cannot come from the record; the theorem does not say where one comes from or that any constant has one.

Not claimed
That any particular constant has the value c, or anything about measurements whose readings do not fit the model.

Proof. (2) The values consistent with a record form a finite intersection of open intervals, hence an open set; so if c is consistent, so is every y with $|y - c| < \delta$ for some $\delta > 0$. A measured world with that record has a consistent value, by its tolerances. Conversely, a consistent y is the value of the world whose readings begin with the record and continue with rationals within 2^{-k} of y.

(1) If the value v of a world differs from c, choose n with $2 \cdot 2^{-n} < |v - c|$. A world with the same reading r_n and value c would give $|v - c| \le |v - r_n| + |r_n - c| < 2 \cdot 2^{-n}$. So the record of length $n + 1$ forces the failure of the question, which is therefore closed and refutable by Theorem 17.13. It is not open: every record of a world with value c is, by part 2, the record of

a world with value $c + \delta/2$. So it is not confirmable, not settled, and the zero test reduces to it, by Theorem 17.15.

(3) Take δ from part 2 for $c = \varphi$. Since $0 < \varphi^{-1} < 1$, the numbers φ^{-K} are positive, decrease strictly and fall below δ. □

A finite agreement with a derived value therefore never separates it from its neighbours. Measurement can refute the identification of a constant with a derived value; it cannot confirm it.

The verdict of a law at finite precision

The same distinction appears inside $\mathbb{R}_\delta$, where no measurement model is needed. Let Σ be a set of states and call maps $\Sigma \to \mathbb{R}_\delta$ quantities. A *law* is built from atoms $x = y$, $x \le y$ and $x < y$ between quantities by $\wedge$, $\vee$ and conjunctions and disjunctions over $i < n$. At a state σ, the law *holds* when it is true with its atoms read in $\mathbb{R}_\delta$. It *passes the test at tolerance* $1/(k+1)$ when it is true after each atom $x \le y$ or $x < y$ is replaced by $x < y + 1/(k+1)$, and each $x = y$ by $x < y + 1/(k+1) \wedge y < x + 1/(k+1)$. It is *refuted* when an atom fails with a margin: $y < x$ refutes $x \le y$ and $x < y$, and $x < y \vee y < x$ refutes $x = y$; a conjunction is refuted when a conjunct is, and a disjunction when every disjunct is. A law is *closed* when it is built from equations and $\le$ by conjunctions only, and *strict* when its atoms are all strict.

Theorem 17.22 (The verdict of a law)**.** *Let ψ be a law, σ a state and k a natural number.*

1. *ψ passes the test at tolerance $1/(k+1)$ at σ, or it is refuted there. If it holds, it passes every test; if it is refuted, it does not hold.*
2. *If ψ is closed, it holds at σ exactly when it passes the test at every tolerance.*
3. *Passing a test, and being refuted, each hold exactly when some entry of a binary sequence is 1. If ψ is closed, it holds exactly when every entry of a binary sequence is 0; if it is strict, it holds exactly when some entry of a binary sequence is 1.*
4. *Let the two quantities of an atom take every pair of values in $\mathbb{R}_\delta$. Deciding the atom at every state is WLPO for $x = y$ and $x \le y$, and LPO for $x < y$. That every failure is a refutation is $\mathrm{MP}_{\mathrm{bin}}$ for $x = y$ and $x \le y$, and false for $x < y$. The law $x \le y \vee y \le x$ holds at every state exactly under LLPO, although it passes every test at every state.*

Parts 1 to 3 use no omniscience principle and no choice principle, and each equivalence in part 4 is proved in both directions without choice.

Conditions and scope.

Identification
Reading a physical law as such a law, and a test at finite precision as the tolerance test, identifies the physical quantities with points of $\mathbb{R}_\delta$; the theorem does not supply that identification.

Not claimed

A price for laws with quantifiers over infinite families, or for any particular physical law.

Proof. (1) Induction on the law. For an atom $x \le y$ or $x < y$, cotransitivity (Proposition 12.19) applied to $y < y + 1/(k+1)$ at x gives $x < y + 1/(k+1)$ or $y < x$; an equation uses this twice. A finite conjunction or disjunction of laws each of which passes or is refuted passes or is refuted, by finitely many case distinctions. The other two statements follow atom by atom: $x \le y < y + 1/(k+1)$ gives $x < y + 1/(k+1)$, and $y < x$ contradicts both $x \le y$ and $x < y$.

(2) If $x < y + 1/(k+1)$ for every k, then $y < x$ is impossible, since a positive $x - y$ exceeds some $1/(k+1)$ by Proposition 12.19; so $x \le y$. Two such inequalities give an equation, and conjunctions pass to their conjuncts.

(3) Fix regular sequences naming the values of the quantities at σ. A strict inequality $u < v$ says that the sequence for $v - u$ has a stage s_N with $s_N > 2/(N+1)$, a comparison of ratios decided at each N; so each atom of a test or of a refutation, and $x < y$ itself, holds exactly when some entry of a binary sequence is 1. Two such forms give one for their conjunction and for their disjunction, by searching both sequences up to each stage, and the same holds for finite families. A closed law holds exactly when it is not refuted, because $x \le y$ is $\neg(y < x)$ and $x = y$ is $x \le y \wedge y \le x$; and the negation of a form with some entry 1 is the form with every entry 0.

(4) Because the quantities take every pair of values, each assertion at every state is the same assertion for all points of $\mathbb{R}_\delta$, priced in Table 12.2; the rows used are the decisions of $x = y$, $x \le y$ and $x < y$, the row priced at $\mathrm{MP}_{\mathrm{bin}}$ that turns $\neg(y \le x)$ into $x < y$ and $x \ne y$ into $x < y \vee y < x$, and the dichotomy. For $x < y$, a state with $x = y$ fails the law and is not refuted, since $y < y$ is impossible. Every test of the dichotomy passes: by part 1, $x \le y$ passes it or $y < x$, and then $y < x + 1/(k+1)$. □

A finite-precision test of a law always has an outcome, and a closed law is the conjunction of its tests. Exactness is what costs: deciding an equation is WLPO, and the step from "not exactly true" to "visibly false" is the binary Markov principle $\mathrm{MP}_{\mathrm{bin}}$, not the restricted schema of Theorem 6.9, which costs nothing under induction on every formula.

17.8 The physical task left by the mathematics

The record results expose a concrete obligation for a physical construction. Specify the allowed preparations and the target. Show how the procedure produces the record, how it is retained, and how its reader returns the required answer within the stated error. Account for all information available to the reader and for the resources the procedure uses. The next two chapters take up that positive construction.

A counting theorem can reject a proposed capacity before an apparatus is built. A large enough capacity does not complete the apparatus. Likewise, an exact logical principle from Chapter 12 concerns which conclusions follow from an infinite presentation; a finite physical record requires an account of how the relevant information reaches the reader. Both questions have exact mathematical forms. Keeping their premises visible is what makes the connection useful.

Questions to work through

1. In Lemma 17.2, identify the assumption that fails if the reader also receives an unrecorded control setting. How should the record space be repaired?

2. Follow the transcript reader through a tree that stops before using its full budget. Explain why the padding symbol need not be distinguishable from every genuine test outcome.

3. Prove Theorem 17.4 for a selected family that is smaller than the whole world space. Which map must be injective?

4. Identify the uses of symmetry and the triangle inequality in Lemma 17.8. Explain why the separated-family theorem uses a strict margin.

5. Compare the hypotheses of Theorems 17.7 and 17.11. Explain why finite length for each record does not supply the same conclusion as a fixed common budget.

6. Show that the question "the run has at least two entries 1" about binary runs is confirmable and not refutable. Give a finite-information map that reduces the event test to it, and say what deciding the question for every run costs.

7. In part 2 of Theorem 17.17, a decision of the question for α alone is not enough to find an entry 1 of α. Which case does it leave open, and how does the shifted run close it?

8. A measured world has the readings $r_0 = 1$, $r_1 = 3/2$ and $r_2 = 13/8$. Which values are consistent with this record? Is the golden ratio φ? Find the largest δ for which every y with $|y - \varphi| < \delta$ is consistent, and the least K for which $\varphi + \varphi^{-K}$ is consistent.

Chapter 18

The construction of finite operations

A description of an apparatus must say more than which mark it prints. The apparatus can change its input, return a quantum system as well as a mark, and act on something correlated with another system. A construction that reproduces the marks while destroying those correlations may perform a different operation.

We will follow a finite instrument through four descriptions. First come the matrices that specify its action. Those matrices give an explicit reversible operation on a larger space. Finite sequences of elementary operations approximate that reversible operation. Finally, positive energy operators enact the required sequence, with its duration, error and scalar energy contribution retained.

There is a second question along the way: can a finite procedure find the approximating sequence from a description of the instrument? We prove an equivalence between two effective descriptions. One supplies rational approximations to the instrument's matrices; the other supplies finite operation sequences with a prescribed accuracy. The proof uses a search with rational certificates, so it never asks an exact equality question about an arbitrary real number. The chapter reasons in classical mathematics; the search, for instance, is shown to end because a sequence that passes its test exists.

The first calculation needs only multiplication of two-by-two matrices. Use it to keep the purpose of the larger construction in view: we must retain both the mark and the returned system. The later proofs use the finite spectral theorem to factor positive matrices and take unitary logarithms. The final control argument uses matrix exponentials and their derivatives. The matrix sections of Appendix C explain how these tools enter, including the difference between an isometry into a larger space and a unitary on that whole space.

18.1 An operation with a retained outcome

Fix positive integers a, b, s. The input has a basis states, the returned system has b basis states, and the classical mark has s possible values. The matrices in this chapter have complex entries. Write $K^{\dagger}$ for the conjugate transpose of K, and I for an identity matrix on the space indicated by the equation. In Part V the italic letters I and U always denote an identity matrix and a unitary matrix; the sans-serif I of Chapter 9 is an iterator, and the sans-serif U of Section 20.3 is a universal program (Appendix N).

A state is a positive semidefinite matrix ρ with trace one. Positivity means $v^{\dagger}\rho v \geq 0$ for every vector v. This includes the state $vv^{\dagger}$ of a unit vector and also statistical mixtures of such states. The trace condition fixes the total probability.

The same marks can conceal a different operation

Consider a system with two basis states and two possible marks, 0 and 1. The matrices

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad K_1 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \tag{18.1}$$

select the first and second basis states. Write an input state as $\rho = \left(\begin{smallmatrix} p & z \\ \bar{z} & q \end{smallmatrix}\right)$, so $p, q \geq 0$ and $p + q = 1$. Multiplication gives the two output blocks

$$K_0 \rho K_0^\dagger = \begin{pmatrix} p & 0 \\ 0 & 0 \end{pmatrix}, \qquad K_1 \rho K_1^\dagger = \begin{pmatrix} 0 & 0 \\ 0 & q \end{pmatrix}.$$

Their traces are p and q: the probabilities of the two marks. Their sum has trace one because $K_0^\dagger K_0 + K_1^\dagger K_1 = I$.

Now keep K_0 but replace the second matrix by

$$L_1 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}.$$

It still satisfies $K_0^\dagger K_0 + L_1^\dagger L_1 = I$, and

$$L_1 \rho L_1^\dagger = \begin{pmatrix} q & 0 \\ 0 & 0 \end{pmatrix}.$$

The probability of mark 1 is still q. For every input, both devices therefore print the same marks with the same probabilities. But after mark 1, the first device leaves the second basis state and the second device returns the first. On input $\rho = K_1$, mark 1 is certain and the returned states are different.

A description that keeps only the two probabilities cannot distinguish these devices. An instrument keeps the output blocks as well. The general definition below adds several possible branches for each mark; the example has one branch per mark.

Definition 18.1 (A finite instrument)**.** Choose a finite branch set Z and matrices $K_{yz} : \mathbb{C}^a \to \mathbb{C}^b$, where y is the retained mark. Require

$$\sum_{y,z} K_{yz}^\dagger K_{yz} = I_a. \tag{18.2}$$

The output is the block diagonal matrix whose yth block is

$$\mathcal{J}_y(\rho) = \sum_z K_{yz} \rho K_{yz}^\dagger.$$

The trace of this block is the probability of mark y. The mark is retained even when the branch label z is not read.

Every block is positive, since $u^\dagger K \rho K^\dagger u = (K^\dagger u)^\dagger \rho (K^\dagger u) \geq 0$. Taking the trace and using (18.2) shows that the traces of the output blocks sum to one. Thus the formula describes both the returned system and the probabilities of all marks.

Different lists of branch matrices can describe the same instrument. To avoid treating a choice of branch decomposition as extra information, form one matrix for each outcome:

$$C_y[(u,i),(v,j)] = \sum_z K_{yz}[u,i]\,\overline{K_{yz}[v,j]}. \tag{18.3}$$

Here i, j are input indices and u, v are output indices. These are the *Choi matrices* [23], with output indices written first. They determine the instrument because

$$\mathcal{I}_y(\rho)[u,v] = \sum_{i,j} C_y[(u,i),(v,j)]\rho[i,j].$$

Proposition 18.2 (Valid matrix descriptions)**.** *A family C_y describes a finite instrument precisely when*

$$C_y \geq 0 \quad \textit{for every } y, \qquad \sum_{y,u} C_y[(u,i),(u,j)] = \delta_{ij}. \tag{18.4}$$

For such a family, one can take $Z = \{1,\dots,b\}\times\{1,\dots,a\}$.

Proof. Given branch matrices, arrange their entries into columns indexed by z. Equation (18.3) is the product of this column matrix with its adjoint, so it is positive. Summing its output diagonal gives the transpose of $\sum_{y,z} K_{yz}^\dagger K_{yz}$, which is I_a.

Conversely, a positive finite matrix has a positive square root. This can be constructed by taking the nonnegative square roots of its eigenvalues in an orthonormal eigenbasis. Let $S_y = C_y^{1/2}$, and reshape its zth column into a b by a matrix:

$$K_{yz}[u,i] = S_y[(u,i),z].$$

The product $S_y S_y^\dagger = C_y$ gives (18.3). The normalization in (18.4), with i, j interchanged, gives (18.2). These are all the required conditions. □

This is a finite-dimensional existence construction. An exact choice of eigenvectors is not yet a procedure for obtaining an operation from successively better rational data. We will obtain that procedure by a different route.

18.2 An explicit reversible extension

The next construction is a finite-dimensional dilation: it realizes an operation as part of a reversible one on a larger space. Dilation theory originates with Stinespring [22]; here the block formula makes the action on the entire enlarged space explicit.

Imagine keeping every branch label for the moment. Define the rectangular matrix V by stacking the branch matrices:

$$V[(u,y,z),i] = K_{yz}[u,i].$$

Equation (18.2) says $V^\dagger V = I_a$. Thus V preserves lengths and inner products. It embeds the input into the larger space D with basis labels (u,y,z).

We need a reversible operation on a whole space, including states outside this embedded input. Rather than leave its action there unspecified, write it down.

Theorem 18.3 (A reversible extension with its unused space retained). *If $V^\dagger V = I_a$, put $P = VV^\dagger$. On $\mathbb{C}^a \oplus D$ define*

$$U_V = \begin{pmatrix} 0 & V^\dagger \\ V & I_D - P \end{pmatrix}. \tag{18.5}$$

Then $U_V^\dagger = U_V$, $U_V^2 = I$, and

$$U_V(v, 0) = (0, Vv).$$

Reading the output and mark coordinates, while retaining the complete branch sum, gives exactly the original instrument.

Conditions and scope.

Conditions
A matrix V with $V^\dagger V = I_a$, here the stacked branch matrices of a valid instrument, and an input state placed in the summand $\mathbb{C}^a$.

Not claimed
A device that enacts U_V, or a preparation that places the input in $\mathbb{C}^a$. The theorem is an identity between matrices; Theorem 18.11 supplies the register, controls and reader that approximate U_V.

Proof. The matrix P is self-adjoint and $P^2 = V(V^\dagger V)V^\dagger = P$. Also $(I_D - P)V = 0$ and $V^\dagger(I_D - P) = 0$. Therefore block multiplication gives

$$U_V^2 = \begin{pmatrix} V^\dagger V & V^\dagger(I_D - P) \\ (I_D - P)V & VV^\dagger + (I_D - P)^2 \end{pmatrix} = \begin{pmatrix} I_a & 0 \\ 0 & I_D \end{pmatrix}.$$

Self-adjointness follows by transposing the blocks and conjugating them. Multiplication by $(v, 0)$ gives $(0, Vv)$. Its (u, y, z) component is $K_{yz}v$ at output index u, so summing the unread branches produces the instrument's yth block. The same calculation applies to mixed input states by matrix multiplication and linearity. □

The extension is a concrete answer to the question, "What happens on the rest of the space?" Its complement is part of the operation. The input preparation must place the state in the designated input summand; that requirement is not supplied by the block identity itself.

18.3 A fixed register and a complete reader

Use a register of n eight-state cells. Its basis is the set of functions from $\{1, \dots, n\}$ to $\{0, \dots, 7\}$, so its dimension is 8^n. The choice of register can depend on a, b, s while remaining fixed for every valid instrument of those dimensions.

There is a convenient way to place a unitary in a determinant-one matrix. If U acts on a space E, use

$$\tilde{U} = U \oplus U^\dagger \oplus I_R. \tag{18.6}$$

This is unitary, has determinant $\det(U)\det(U^\dagger) = 1$, and agrees with U on the first summand. Choose $n \geq 2$ with $8^n \geq 2\dim E$, take $\dim R = 8^n - 2\dim E$, and fix a bijection of basis labels. Such an n exists; the deliberately generous choice $n = 2\dim E + 2$ suffices. Applied to (18.5), this supplies one layout for all instruments with the chosen dimensions.

An approximation to $\tilde{U}$ need not keep the input entirely within the intended output rows. The reader must still account for the whole output. Split the rows into normal rows (u, y, z) and complementary rows ℓ. Choose a default output u_0 and mark y_0. Each normal row retains its own output and mark. Each complementary row has a separate unread branch and is assigned to (u_0, y_0).

Proposition 18.4 (Complete readout preserves normalization)**.** *Let W be the columns of a unitary selected by the fixed input embedding. The branch matrices obtained by the above reader satisfy*

$$\sum_{y,z'} K_{yz'}^\dagger K_{yz'} = W^\dagger W = I_a,$$

where z' ranges over both normal and complementary branches. For the ideal placed unitary, the complementary branches vanish and its Choi matrices are the specified C_y.

Proof. Each row of W occurs exactly once in the sum of branch Gram matrices. Normal rows occur with their own output labels. A complementary row occurs at the default output and mark, with its own branch label. Expanding a matrix entry of the sum therefore gives exactly the same row sum as $W^\dagger W$. Distinct columns of a unitary are orthonormal. For the ideal operation, Theorem 18.3 puts the selected columns in the normal rows with entries $K_{yz}[u, i]$ and zero elsewhere. □

No outcome has been discarded or conditionally renormalized. Leakage into an unintended row is an error in the instrument, and the comparison below counts it.

18.4 An error bound that keeps a reference system

Suppose the input is correlated with a retained reference Q of any finite dimension. Its joint state τ is a positive trace-one matrix on $Q \otimes \mathbb{C}^a$. Define the joint output by retaining the reference, the returned system and the mark. Its yth diagonal block has entries

$$\mathcal{J}_C^Q(\tau)[(y, r, u), (y, r', v)] = \sum_{i,j} C_y[(u, i), (v, j)]\tau[(r, i), (r', j)]. \tag{18.7}$$

Blocks with different marks are zero. The branch factorization proves positivity, since this is a sum of $(I_Q \otimes K_{yz})\tau(I_Q \otimes K_{yz})^\dagger$.

For a Hermitian matrix X, write $\|X\|_1$ for the sum of the absolute values of its eigenvalues. We say that two instruments differ by at most ε on retained references if

$$\|\mathcal{J}_C^Q(\tau) - \mathcal{J}_D^Q(\tau)\|_1 \leq \varepsilon \tag{18.8}$$

for every finite Q and every joint state τ. This convention has no factor of one half. It requires no independence between input and reference.

Lemma 18.5 (Entry errors control the joint output)**.** *Suppose C, D are valid instruments and, for every entry and mark, $|C_y[p,q] - D_y[p,q]| \le \eta$, with $\eta \ge 0$. Then their error on retained references is at most*

$$sab^2\eta. \tag{18.9}$$

The bound does not grow with the reference dimension.

Proof. For a matrix A of size ab with entries bounded in absolute value by η, the triangle inequality and Cauchy–Schwarz give

$$|v^\dagger A v| \le \eta\Big(\sum_p |v_p|\Big)^2 \le ab\eta \sum_p |v_p|^2.$$

Take $A = C_y - D_y$, which is Hermitian. With $r = ab\eta$, this proves $rI \pm (C_y - D_y) \ge 0$ for every y.

Apply the positive output construction (18.7) to these two families. If X is the output difference and F is the output of the family with every block equal to rI, then $F + X \ge 0$ and $F - X \ge 0$. Thus, for every unit vector v, $|v^\dagger X v| \le v^\dagger F v$. Choose an orthonormal eigenbasis of X and sum this inequality. It gives $\|X\|_1 \le \operatorname{tr} F$.

The diagonal sum in (18.7), applied to the family rI, is $\operatorname{tr} F = sbr \operatorname{tr}\tau = sbr$. Substituting $r = ab\eta$ proves (18.9). The only reference contribution was its joint state inside $\operatorname{tr}\tau = 1$. □

Let m be the number of normal plus complementary unread branch labels in the fixed complete reader. If two unitaries are within η in operator norm, every corresponding entry differs by at most η. Their entries also have absolute value at most one. The elementary identity

$$x\bar{y} - u\bar{v} = (x-u)\bar{y} + u\overline{(y-v)}$$

therefore bounds each product difference by 2η. A Choi entry sums over m branches. Applying the lemma gives the useful implication

$$\|U - W\| \le \eta \quad \Longrightarrow \quad \text{joint output error} \le L\eta, \qquad L = 2msab^2. \tag{18.10}$$

All dimensions and the branch count are fixed before the target instrument and requested tolerance.

18.5 Two descriptions of finite operations

We now distinguish a finite alphabet used to describe operations from the continuous controls used to enact them. A cell label has three binary coordinates. On these coordinates use the Hadamard matrix

$$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

the phase matrix $\operatorname{diag}(1, i)$, and the Toffoli permutation that flips one coordinate when two selected control coordinates are both one. The target differs from each control, but the controls

may coincide; that case is controlled-NOT. A word is a finite list of such gates with their coordinate labels. Matrix multiplication assigns a unitary to each word.

Two properties of this alphabet do different jobs. First, a word's matrix and complete Choi readout admit effective rational approximations. Every entry is obtained by finitely many sums and products in $\mathbb{Q}(\sqrt{2}, i)$; certified rational enclosures for $\sqrt{2}$, propagated through those finite operations, give any requested entry accuracy. Second, on a fixed register with at least two cells, these words are dense in its special unitary group. The finite gate and matrix-generation arguments are developed in Appendix A. We need the existence of an approximating word here, without a runtime estimate for finding it.

Together with the explicit dilation and fixed placement, density gives a word whose complete Choi readout is within any positive entry tolerance of any valid target C. Indeed, approximate the placed unitary in operator norm and use the product estimate preceding (18.10).

Definition 18.6 (An effective instrument description)**.** An ordinary name of C is one finite procedure which, on input k, returns the full array of rational complex entries $q_y^{(k)}[p, q]$ and guarantees

$$|q_y^{(k)}[p, q] - C_y[p, q]| \le 2^{-k}.$$

A word name is one finite procedure which, on input k, returns a word whose complete readout differs from C by at most 2^{-k} on every finite retained reference. Its register and layout remain fixed as k varies.

The procedures are required to finish at every requested precision for the instrument they name. A mere assertion that a suitable word exists for each k does not yet give a word name.

18.6 Searching with a margin

To find a word, enumerate all finite words and test a rational certificate. For complex rationals z, w, use

$$d_1(z, w) = |\operatorname{Re}(z - w)| + |\operatorname{Im}(z - w)|.$$

This is decidable by rational arithmetic, and

$$|z - w| \le d_1(z, w) \le 2|z - w|. \tag{18.11}$$

The left inequality is the triangle inequality for real and imaginary parts; each part has absolute value at most $|z - w|$, proving the right. Test every Choi entry, not just the outcomes most likely on one input.

For requested output error 2^{-k} put

$$M = sab^2, \qquad h = k + M + 3, \qquad r = 2^{-h}, \qquad e = 2^{-(h+3)} = r/8. \tag{18.12}$$

Obtain target data q at entry accuracy e. For each candidate word, compute its complete readout data q_W at the same accuracy. Accept the first word for which $d_1(q_W[y, p, q], q[y, p, q]) \le r$ at every entry.

Lemma 18.7 (Soundness and termination of the search)**.** *For a valid named target, the search terminates. Every accepted word has joint output error at most 2^{-k}.*

Proof. If a word is accepted, its exact Choi entries differ from those of the target by at most

$$e + r + e = \tfrac{5}{4}r \le 2r.$$

The three terms are word-evaluation error, accepted rational discrepancy and target-naming error. Lemma 18.5 bounds the joint output error by $M(2r)$. Since $M \le 2^M$,

$$M(2r) \le 2^M\, 2\, 2^{-(k+M+3)} = 2^{-k}/4 \le 2^{-k}.$$

For termination, density supplies a word whose exact Choi entries are within e of the target. Its rational data and the target data are then within $3e = 3r/8 < r/2$ in absolute complex value. By (18.11), their rational discrepancy is less than r, so this word passes. Every individual test finishes, and enumeration eventually reaches a passing word. □

The slack has a purpose. Testing exact equality of two limits would not give a terminating decision. Here the acceptance test is finite, and density supplies a word strictly inside its tolerance. A nearby rejected candidate simply causes the search to continue.

18.7 Recovering the matrix description

The reverse direction also needs the retained reference. Suppose an operation is known to approximate an instrument on every joint input. Use a reference of dimension a and the normalized state

$$\tau_a = \frac{1}{a}\,\Omega\Omega^{\dagger}, \qquad \Omega = \sum_{i=1}^{a} e_i \otimes e_i. \tag{18.13}$$

Its trace is one, and it is positive. Substitution in (18.7) gives

$$\mathcal{J}_C^{Q}(\tau_a)[(y,i,u),(y,j,v)] = \frac{1}{a} C_y[(u,i),(v,j)].$$

Thus this one joint input exposes every Choi entry, with the known factor $1/a$.

Lemma 18.8 (Joint output control recovers every entry)**.** *If C, D have retained-reference error at most ε, then $|C_y[p,q] - D_y[p,q]| \le a\varepsilon$ at every entry.*

Proof. Apply the error bound to (18.13). Every entry of a Hermitian matrix has absolute value at most its trace norm: expand it in an orthonormal eigenbasis, use the triangle inequality, and bound each product of eigenvector coordinates by one. The displayed probe identity therefore gives $|C_y[p,q] - D_y[p,q]|/a \le \varepsilon$. □

Theorem 18.9 (Equivalence of effective finite descriptions)**.** *For fixed positive a, b, s and a valid finite instrument C, an ordinary name exists if and only if a word name exists. The forward translation can be carried out by one procedure fixed for those dimensions and their register layout, taking the ordinary name as an input.*

Conditions and scope.

Conditions
Fixed dimensions a, b, s, a valid instrument C, and a supplied name; both names are required to finish at every precision.

Not claimed
A procedure deciding whether a proposed description is valid, or an efficient search bound. The theorem concerns descriptions; it constructs no apparatus.

Proof. Given an ordinary name, run the rational search at each requested precision. Lemma 18.7 proves both termination and the required joint output accuracy. The instructions for evaluation, enumeration and testing are fixed; they call the supplied name at the precision in (18.12). This is the stated uniform forward translation.

Conversely, given a word name and requested entry accuracy 2^{-k}, call the word name at precision $j = k+(a+1)+3$. Evaluate that word's Choi entries to accuracy 2^{-j}. The probe lemma bounds the difference between its exact entries and the target entries by $a2^{-j}$. The triangle inequality gives total entry error at most $(a+1)2^{-j} \le 2^{-k}$. The last inequality follows from $a+1 \le 2^{a+1}$ and the extra factor 2^{-3}. This constructs a single ordinary naming procedure. □

The equivalence concerns descriptions of the whole instrument. It neither decides whether an arbitrary proposed description is valid nor gives a general efficient search bound. Validity and the supplied name are the premises under which termination has been proved.

18.8 Enacting a sequence with positive energy

The word description is now connected to a physical evolution. We state the controls as well as the energy they require. On the native register, the continuous elementary operations are cyclic three-state rotations within a cell and the two orderings of the adjacent-cell coupling

$$E = \frac{I + iX}{\sqrt{2}}, \qquad X = S \otimes F.$$

Here S is diagonal, with

$$S = \mathrm{diag}(1, -1, -1, 1, -1, 1, 1, -1).$$

The operator F swaps each even label with the following odd label. Both S and F are Hermitian involutions. Each elementary operation is e^G for an explicitly specified skew-Hermitian generator G. The rotations have continuously selectable real angles. These controls generate the full traceless skew-Hermitian matrix algebra on registers of at least two cells; the bracket argument and passage to finite words appear in Appendix A. Consequently their finite words approximate every special unitary on that register.

Fix a positive background energy operator $H \geq 0$, independently of the target operation. Let $\hbar > 0$ and choose a pulse duration $t > 0$. For a skew-Hermitian generator G, use the full energy operator

$$H_{G,t} = H + \frac{\hbar}{t}\big(iG + \|G\|I\big). \tag{18.14}$$

Since iG is Hermitian and its eigenvalues are at least $-\|G\|$, the parenthesized operator is positive. Hence $H_{G,t} \geq 0$. The scalar term is part of the energy operator even when a particular readout is insensitive to its phase.

The evolution for duration t is $e^{-itH_{G,t}/\hbar}$. The scalar part commutes with everything, so this equals

$$e^{-i\|G\|}\exp\big(G - itH/\hbar\big).$$

For skew-Hermitian matrices A, B, differentiating $e^{sA}e^{(1-s)B}$ and integrating from zero to one gives $\|e^A - e^B\| \leq \|A - B\|$: both exponential factors in the integrand are unitary and have norm one. Therefore

$$\big\|e^{-itH_{G,t}/\hbar} - e^{-i\|G\|}e^G\big\| \leq t\|H\|/\hbar. \tag{18.15}$$

For a word w of ℓ pulses, subtract the two products one factor at a time. Every other factor has norm one. The errors add, giving

$$\|U_{w,t} - e^{-ic(w)}W_w\| \leq \ell t\|H\|/\hbar, \qquad c(w) = \sum_{G \text{ in } w} \|G\|. \tag{18.16}$$

Here W_w is the ideal word matrix and $U_{w,t}$ is its actual evolution under the full pulse energies.

18.8.1 Retaining the phase

One can also match a target's full scalar phase. This matters when claiming an operator approximation, even though a common phase cancels in the quadratic instrument readout. A pair of inverse cyclic rotations leaves the ideal word unchanged and contributes 2θ to $c(w)$ when $\theta \geq 0$. For a desired phase e^{-ir}, choose

$$z = \left\lceil \frac{c(w) - r}{2\pi} \right\rceil, \qquad \theta = \frac{r + 2\pi z - c(w)}{2}. \tag{18.17}$$

The defining inequalities for the ceiling give $0 \leq \theta < \pi$. Appending the inverse pair makes the total scalar action $r + 2\pi z$, so the phase is exactly e^{-ir}. Both added pulses retain H and their positive scalar baseline.

Every finite unitary has a Hermitian logarithm: diagonalize the unitary, choose a real argument for each unit-modulus eigenvalue, and conjugate the diagonal arguments back. Subtracting the mean trace separates this logarithm into a scalar part and a traceless part. Approximate the latter by the native controls, and apply (18.17) to the former. This supplies an ideal word with the requested phase to any positive operator tolerance.

Theorem 18.10 (Finite positive-pulse realization)**.** *Fix a native register with at least two cells, $H \geq 0$, and $\hbar > 0$. For any unitary target U, error tolerance $\delta > 0$ and total duration bound $T > 0$, there is a finite native word and a positive common pulse duration t such that its full energy operators are positive, $\ell t < T$, and its actual evolution differs from U by less than δ in operator norm. The construction allows the amplitudes in* (18.14) *and externally selected switching.*

Conditions and scope.

Control
Pulses chosen from the native generators and switched by an external controller, each with the amplitude $\hbar/t$ of (18.14).

Resources counted
A fixed background energy $H \geq 0$, the scalar action $\hbar c(w)$ of (18.19), and total duration below T.

Not claimed
A bound on drive strength, which shrinking t would violate; an autonomous controller; or a model of actuator work and switching equipment.

Proof. Choose the ideal word and phase correction with error less than $\delta/2$, and let ℓ be its full length, including the two phase pulses. Set

$$t = \min\left\{\frac{\delta\hbar}{2(\ell\|H\| + 1)}, \frac{T}{\ell + 1}\right\}. \tag{18.18}$$

Both quantities are positive. The first gives $\ell t\|H\|/\hbar \leq \delta/2$, while the second gives $\ell t \leq \ell T/(\ell + 1) < T$. Equation (18.16) and the ideal approximation error then give a total error less than δ. Positivity was proved directly from (18.14). □

Shorter duration does not make the controls free. Their strength includes the factor $\hbar/t$. The integrated scalar baseline is exactly

$$\sum_{G \text{ in } w} t\frac{\hbar}{t}\|G\| = \hbar c(w). \tag{18.19}$$

The duration cancels; the action remains. This equality records that baseline contribution, rather than a complete model of actuator work, switching equipment or total experimental cost. A bound on available drive strength would add a constraint that Theorem 18.10 does not impose.

18.9 The finite bridge and its physical interfaces

Combine the constructions in their actual order (Figure 18.1). Positivity and normalization give branch matrices. Stacking gives an isometry. The block matrix gives a reversible extension. Adjoint padding puts it on a fixed register, complete readout counts every row, and the pulse construction approximates the placed unitary.

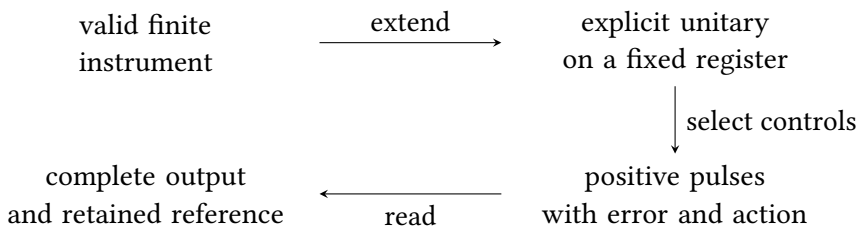

Figure 18.1. The finite bridge retains the whole operation. Input preparation, selectable controls and the complete reader are physical interfaces required by the construction. Error is compared on the returned system, mark and every finite retained reference.

Theorem 18.11 (Realization of a complete finite instrument)**.** *Fix positive dimensions a, b, s and default output and mark labels. There is a finite native register and a fixed input and complete-output layout, chosen before the target instrument, with the following property. For any valid C, any fixed positive background energy H on that register, $\hbar > 0$, tolerance $\varepsilon > 0$ and duration bound $T > 0$, the positive-pulse construction produces a complete instrument whose retained-reference error is at most ε, with total pulse duration less than T. It retains the scalar baseline* (18.19)*. It uses the selectable controls, input preparation and complete readout described above.*

Conditions and scope.

Preparation
The input is placed in the designated input summand of the fixed register layout.

Control
Externally selected positive-energy pulses, as in Theorem 18.10.

Reader
The complete readout of Proposition 18.4, which counts every normal and complementary row.

Resources counted
The background energy H, the scalar action $\hbar c(w)$, and total duration below T.

Identification
Applying the theorem to a laboratory apparatus identifies its cells, generators, preparation and reader with the native register, its controls and the complete readout.

Not claimed
An autonomous apparatus with bounded controls; access to every physical carrier; or a construction of the source fixture of Section A.8, whose Hamiltonian is an input.

Proof. Choose the register and layout using the fixed branch size ab and the dilation space; neither depends on the entries of C. Construct its ideal placed unitary U_C as above. Let $L = 2msab^2$ be the constant of the complete reader in (18.10). Apply Theorem 18.10 with operator tolerance $\eta = \varepsilon/(L+1)$ and duration bound T. Its output is unitary, so the complete reader remains normalized. Its error on every retained reference is at most $L\eta \le \varepsilon$. The ideal reader gives C exactly, and every pulse retains its positive energy and baseline contribution. □

Section A.8 gives a concrete record-and-field assembly to which the pulse theorem applies. It retains an old source on $14+2N$ cells, adds three complete record–reference pairs and two field banks, and specifies the added holding and edge energies. Its full register has $20+2N+4a+4b$ eight-state cells. Positivity follows on the whole register, including coordinates unused by the field code.

The old source's positive interior Hamiltonian is an explicit input to that assembly. The appendix does not derive the material source fixture or a microscopic actuator for it. Thus the application to the native two-flux source retains this supplied Hamiltonian, its fixed external fluxes and the same preparation, readout and control interfaces. The on-page construction establishes the record-and-field extension and the full-register transport needed here. It does not replace an unprovided source construction by a claim of universal physical access.

The conclusion has two complementary strengths. The naming equivalence shows that effective matrix descriptions and effective finite operation descriptions determine the same valid finite instruments. The pulse construction supplies explicit positive energy operators and carries their error through the complete reader. Establishing an autonomous apparatus with bounded controls, or establishing that every possible physical carrier belongs to this finite class, requires additional constructions. Those questions concern the remaining interfaces of this particular result.

Questions to work through

1. In the proof of Theorem 18.3, identify the exact use of $V^{\dagger}V = I$. Explain the role of $I_D - VV^{\dagger}$.

2. Expand one entry of the Gram sum for the complete reader. Explain why two complementary rows must not be combined into a single coherent branch before taking their Gram matrices.

3. Reproduce the three error terms in an accepted rational certificate and the three terms used to prove that some word is accepted. Why are these different arguments?

4. Trace the input-dimension factor a in Lemma 18.8. Identify the normalization that produces it.

5. Verify the two duration inequalities in (18.18) and the baseline identity (18.19). State which resource grows when the duration shrinks.

Chapter 19

Conservation and the cost of keeping a record

A recorder can have enough possible marks and still be unable to produce the right one. Imagine asking whether the first of two cells is occupied and the second is empty. The apparatus must couple to those cells, leave an outcome in a readable pointer, and obey its conservation laws throughout the interaction. These are requirements on one operation. They cannot be satisfied by choosing the record and the dynamics independently.

We will prove a quantitative limit for this question. Suppose the source is two native eight-state cells and the recorder supplies r more such cells, together with any finite neutral memory. Suppose the interaction exactly conserves the specified total clock energy and total occupation, and the final yes/no pointer is a sharp event in the neutral memory. If its yes probability differs from the desired one by at most e for every source state, then

$$e \geq \frac{1}{2(r^2+3)}. \tag{19.1}$$

The recorder's cells may be correlated with one another and with its neutral memory. The initial source and the complete recorder must be separate. We will state these conditions precisely before using them. The chapter reasons in classical mathematics, as Chapter 18 does.

The proof has three physical steps. Conservation restricts the event that can be read at the end of the interaction. Accuracy bounds the noise of that event. A particular source state then makes the restriction incompatible with arbitrarily small noise unless the recorder supplies sufficient charge spread. The constants in (19.1) come from a four-entry vector and a bound on a sum of r projections.

The conservation argument belongs to the line of work begun by Wigner and Araki and Yanase [26, 27], with quantitative measurement-error bounds developed by Ozawa [28]. The native charges and explicit witness below determine the particular bound here.

19.1 The event, the interaction and the pointer

Work first with an arbitrary finite-dimensional source space $\mathscr{H}_S$ and recorder space $\mathscr{H}_R$. The inner product is conjugate-linear in its first argument, and A^* is the adjoint of an operator A, the conjugate transpose written $A^\dagger$ in Chapter 18. A *sharp event* is an orthogonal projection: an operator P satisfying $P^* = P = P^2$. For a unit source vector x, the desired yes probability is $\langle x, Px\rangle$.

Prepare the recorder in a unit vector $p \in \mathscr{H}_R$. Inserting that preparation gives the isometry

$$J : \mathscr{H}_S \longrightarrow \mathscr{H}_S \otimes \mathscr{H}_R, \qquad Jx = x \otimes p.$$

The interaction is a unitary U on the full tensor product. (As in Chapter 18, the italic U is a unitary matrix and I an identity matrix; they are unrelated to the universal program U and the iterator I.) A sharp pointer B is read after the interaction. Its actual yes probability is

$$\langle UJx, BUJx\rangle.$$

Pull this final event back to the initial time:

$$Z = U^*BU, \qquad M = J^*ZJ. \tag{19.2}$$

The operator Z is a projection. The compressed operator M is an effect, meaning $0 \le M \le I$, but it need not be a projection. Its expectation is exactly the probability the apparatus produces:

$$\langle x, Mx\rangle = \langle UJx, BUJx\rangle.$$

Compression describes the given preparation and interaction. It does not supply a new event that the apparatus is free to choose.

Definition 19.1 (Uniform event accuracy)**.** The recorder has error at most e for the event P if

$$\big|\langle x, (M-P)x\rangle\big| \le e \qquad \text{for every unit } x \in \mathscr{H}_S. \tag{19.3}$$

The expression inside the absolute value is real. The preparation p, interaction U and pointer B are fixed across these source inputs.

Uniformity matters. An apparatus designed for one known state need not answer the same question on an unknown state. Our lower bound concerns a single recorder that meets (19.3) for all inputs.

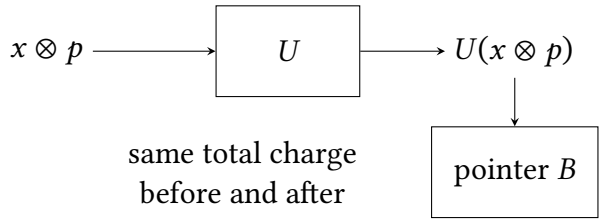

Figure 19.1. The pointer is read after the conserving interaction. Pulling it back gives the event $Z = U^*BU$ on the initial source and recorder.

19.2 Accuracy controls the noise of a sharp event

The discrepancy between the actual event and the ideal one can be measured on the full state, before any compression. Put $Q = P \otimes I$, so that $QJ = JP$, and define the noise operator $E = Z - Q$. On an input Jx, its squared norm is

$$\|EJx\|^2 = \langle x, (P + M - MP - PM)x\rangle. \tag{19.4}$$

Indeed, expand $(Z-Q)^2 = Z + Q - ZQ - QZ$, then use $Z^2 = Z$, $Q^2 = Q$, $J^*J = I$ and $QJ = JP$.

The following identity is what gives the useful constant. Let $D = M - P$. Expansion using $P^2 = P$ yields

$$P + M - MP - PM = (I-P)D(I-P) - PDP. \tag{19.5}$$

Thus the two contributions to the noise involve orthogonal parts of the same input.

Lemma 19.2 (Probability error bounds projection noise)**.** *If* (19.3) *holds, then*

$$\|(Z-Q)Jx\|^2 \le e\|x\|^2 \qquad \text{for every } x \in \mathscr{H}_S.$$

Proof. Rescaling a nonzero vector in (19.3) gives $|\langle y, Dy\rangle| \le e\|y\|^2$ for every y; the zero vector satisfies the same inequality directly. Apply this bound to $(I-P)x$ and Px in (19.5). Then

$$\begin{aligned}\|(Z-Q)Jx\|^2 &\le e\|(I-P)x\|^2 + e\|Px\|^2\\ &= e\|x\|^2.\end{aligned}$$

The last equality is the orthogonal decomposition given by P. □

The orthogonal decomposition is essential to this estimate. Bounding the two terms separately by $e\|x\|^2$ would lose a factor of two.

19.3 What exact conservation does to the pulled-back event

Let A and R be Hermitian charge operators on the source and recorder. Their total charge is

$$C = A \otimes I + I \otimes R. \tag{19.6}$$

Suppose the interaction conserves it exactly, $UC = CU$, and the final pointer commutes with it, $BC = CB$. The pulled-back event also commutes:

$$ZC = U^*BUC = U^*BCU = U^*CBU = CZ.$$

A pointer that is neutral for this charge supplies the second commutation condition. It is an actual requirement on the readout.

For Hermitian operators E, C, any vector ξ and any real number c,

$$\langle \xi, [E,C]\xi\rangle = \langle E\xi, (C-cI)\xi\rangle - \langle (C-cI)\xi, E\xi\rangle.$$

Here $[E,C] = EC - CE$. The scalar c cancels. The triangle and Cauchy–Schwarz inequalities give

$$|\langle \xi, [E,C]\xi\rangle|^2 \le 4\|E\xi\|^2\|(C-cI)\xi\|^2. \tag{19.7}$$

Take $E = Z - Q$. Since $[Z,C] = 0$, we have $[E,C] = -[Q,C]$. Combining (19.7) with Lemma 19.2, for a unit source vector x, gives

$$|\langle Jx, [Q,C]Jx\rangle|^2 \le 4e\|(C-cI)Jx\|^2. \tag{19.8}$$

This is the required measurement constraint. A nonzero commutator on the left forces either noise or charge spread on the right.

19.4 The native source and its two charges

We now specify the cells. One cell has basis $e_0, \dots, e_7$. Use the parity operator S and adjacent-pair flip F from Chapter 18. They obey

$$S^2 = F^2 = I, \qquad SF = -FS.$$

Consequently iSF is a Hermitian involution, and

$$N = \frac{I - iSF}{2} \tag{19.9}$$

is the occupation projection. The four-step cyclic shift Q_4 sends e_j to $e_{j+4 \bmod 8}$. It is another Hermitian involution. Write

$$P_c = \frac{I - Q_4}{2}. \tag{19.10}$$

It projects onto the odd Fourier modes. We will use its sum across cells as a charge count.

For completeness, let W be the normalized Fourier matrix

$$W_{jk} = \frac{\omega^{jk}}{\sqrt{8}}, \qquad \omega = e^{-2\pi i/8},$$

and define the dimensionless clock $K = W\mathrm{diag}(0, 1, \dots, 7)W^*$. The native clock energy is $H_0 = \varepsilon_0 K$, with $\varepsilon_0 > 0$. The value of this positive scale will cancel from the argument. The other conserved native quantity is N.

For any one-cell operator T, let

$$\mathscr{L}(T) = \sum_{j=1}^{r+2} T^{(j)} \otimes I_{\mathscr{H}_0}$$

act on the two source cells, r recorder cells and neutral memory $\mathscr{H}_0$. Superscript (j) means that T acts in slot j and identities act in the other slots.

Lemma 19.3 (The two native charges conserve the count)**.** *If U commutes with $\mathscr{L}(H_0)$ and $\mathscr{L}(N)$, then it commutes with $\mathscr{L}(P_c)$.*

Proof. Since $\varepsilon_0 \neq 0$, energy conservation implies commutation with $\mathscr{L}(K)$. Appendix B gives an explicit finite expression for P_c using I, K, N, complex linear combinations and commutators. It derives that expression from the entries of the specified eight-state matrices.

Operators on different slots commute. Hence $\mathscr{L}$ is linear and

$$\mathscr{L}([T_1, T_2]) = [\mathscr{L}(T_1), \mathscr{L}(T_2)].$$

It sends I to $(r+2)I$, which commutes with U. Commutation with U is preserved by sums, scalar multiples and commutators. Applying these facts in order to the finite expression proves the assertion. □

The count is therefore derived from the two specified conservation laws. It has not been added as a third conservation assumption. The calculation in the appendix is needed for that distinction.

On the two source cells, set

$$A = P_c \otimes I + I \otimes P_c, \qquad P = N \otimes (I - N). \tag{19.11}$$

The event P asks precisely whether the first cell is occupied and the second is empty. The count A and the event P do not commute. We next exhibit a source vector that quantifies their incompatibility.

19.5 A four-entry witness inside the actual source

The necessary calculation fits in a two-dimensional subspace of each cell. Define the eight-by-two matrix

$$V = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ -i & i \\ 0 & 0 \\ 0 & 0 \\ -1 & -1 \\ -i & i \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \qquad C_2 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \quad N_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}. \tag{19.12}$$

Its columns have norm one and are orthogonal. Substitution in (19.9) and (19.10) gives

$$V^*V = I, \qquad P_cV = VC_2, \qquad NV = VN_2.$$

Thus $V \otimes V$ is an isometric embedding of a four-dimensional space into the actual two-cell source, and it intertwines the source operators with

$$A_2 = C_2 \otimes I + I \otimes C_2, \qquad P_2 = N_2 \otimes (I - N_2).$$

These are restrictions of the stated native matrices, with the same inner products and expectations.

Use the coordinate order $00, 01, 10, 11$, and let

$$v_a = (i, 0, a, i)^T \qquad (a \in \mathbb{R}).$$

Direct multiplication gives

$$\|v_a\|^2 = a^2 + 2, \tag{19.13}$$

$$(A_2 - I)v_a = (a/2, i, i, a/2)^T, \tag{19.14}$$

$$\langle v_a, (A_2 - I)v_a \rangle = 0, \tag{19.15}$$

$$\|(A_2 - I)v_a\|^2 = a^2/2 + 2, \tag{19.16}$$

$$\langle v_a, [P_2, A_2]v_a \rangle = 2ia. \tag{19.17}$$

For example, $P_2 v_a = (0, 0, a, 0)^T$. The two terms in the last commutator expectation are $a^2 + ia$ and $a^2 - ia$, explaining their difference. In (19.15), the four contributions are $-ia/2, 0, ia, -ia/2$ and cancel.

Choose $a = \sqrt{2}$ and return to the source:

$$\psi = \frac{1}{2}(V \otimes V)v_{\sqrt{2}}.$$

Equations (19.13)–(19.17) then give

$$\begin{aligned} \|\psi\| = 1, \qquad & \langle \psi, (A - I)\psi \rangle = 0, \\ \|(A - I)\psi\|^2 = \frac{3}{4}, \qquad & |\langle \psi, [P, A]\psi \rangle|^2 = \frac{1}{2}. \end{aligned} \tag{19.18}$$

This one vector will suffice. We need no assumption that every source state has a large commutator expectation.

19.6 How much charge spread can the recorder supply?

Let the recorder consist of r eight-state cells and a finite neutral memory. Its space and count are

$$\mathscr{H}_R = (\mathbb{C}^8)^{\otimes r} \otimes \mathscr{H}_0, \qquad R = \sum_{j=1}^{r} P_c^{(j)} \otimes I_{\mathscr{H}_0}.$$

No product decomposition of $p \in \mathscr{H}_R$ is assumed. Its cells and memory may share arbitrary correlations.

Lemma 19.4 (A projection-sum budget)**.** *For any r orthogonal projections $R_1, \dots, R_r$ on the same space and any unit vector p,*

$$\left\| \left(\sum_{j=1}^{r} R_j - \frac{r}{2} I \right) p \right\|^2 \le \frac{r^2}{4}.$$

The projections need not commute with one another.

Proof. For each projection, $(R_j - I/2)^2 = I/4$. Hence $\|(R_j - I/2)p\| = \|p\|/2 = 1/2$. The triangle inequality gives

$$\left\| \sum_{j=1}^{r} (R_j - I/2)p \right\| \le \sum_{j=1}^{r} \|(R_j - I/2)p\| = r/2.$$

Squaring proves the claim. The empty sum also satisfies it. □

Applied to the recorder count, this proves

$$\|(R - rI/2)p\|^2 \le r^2/4. \tag{19.19}$$

The estimate already allows coherent and correlated recorder states. It has the quadratic scale required by that freedom. An independent-cell variance calculation would be a different premise and cannot be inserted here.

The complete initial state is $\psi \otimes p$. For $C = A \otimes I + I \otimes R$, we have

$$(C - (1+b)I)(\psi \otimes p) = (A - I)\psi \otimes p + \psi \otimes (R - bI)p.$$

The two terms are orthogonal because $\langle \psi, (A-I)\psi \rangle = 0$. The source is a separate tensor factor from the whole recorder, even when the recorder is internally correlated. Using (19.18),

$$\|(C - (1+b)I)(\psi \otimes p)\|^2 = \frac{3}{4} + \|(R - bI)p\|^2. \tag{19.20}$$

Also, $[P \otimes I, C] = [P, A] \otimes I$. Thus the left side of (19.8), on this input, is exactly $1/2$. We obtain the state-dependent inequality

$$\frac{1}{2} \le e\big(3 + 4\|(R - bI)p\|^2\big) \qquad \text{for every real } b. \tag{19.21}$$

19.7 The two-charge recorder theorem

We can now collect the physical requirements in one statement. A neutral memory carries the identity action of both native charges: it supplies storage and a pointer, but contributes no charge term.

Theorem 19.5 (Finite native recorder bound)**.** *Let the source be two native cells, with the event $P = N \otimes (I - N)$. Let the recorder consist of r native cells and an arbitrary finite neutral memory $\mathscr{H}_0$. Assume:*

1. *The initial state is $x \otimes p$, where p is one fixed unit recorder vector and x ranges over every unit source vector.*
2. *The interaction U is unitary on the whole source–recorder space and exactly conserves both $\mathscr{L}(H_0)$ and $\mathscr{L}(N)$.*
3. *The final pointer is $B = I_{\text{source}} \otimes I_{\text{recorder cells}} \otimes D$, where $D = D^* = D^2$ acts on the neutral memory.*
4. *For every unit source vector x,*

$$\big|\langle U(x \otimes p), BU(x \otimes p)\rangle - \langle x, Px\rangle\big| \le e.$$

Then

$$e \ge \frac{1}{2(r^2+3)}.$$

Conditions and scope.

Preparation
One fixed recorder vector p, separate from the source, and every unit source vector x; the recorder's cells and memory may be correlated with one another.

Conservation and pointer
Exact conservation of the two native charges $\mathscr{L}(H_0)$ and $\mathscr{L}(N)$ by the whole interaction, and a sharp pointer acting on the neutral memory alone.

Resources counted
The number r of charge-carrying recorder cells. The size of the neutral memory is unrestricted and does not enter.

Accuracy
Uniform event-probability error e over all source inputs.

Identification
Applying the bound to a device identifies its clock energy and occupation with the two native charges.

Not claimed
That the bound is attained, that a conserving recorder of this event exists for any r, or that other tasks obey the same constant.

Proof. Lemma 19.3 shows that U commutes with the total count C. The pointer B commutes with C because they act in different tensor factors. Thus $Z = U^*BU$ is a projection commuting with C. Its compression $M = J^*ZJ$ satisfies the uniform event bound.

Apply (19.21) with $b = r/2$, then Lemma 19.4. Accuracy implies $e \geq 0$, so the resulting inequalities have the indicated direction:

$$\frac{1}{2} \leq e\big(3 + 4\|(R - rI/2)p\|^2\big) \leq e(3 + r^2).$$

Divide by the positive number $r^2 + 3$. □

For every finite r, the lower bound is positive. An exact recorder of this event cannot satisfy all four conditions. A larger neutral memory alone does not remove the bound: its dimension never enters the charge budget. Increasing the number of charged cells relaxes the obstruction, but this inequality alone does not construct a recorder attaining it.

19.8 What the resource is, and what the result establishes

The resource appearing in the proof is the recorder's spread in the conserved count. Equation (19.21) retains the actual prepared state; (19.1) replaces that spread by a bound depending only on the number of native cells. The reference cells can exchange this count with the source while the total remains fixed. The neutral pointer reports an outcome without supplying that exchange itself.

The argument belongs to the conservation-law constraints on measurement associated with Wigner, Araki and Yanase. Its specific content here is the native realization: two stated charges imply the count conservation, an explicit embedded source vector fixes the constants, and the projection budget allows arbitrary internal recorder correlations. The statement is about uniform probability accuracy for one specified event. It is not a claim that every task has the same error bound or that the displayed constant is attainable by a conserving apparatus.

There is no conflict with the controlled constructions of Chapter 18. That chapter permits selectable pulses and records their positive energy operators. The theorem here requires an interaction conserving two exact total charges and a neutral sharp pointer. The control supply belongs in the complete physical account when those conditions are imposed. An operation that can be described and approximated with supplied controls need not be available to a closed recorder with a fixed finite charge resource.

The result sharpens the question raised by finite readout. We must ask both which distinctions a record can carry and which interactions can produce it. A physical construction answers the second question only after its preparation, conserved quantities, reference supply and readout have been specified together.

Questions to work through

1. Expand $(Z - Q)^2$ and derive (19.4). Identify every use of idempotence.
2. Verify (19.5). Explain why the two squared norms in Lemma 19.2 add to $\|x\|^2$.
3. Multiply the matrices in (19.12) to check $V^*V = I$, $P_cV = VC_2$ and $NV = VN_2$. Then check the four-entry witness.
4. Derive (19.20). Locate the exact step that uses the initial separation between source and recorder.
5. Trace where each of the four assumptions of Theorem 19.5 enters its proof. Which part of the proof permits correlations inside the recorder?

Chapter 20

What has been forced

Return to the first tally. One arrival leaves a mark; another arrival adds another. We wanted to know what survives when the marks change their shape, their material or their names. We now have several answers, because the question contains several requirements.

If a record preserves every finite step, its arithmetic structure is fixed up to the unique map that preserves the start and the step. If a reader identifies some records, the identifications must be studied as part of that reader. If a procedure answers a question at every requested precision, one rule must cover all those requests. And if an apparatus produces the record, its interaction must actually carry the required information into the available output.

These conclusions were reached by different arguments. Keeping the arguments connected, with their conditions intact, tells us what is unavoidable and what a further construction must provide.

20.1 The arithmetic structure is unique

The starting construction has two clauses: a start, and one further step. Every record is finite and has been obtained by those clauses. Structural induction follows that construction. It supplies the first proofs, including the facts that a step is never the start and that equal stepped expressions have equal predecessors. In the arithmetic language of Part II, each of these two facts, and induction, supplies statements that the other rules cannot (Section 5.7).

Now give any system a designated start and a step operation. There is exactly one map from the finite distinction orbit into that system that preserves those two operations. Theorem 2.3 constructs it: send the start to the designated start, then follow each step. Uniqueness comes from the same finite construction.

That map need not preserve every distinction. A clock that returns to a previous state is one possible target. Faithfulness and generation are the conditions that turn the unique map into an isomorphism. The target step must be injective, its start must not be a step, and every target element must be generated from the start. Under those conditions, no two finite records merge and no target element is omitted. This is Theorem 2.7.

Addition and multiplication are then fixed by their recursive clauses. Their algebraic laws follow by induction; they were not separately chosen to make the tally resemble familiar arithmetic. Conversely, a commutative semiring structure on the orbit in which adding its unit is the step must be the constructed one, and the orbit maps uniquely into every commutative semiring (Section 3.4). The reading into ordinary natural numbers preserves those operations and reflects equality. Signed differences and rational ratios extend the construction through explicit equivalence relations. Their operations are legitimate because changing a representative leaves the result in the same class. Each extension is also determined by its task (Section 4.9). The signed records complete the orbit's addition; the constructed

integers map uniquely into every commutative ring, and the constructed rationals into every field of characteristic zero; and each carries exactly one order compatible with its arithmetic. The line built from ratios in Chapter 12 is determined by its task in the same way, once countable choice is granted: every Archimedean ordered field maps into it in exactly one way that preserves the operations and the order (Theorem 12.38).

The necessity here has a precise form. A step system is faithful and generated exactly when its canonical reading is a bijection (Proposition 2.8), so any faithful generated tally has the same structure. Any operation satisfying the stated recursive clauses agrees with the constructed one; so does any associative operation for which adding 0 changes nothing and adding 1 takes one step (Theorem 3.10). The argument uses finite expressions, equality and induction in the mathematics with which the construction is studied. That induction ranges over all properties. Restricted to the formulas of an arithmetic language, it admits systems with elements that no tally reaches. Naming those resources makes the uniqueness claim exact.

20.2 Identifying records and extending logic are visible choices

A reader may retain less than the full tally. Chapter 7 describes identifications compatible with addition. Once a decidable congruence comes with an exhibited collision between distinct records, its form is forced: an initial segment followed by a repeating period. The classification proves that every collision has this form and that the least period controls all later identifications.

Changing the information supplied with the congruence, or the answer demanded of it, changes the price, and each price is exact. With a decision procedure and an exhibited collision the classification costs nothing. Replacing the collision by the assertion that the congruence is not equality costs Markov's principle MP, for decidable predicates (Definition 6.1). Keeping only the decision procedure, the parity of the index costs LLPO, the question whether the congruence is equality costs WLPO, and the full alternative costs LPO. With no decision procedure the alternative costs excluded middle. Theorems 7.6, 7.7, 7.9 and 7.10 prove these rows, and Theorem 7.11 gives the same prices for readers. In each case the reverse construction matters: the catalogue itself recovers the additional principle. These are equivalences, not merely observations that one familiar proof happens to use a stronger rule. The six prices are also different from one another. For each pair of principles, a model of intuitionistic second-order arithmetic satisfies one and refutes the other, and in each model every version of the classification has the truth value of its principle (Theorem 7.38). That system does not prove MP, so the classification from negative nontriviality genuinely needs it. Among the index–period congruences, exactly those of index zero extend to the signed records, each in one way, and the prices do not change there, provided the parity question is asked of the period: every index is zero, so its parity costs nothing, while the parity of the period costs exactly LLPO (Section 7.8).

The proof ledger of Chapter 6 makes a related distinction at the level of derivations. It records which of the specified additional rules occur, and combination retains every resource used by a premise. Soundness states which principles suffice to interpret the result, and interpreting any derivation needs at most the limited principle of omniscience in the metatheory, applied

to the predicates that formulas define; for the derivations with an EM or LPO entry, taken together, that is also the least assumption that serves. The rules themselves have exact prices. With induction on every formula, every instance of the MP rule, which is restricted to quantifier-free formulas, has a posit-free derivation, because a quantifier-free formula is eventually constant in its searched variable, and the LPO rule, which applies to every formula, derives every instance of excluded middle. The three names then mark only two strengths. Without induction, or with induction on quantifier-free formulas only, the LPO and MP rules are independent and EM is equivalent to the two together. The induction entry stays part of the accounting because these prices depend on it. The collapse concerns these arithmetic rules, not the principles about arbitrary decidable predicates priced in Chapters 7 and 12.

Chapter 9 goes further by separating rules of repetition inside a specified language. Repeating a fixed update, performing an indexed recursion and eliminating into an index-dependent family are different resources there. The countermodels satisfy the weaker rules while failing the proposed stronger judgment. The additional start discriminator has its own separating argument. These concrete models establish the strict boundaries in Theorem 9.10; the boundaries are attached to that calculus and its expressible judgments. The strongest fragment, $\mathscr{E}^{+}$, is the one compared with Peano arithmetic in Section 20.3.

Changing notation does not remove a logical cost. Where a translation is claimed to preserve a result, the translation must carry the relevant operations, assignments and quantifiers. Chapter 8 does this for numbers and lists of one mark. Every arithmetic formula has the same truth under related assignments. The proof transports witnesses in one direction and back in the other; the two round trips are what make the quantified statement possible.

With only one round trip, less transfers, and Theorem 8.8 with Proposition 8.9 says exactly what. Inside any structure obeying the six arithmetic rules the numerals form a copy of the numbers: quantifier-free statements transfer in both directions, purely existential statements go up and purely universal statements come down. A structure with two looping points shows that no other quantifier prefix transfers: a prefix containing a universal quantifier does not go up, and one containing an existential quantifier does not come down. The statement concerns all the formulas with a given prefix; a single universal sentence such as $\forall x(x + 0 = x)$ goes up because it is one of the six rules. The derivations can also be compared with an independent proof system. With excluded middle allowed and LPO and MP excluded, the rules of Chapter 5 prove exactly the theorems of Peano arithmetic, from every finite context (Theorem 8.11). With no added principle they prove exactly the theorems of Heyting arithmetic, and the posit-free derivations are the translations of its derivations, up to the way the injectivity of the successor is written (Corollary 8.12). Section 20.4 then asks, for each shape of statement, what a classical proof gives without excluded middle.

20.3 Peano arithmetic and a richer language

The first question a mathematician asks of these rules has a complete answer: with excluded middle they are Peano arithmetic, the system most mathematicians mean by arithmetic. A second question follows. Could a richer language, one that names functions and functions of functions, prove facts about numbers that those rules cannot? For sentences built from $=$, $\bot$, $\to$ and $\forall$, it cannot. Every such sentence that the richer language proves has a derivation by

the rules of Chapter 5 with no added principle, and the strongest typed fragment of Chapter 9 proves the translations of exactly the theorems of Peano arithmetic.

The proof runs the functions as programs. A proof about functions becomes a derivation, by the arithmetic rules, about the programs that compute them. Three ingredients make this possible, and the section supplies them in order: arithmetic formulas that describe computations, with derivations of their basic laws; one universal program whose correctness the rules themselves derive; and a reading of every formula about functions as a formula about programs, under which each of the nineteen rules of the richer language becomes a derivation. The central steps are proved here. Lengthy routine cases are proved in Appendix K: order and pairing, the coding of finite tables, the closure laws of computation, the test programs inside the record check, the closure generator, the reading of a variable, and the cases of conversion and of the dependent calculus.

A convention for this section. Every derivation constructed in this section is posit-free: its ledger records none of EM, LPO and MP. Its induction entry is usually true, because the derivations induct on formulas with quantifiers. We write $\Delta \vdash \varphi$ for a posit-free derivation of φ from the finite list of hypotheses Δ. Many results are *derived rules*: whenever a context Δ derives the premises, it derives the conclusion. Terms of the arithmetic language may stand for numbers in such statements; a result stated with free variables holds for every substitution of terms for them, because substitution preserves derivations. As in Chapter 5, we use named variables where the binding is clear.

20.3.1 The classical derivations are Peano arithmetic

Chapter 8 presents first-order *Peano arithmetic*, abbreviated PA, as a classical calculus of its own over the formulas of Definition 5.1: six axioms for the start, the step, addition and multiplication, the rules of natural deduction with equality, induction for every formula, and excluded middle. It keeps no ledger. Write $\Gamma \vdash_{\mathrm{PA}} \varphi$ when it derives φ from Γ. By Theorem 8.11, for every finite context Γ and every formula φ, $\Gamma \vdash_{\mathrm{PA}} \varphi$ holds exactly when the rules of Chapters 5 and 6 derive φ from Γ by a derivation whose ledger records neither LPO nor MP.

The theorem places a familiar system inside the accounting of Chapter 6. Peano arithmetic is what the rules prove when the ledger may record EM and quantified induction but neither of the other two principles. The rest of this section uses it to compare a richer language with both systems, and then asks what each system can prove about its own consistency.

20.3.2 A language of functions

The calculus of Chapter 9 can name more than numbers. We use its simplest part. The *finite types* are generated by

$$A ::= O \mid (A \to B).$$

Terms are variables $x_0, x_1, \ldots$, numbered by their distance from a binder as in Chapter 5, together with 0, $S(t)$, abstractions $\lambda A.\, b$, which bind x_0 in b, applications $f a$, iterations $\mathsf{I}(B, b, g, n)$ and indexed recursions $\mathsf{R}(B, b, g, n)$. The sans-serif I and R are the iterator and indexed recursor of Section 9.2, not the identity matrix I or the reading r of earlier chapters. A *type context* Θ lists

the types of the free variables, newest first. Seven typing rules give every term its type: x_k has the kth type of Θ, counting the newest as the 0th; $0 : O$; $S(t) : O$ when $t : O$; $\lambda A.\, b : A \to B$ when $b : B$ in the context A, Θ; $f a : B$ when $f : A \to B$ and $a : A$; $\mathsf{I}(B, b, g, n) : B$ when $b : B$, $g : B \to B$ and $n : O$; and $\mathsf{R}(B, b, g, n) : B$ when $b : B$, $g : O \to (B \to B)$ and $n : O$.

Two terms are *convertible*, $t \equiv u$, when they are related by the least equivalence relation that is closed under every term constructor and under substitution and contains the five computation equations

$$\begin{gathered} (\lambda A.\, b)\, t \equiv b[t], \\ \mathsf{I}(B, b, g, 0) \equiv b, \qquad \mathsf{I}(B, b, g, S(t)) \equiv g\, \mathsf{I}(B, b, g, t), \\ \mathsf{R}(B, b, g, 0) \equiv b, \qquad \mathsf{R}(B, b, g, S(t)) \equiv g\, t\, \mathsf{R}(B, b, g, t). \end{gathered} \tag{20.1}$$

As in Section 9.2, the intermediate terms of a conversion need not be typed. A *parallel step* $t \Rrightarrow u$ contracts any set of the redexes present in t at once: it is generated by the congruences for every constructor and by the five contractions, in which the parts of the redex may themselves take parallel steps. Write $\Rrightarrow^*$ for a finite chain of parallel steps.

Lemma 20.1 (Convertible terms meet)**.** *If $t \equiv u$, there is a term v with $t \Rrightarrow^* v$ and $u \Rrightarrow^* v$. If t has type A in Θ and $t \Rrightarrow^* v$, then v has type A in Θ.*

Proof. The first assertion is the argument of Lemma 9.12 for these five contractions. Let t° contract every redex present in t, recursively in its parts. Induction on a parallel step $t \Rrightarrow u$ shows $u \Rrightarrow t^\circ$; the substitution case uses that parallel steps commute with substitution. So two parallel steps from one term meet in one step each, finite chains meet by induction on their lengths, and having a common reduct is an equivalence relation that contains the computation equations and is closed under constructors and substitution. It therefore contains conversion. For the second assertion, induct on the parallel step and invert the typing of t at each constructor. In the abstraction contraction the body has type B in A, Θ and the argument has type A, and substituting a term of type A for the bound variable keeps type B. The four orbit contractions retype their right sides from the types of b, g and the count. □

The lemma concerns finite terms. It will be used only to choose which derivation to build.

Formulas and rules. Formulas are truth $\top$, falsehood $\bot$, equations $t =_A u$ between terms of type A, conjunctions $P \wedge Q$, implications $P \to Q$ and universal statements $\forall x{:}\, A\ P$, the last binding x_0 in P. A proof derives a judgment $\Theta; \Xi \vdash P$, in which Ξ is a finite list of hypotheses. Each rule carries the typing data of the terms it mentions; these are finite syntactic premises. Write $t{\uparrow}$, $P{\uparrow}$ and $\Xi{\uparrow}$ for the shift that raises every free variable index by one in a term, a formula or a list of formulas, as in Definition 5.2, $P[t]$ for substitution of t at position zero, written $P(t)$ in that definition, and P^S for the formula that replaces the variable x_0 of P by $S(x_0)$ and keeps every other variable. The nineteen rules are these.

(1) *Hypothesis*: $\Theta; \Xi \vdash P$ when P is a member of Ξ.

(2) *More hypotheses*: from $\Theta; \Xi \vdash P$ infer $\Theta; \Xi' \vdash P$ when every member of Ξ is a member of Ξ'.

(3) *Truth*: $\Theta; \Xi \vdash \top$.

(4) *Falsehood*: from $\Theta; \Xi \vdash \bot$ infer $\Theta; \Xi \vdash P$.

(5–7) *Conjunction*: introduction and the two eliminations.

(8–9) *Implication*: introduction, which discharges the newest hypothesis, and elimination.

(10) *Universal introduction*: from $A, \Theta; \Xi{\uparrow} \vdash P$ infer $\Theta; \Xi \vdash \forall x{:}A\ P$.

(11) *Universal elimination*: from $\Theta; \Xi \vdash \forall x{:}A\ P$ and $t : A$ infer $\Theta; \Xi \vdash P[t]$.

(12) *Reflexivity*: $\Theta; \Xi \vdash t =_A t$ for $t : A$.

(13) *Computation*: $\Theta; \Xi \vdash t =_A u$ when $t, u : A$ and $t \equiv u$.

(14) *Replacement*: from $\Theta; \Xi \vdash t =_A u$ and $\Theta; \Xi \vdash P[t]$ infer $\Theta; \Xi \vdash P[u]$, for P formed in A, Θ.

(15) *Successor is not zero*: $\Theta; \Xi \vdash S(t) =_O 0 \to \bot$.

(16) *Successor injectivity*: from $\Theta; \Xi \vdash S(t) =_O S(u)$ infer $\Theta; \Xi \vdash t =_O u$.

(17) *Function extensionality*: from $A, \Theta; \Xi{\uparrow} \vdash (f{\uparrow})\, x_0 =_B (g{\uparrow})\, x_0$ infer $\Theta; \Xi \vdash f =_{A \to B} g$.

(18) *Induction*: from $\Theta; \Xi \vdash P[0]$ and $O, \Theta; \Xi{\uparrow} \vdash P \to P^S$ infer $\Theta; \Xi \vdash \forall x{:}O\ P$, for every formula P formed in O, Θ, with parameters and quantifiers.

(19) *Substitution*: from $\Theta; \Xi \vdash P$ and a substitution σ that assigns to each variable of Θ a term of its type in Θ', infer $\Theta'; \Xi\sigma \vdash P\sigma$.

Systems of this kind are known as extensional arithmetic in all finite types [5, 6].

Arithmetic inside the language. The language has 0 and S but no addition or multiplication. They are terms defined by iteration:

$$\mathrm{add}(a, b) := \mathsf{I}\big(O, a, \lambda O.\, S(x_0), b\big), \qquad \mathrm{mul}(a, b) := \mathsf{I}\big(O, 0, \lambda O.\ \mathrm{add}(x_0, a{\uparrow}), b\big). \tag{20.2}$$

Addition starts at a and applies the successor b times; multiplication starts at 0 and adds a, b times. Under the binder, $a{\uparrow}$ is a shifted past the new variable. The defining equations are computations: $\mathrm{add}(a, 0) \equiv a$, $\mathrm{add}(a, S(b)) \equiv S(\mathrm{add}(a, b))$, $\mathrm{mul}(a, 0) \equiv 0$ and $\mathrm{mul}(a, S(b)) \equiv \mathrm{add}(\mathrm{mul}(a, b), a)$.

A formula of the arithmetic language built from $=$, $\bot$, $\to$ and $\forall$ is called *negative*. It embeds into the language of functions by the map $A \mapsto A^*$ that keeps variables, 0, S, $\bot$ and $\to$, sends $t + u$ to $\mathrm{add}(t^*, u^*)$ and $t \cdot u$ to $\mathrm{mul}(t^*, u^*)$, sends an equation $t = u$ to $t^* =_O u^*$, and sends $\forall A$ to $\forall x{:}O\, A^*$. If A is closed, A^* is formed in the empty type context. We say that the language of functions *proves* A when it proves A^* from no hypotheses in the empty context.

20.3.3 Computations described by arithmetic

The programs are those of Definition 10.5, with the numerical codes of (10.4): the basic programs zero, succ, left, right have codes 0, 1, 2, 3, and pair(f,g), rec(f,g), $f \circ g$ and search(f) have codes $4\langle u,v\rangle + 4$, $4\langle u,v\rangle + 5$, $4\langle u,v\rangle + 6$ and $4u + 7$ when f, g have codes u, v. Inside a formula a program letter stands for its code. Write id $:=$ pair(left, right), which returns its input.

Order and pairing are formulas of the arithmetic language. Write

$$a < b \ \text{ for } \ \exists k\,(a + S(k) = b), \qquad b \le a \ \text{ for } \ \exists l\,(b + l = a),$$

and let the *pairing graph* be

$$G(a,b,z) \ := \ \big(a < b \wedge z = b \cdot b + a\big) \vee \big(b \le a \wedge z = (a \cdot a + a) + b\big).$$

In $\mathbb{N}$ it says $z = \langle a,b\rangle$ for the pairing (10.3). Formulas use the graph, so no pairing symbol is added to the language.

Lemma 20.2 (Order and pairing in the rules)**.** *There are derivations from no hypotheses of: either $a < b$ or $b \le a$, and not both; for all a, b some z satisfies $G(a,b,z)$; $G(a,b,z)$ and $G(a,b,z')$ imply $z = z'$; $G(a,b,z)$ and $G(c,d,z)$ imply $a = c$ and $b = d$; and every z has some a, b with $G(a,b,z)$.*

The proofs are in Appendix K.1. They follow the arguments of Chapter 10 for the pairing (10.3), written as inductions inside the rules. Two of them, the order split and the decoding of every number, induct on formulas with quantifiers.

A successful computation is a finite table of evaluation facts. A row (k,e,n,y) says that the program with code e returns y on input n with *allowance* k: the allowance bounds the input and decreases at each step of a recursion or a search. A table is coded by two numbers through Gödel's remainder function. Let

$$\mathrm{Rem}(a,d,r) \ := \exists q, s\,\big(a = q \cdot d + r \wedge r + S(s) = d\big), \qquad \beta(A,B,i,w) \ := \mathrm{Rem}\big(A, 1 + (i+1)B, w\big).$$

Then $\beta(A,B,i,w)$ says that the ith entry of the table named by A, B is w. Row i of the table is (k,e,n,y) when its entry is the packed number $\langle k,\langle e,\langle n,y\rangle\rangle\rangle$, which we write $\mathrm{Row}(A,B,i;k,e,n,y)$, through three pairing graphs.

Table 20.1 lists the ten alternatives of the formula $\mathrm{Local}_{N,A,B,i}(K,e,n,y)$: the row at position i obeys one of the evaluation clauses of Definition 10.5, with the values it needs supplied by rows that stand later in the table. Define

$$\mathrm{Indexed}(N,A,B) \ := \forall i < N\, \exists K,e,n,y\,\big(\mathrm{Row}(A,B,i;K,e,n,y) \wedge \mathrm{Local}_{N,A,B,i}(K,e,n,y)\big),$$
$$\mathrm{App}(e,n,y) \ := \exists K,N,A,B,i\,\big(\mathrm{Indexed}(N,A,B) \wedge i < N \wedge \mathrm{Row}(A,B,i;K,e,n,y)\big).$$

The formula $\mathrm{App}(e,n,y)$ says that program e returns y on input n. It is a formula of the arithmetic language built from 0, S, $+$ and $\cdot$, with quantifiers.

Alternative	Conditions on the row (K, e, n, y), with $K = k + 1$ and $n \le k$
zero	$e = 0$, $y = 0$
successor	$e = 1$, $y = n + 1$
left	$e = 2$; $G(a, b, n)$; $y = a$
right	$e = 3$; $G(a, b, n)$; $y = b$
pairing	$e = \mathrm{pair}(f, g)$; $G(a, b, y)$; later rows (K, f, n, a) and (K, g, n, b)
composition	$e = f \circ g$; later rows (K, g, n, a) and (K, f, a, y)
recursion, start	$e = \mathrm{rec}(f, g)$; $G(a, 0, n)$; a later row (K, f, a, y)
recursion, step	$e = \mathrm{rec}(f, g)$; $G(a, m + 1, n)$; later rows $(k, e, \langle a, m\rangle, x)$ and $(K, g, \langle a, \langle m, x\rangle\rangle, y)$
search, stop	$e = \mathrm{search}(f)$; $G(a, m, n)$; $y = m$; a later row $(K, f, n, 0)$
search, continue	$e = \mathrm{search}(f)$; $G(a, m, n)$; $0 < x$; later rows (K, f, n, x) and $(k, e, \langle a, m + 1\rangle, y)$

Table 20.1. The local condition of a row. A later row is a row at a position j with $i < j < N$. Calls of a part of the program keep the allowance K; the two calls that repeat the program, the previous step of a recursion and the rest of a search, use $k = K - 1$. The letters a, b, m, x, f, g are existentially quantified, and every pairing is read through its graph.

Theorem 20.3 (Computation inside arithmetic)**.**

1. *For every program c and all numbers n, y, $\mathrm{App}(c, n, y)$ holds in $\mathbb{N}$ exactly when c returns y on n.*

2. Functionality*: there is a derivation from no hypotheses of* $\mathrm{App}(e, n, y) \to \mathrm{App}(e, n, y') \to y = y'$.

3. Closure*: there are derivations from no hypotheses of the following laws, one for each evaluation clause, with every variable universally quantified:*

$$\mathrm{App}(\mathrm{zero}, n, 0), \quad \mathrm{App}(\mathrm{succ}, n, n + 1), \quad \mathrm{App}(\mathrm{id}, n, n),$$
$$G(a, b, n) \to \mathrm{App}(\mathrm{left}, n, a), \qquad G(a, b, n) \to \mathrm{App}(\mathrm{right}, n, b),$$
$$G(a, b, y) \to \mathrm{App}(f, n, a) \to \mathrm{App}(g, n, b) \to \mathrm{App}(\mathrm{pair}(f, g), n, y),$$
$$\mathrm{App}(g, n, a) \to \mathrm{App}(f, a, y) \to \mathrm{App}(f \circ g, n, y),$$
$$G(a, 0, n) \to \mathrm{App}(f, a, y) \to \mathrm{App}(\mathrm{rec}(f, g), n, y),$$
$$G(a, m + 1, n) \to G(a, m, p) \to G(m, x, v) \to G(a, v, q) \to$$
$$\mathrm{App}(\mathrm{rec}(f, g), p, x) \to \mathrm{App}(g, q, y) \to \mathrm{App}(\mathrm{rec}(f, g), n, y),$$
$$G(a, m, n) \to \mathrm{App}(f, n, 0) \to \mathrm{App}(\mathrm{search}(f), n, m),$$
$$G(a, m, n) \to 0 < x \to G(a, m + 1, p) \to \mathrm{App}(f, n, x) \to$$
$$\mathrm{App}(\mathrm{search}(f), p, y) \to \mathrm{App}(\mathrm{search}(f), n, y).$$

   Here f, g range over codes, and the code of a compound program is given through its pairing graph, as in $e = 4p + 6$ with $G(f, g, p)$.

4. Finite choice*: for every formula $\varphi(i, r)$ there is a derivation of*

$$\forall i\, \exists r\, \varphi(i, r) \to \forall j\, \exists A, B\, \forall i < j\, \exists r \big(\beta(A, B, i, r) \wedge \varphi(i, r)\big).$$

Each derivation is posit-free and records the induction entry.

The proofs are in Appendix K.2. The first assertion lists the nodes of a computation tree with each parent before its children, and conversely rebuilds a tree from an indexed table by induction on the number of rows that follow a selected row. Functionality compares two independent tables by strong induction on that same number, which shrinks along every dependency of the first table; the bounds of the two tables need not agree. Finite choice appends one entry at a time to a coded table, using a Chinese remainder construction whose coefficients are written down explicitly. The closure laws raise the bounds of the premise tables, place them in one table, and add the parent row in front.

20.3.4 A universal program whose correctness the rules derive

How can rules that speak only about numbers check a proof that quantifies over functions? By running the functions. Each term of the language of functions will be compiled into a program, a function will be represented by the code of its program, and it will be applied through one fixed *universal program* U. (The sans-serif U is this program throughout; the italic U of Chapters 18 and 19 is a unitary matrix.) On an input $\langle e, n\rangle$, the program U searches $c = 0, 1, 2, \ldots$ for a number that a fixed *record test* accepts as a record of a computation of program e on input n, and returns the output written in that record.

Every compiled application runs through U, and so does every step of a compiled iteration. The compiled proofs therefore need one property of U as a derivation of the arithmetic rules, not merely as a true statement: if e returns y on n, then U returns y on $\langle e, n\rangle$. That property depends on how the record and its test are built.

A record that carries its justifications. The table formula of Table 20.1 would be a poor test. Its local condition says that suitable rows exist somewhere later in the table, so checking one row would itself require a search, and a derivation about the test would have to follow that inner search. The record removes the inner searches by writing down, for every row, the values its justification uses.

A record therefore has two tables. The first is a computation table (N, A, B). The second, (C, D), holds one *justification* for each row:

$$w_j = \langle q, s, f, g, u, v, x, j_1, j_2\rangle,$$

a list packed by repeated pairing, $\langle x_0, \ldots, x_m\rangle = \langle \cdots \langle\langle x_0, x_1\rangle, x_2\rangle \cdots, x_m\rangle$. Its eight read fields are the predecessor s of the row's allowance, the codes f, g of the parts of the row's program, the components u, v of a paired value the clause builds or decodes, the previous recursion value or the positive test value x, and the positions j_1, j_2 of the rows the justification relies on. The first field q is never read. A clause that needs fewer values ignores the remaining fields.

Definition 20.4 (The explicit row check and a valid record)**.** Let (N, A, B) be a table whose row j is (K, e, n, y). A number w, read as $\langle q, s, f, g, u, v, x, j_1, j_2\rangle$, *passes the explicit check at row* j when $K = s + 1$, $n \le s$, and one of the ten cases of Table 20.2 holds; there $j' \mapsto (k', e', n', y')$ means that $j < j' < N$ and row j' is (k', e', n', y'). A number

$$c = \langle q, C, D, N, A, B, i, K, y\rangle$$

is a *valid record* for $\langle e, n\rangle$ when, for every $j < N$, the w with $\beta(C, D, j, w)$ passes the explicit check at row j, when $i < N$, and when row i is (K, e, n, y). Its *output* is y, its last entry.

Case	Program e	Further conditions
zero	$e = 0$	$y = 0$
successor	$e = 1$	$y = n + 1$
left	$e = 2$	$n = \langle u, v\rangle$, $y = u$
right	$e = 3$	$n = \langle u, v\rangle$, $y = v$
pairing	$e = 4\langle f, g\rangle + 4$	$y = \langle u, v\rangle$, $j_1 \mapsto (K, f, n, u)$, $j_2 \mapsto (K, g, n, v)$
composition	$e = 4\langle f, g\rangle + 6$	$j_1 \mapsto (K, g, n, u)$, $j_2 \mapsto (K, f, u, y)$
recursion, start	$e = 4\langle f, g\rangle + 5$	$n = \langle u, 0\rangle$, $j_1 \mapsto (K, f, u, y)$
recursion, step	$e = 4\langle f, g\rangle + 5$	$n = \langle u, v + 1\rangle$, $j_1 \mapsto (s, e, \langle u, v\rangle, x)$, $j_2 \mapsto (K, g, \langle u, \langle v, x\rangle\rangle, y)$
search, stop	$e = 4f + 7$	$n = \langle u, v\rangle$, $y = v$, $j_1 \mapsto (K, f, n, 0)$
search, continue	$e = 4f + 7$	$n = \langle u, v\rangle$, $x > 0$, $j_1 \mapsto (K, f, n, x)$, $j_2 \mapsto (s, e, \langle u, v+1\rangle, y)$

Table 20.2. The ten cases of the explicit row check. The guard $K = s + 1$, $n \le s$ is common to all of them. They are the ten alternatives of Table 20.1, with every intermediate value and every supporting position written into the justification.

Every condition in the table is an equation, an inequality, or a comparison of one named row with four given numbers. The check is told which rows to look at and which intermediate values to use. It searches for nothing inside a row.

A worked record. The program succ $\circ$ succ has code $4\langle 1, 1\rangle + 6 = 18$, since $\langle 1, 1\rangle = 3$. On input 0 it returns 2. List the parent row first:

$$\text{row } 0 = (2, 18, 0, 2), \qquad \text{row } 1 = (2, 1, 0, 1), \qquad \text{row } 2 = (2, 1, 1, 2).$$

The allowance is 2 because the third row has input 1, and allowance $s + 1$ admits inputs up to s. The justifications are $w_0 = \langle 0, 1, 1, 1, 1, 0, 0, 1, 2\rangle$ and $w_1 = w_2 = \langle 0, 1, 0, 0, 0, 0, 0, 0, 0\rangle$. In w_0, the predecessor is $s = 1$, the part codes are $f = g = 1$, the intermediate value is $u = 1$, and the supporting rows are $j_1 = 1$ and $j_2 = 2$. The composition case holds at row 0: its guard is $2 = 1 + 1$ with $0 \le 1$; rows 1 and 2 are later rows below 3; row 1 is $(K, g, n, u) = (2, 1, 0, 1)$; and row 2 is $(K, f, u, y) = (2, 1, 1, 2)$. Rows 1 and 2 pass the successor case. With (A, B) coding the three packed rows and (C, D) the three justifications, $\langle 0, C, D, 3, A, B, 0, 2, 2\rangle$ is a valid record for $\langle 18, 0\rangle$ with output 2.

The test and the universal program. The checking programs are built from the eight constructors without the search constructor; their constructor expressions are given or described in Appendix K.3. A *test* is a program whose value is read as a verdict, positive for yes. The *zero indicator* ζ returns 1 on 0 and 0 elsewhere. The equality test of two programs adds the two truncated differences of their values and applies ζ; the test $a \le b$ applies ζ to $a \dot{-} b$; conjunction and disjunction of tests multiply and add their values. The *recognizer* Ver receives $\langle\langle e, n\rangle, c\rangle$, reads the fields of c by projections, and returns the conjunction of three tests: the bounded universal test over $j < N$ of the explicit row check at row j, the order test $i < N$, and the comparison of row i with (K, e, n, y). Then

$$T := \zeta \circ \mathrm{Ver}, \qquad \mathsf{U} := \mathrm{right} \circ \mathrm{search}_0(T), \qquad \mathrm{search}_0(T) := \mathrm{search}(T) \circ \mathrm{pair}(\mathrm{id}, \mathrm{zero}).$$

The test T returns 0 to accept and 1 to reject. On input p, the program $\mathrm{search}_0(T)$ tests T at $\langle p, 0\rangle, \langle p, 1\rangle, \ldots$ and returns the first c with $T(\langle p, c\rangle) = 0$; the final right projection returns the last entry of c, which is the output written in the record. In $\mathbb{N}$, by Theorem 20.3(1), U returns y on $\langle e, n\rangle$ exactly when e returns y on n. The compiled proofs need more than that truth: they need derivations.

Theorem 20.5 (The record test is correct)**.** *The rules of Chapter 5 give posit-free derivations, from no hypotheses, of the following two statements.*

Acceptance. *If* $\mathrm{Indexed}(N, A, B)$, $i < N$, $\mathrm{Row}(A, B, i; K, e, n, y)$ *and* $G(e, n, p)$*, then for some* c *and* z *with* $G(p, c, z)$*, the test returns* 0 *on* z*:* $\mathrm{App}(T, z, 0)$.

Record soundness. *If* $G(e, n, p)$*,* $G(p, c, z)$ *and* $\mathrm{App}(T, z, 0)$*, then there are* y *and* q *with* $G(q, y, c)$ *and* $\mathrm{App}(e, n, y)$.

Each derivation records the induction entry and none of EM, LPO and MP.

The proof rests on three lemmas. The first runs the checking programs; it is proved in Appendix K.3 by following the program, using the closure laws of Theorem 20.3 at each constructor and induction along each recursion.

Lemma 20.6 (The row check returns and decides)**.** *There are derivations of the following, for all* X, j, p *such that the field programs return* A, B, N, C, D *on* X *and* $G(X, j, p)$*: the explicit row-check program returns a value on* p*, and that value is positive exactly when some* w *with* $\beta(C, D, j, w)$ *passes the explicit check at row* j *of* (N, A, B)*. The bounded universal test over* $j < N$ *returns a value, which is positive exactly when the row check is positive at every* $j < N$*. The test* T *returns* 0 *or* 1 *on every input.*

Lemma 20.7 (A justification and the local condition say the same thing)**.** *There are derivations of: if* w *passes the explicit check at row* j *of* (N, A, B)*, then row* j *has some coordinates* (K, e, n, y) *satisfying* $\mathrm{Local}_{N,A,B,j}(K, e, n, y)$*; and conversely, if row* j *is* (K, e, n, y) *and* $\mathrm{Local}_{N,A,B,j}(K, e, n, y)$ *holds, then some* w *passes the explicit check at row* j.

Proof. For the first, open the nine fields of w and the coordinates of row j. The guard gives the allowance predecessor and the input bound of the local condition. Each case of Table 20.2

gives the alternative of Table 20.1 with the same name: a named row $j_1 \mapsto (\cdots)$ is a later row, with j_1 as the witness and $j < j_1 < N$ together with the row comparison as its matrix; the paired values are the pairing-graph witnesses; and f, g are the code witnesses. Disjunction elimination over the ten cases and existential introduction finish the derivation, which uses no induction.

For the converse, open the alternative that holds and its witnesses: the allowance predecessor, the part codes, the paired values and the later positions. These are the eight read fields; set a field the alternative does not use to 0. Pairing totality (Lemma 20.2), applied eight times starting from 0, gives $w = \langle 0, s, f, g, u, v, x, j_1, j_2 \rangle$ together with the pairing graphs that the check reads back, and the case with the same name holds of w. □

Lemma 20.8 (Collecting the justifications)**.** *There is a derivation of: if* Indexed(N, A, B)*, then there are C, D such that for every $j < N$ some w with $\beta(C, D, j, w)$ passes the explicit check at row j.*

Proof. Apply finite choice, Theorem 20.3(4), to the formula $\varphi(i, w)$: if $i < N$, then w passes the explicit check at row i. Its premise holds at every i. By the order split, either $i < N$, and then indexedness gives row i with its local condition and Lemma 20.7 gives a justification; or $N \leq i$, and then $i < N$ is refuted by the disjointness of the two order branches, so $w = 0$ serves. Finite choice at $j = N$ gives C, D; for $j < N$, the stored w satisfies $\varphi(j, w)$, and $j < N$ discharges its implication. □

Proof of Theorem 20.5. Acceptance. Lemma 20.8 gives C, D holding a justification for every row below N. Pairing totality packs the record $c = \langle 0, C, D, N, A, B, i, K, y \rangle$ and the input z with $G(p, c, z)$, and supplies every pairing graph used in the packing. On z the field programs return the packed fields, and the projections of p return e and n. At every cell $\langle z, j \rangle$ with $j < N$ the stored justification passes the explicit check, so by Lemma 20.6 the row check is positive there and the bounded universal test is positive on z. The order test for $i < N$ and the comparison of row i with (K, e, n, y) return values, positive by hypothesis, by Lemma K.5. Their product is a positive value $r = d + 1$ of Ver on z, and ζ sends a successor to 0, so the composition law gives App$(T, z, 0)$.

Record soundness. Decode c into $\langle q_0, C, D, N, A, B, i, K, y \rangle$ with the decoder of Lemma 20.2; its last pairing gives $G(q, y, c)$. By Lemma 20.6, Ver returns some value r on z, and ζ returns some b on r, so App(T, z, b). Functionality, Theorem 20.3(2), and the hypothesis App$(T, z, 0)$ give $b = 0$. The zero indicator returns 0 only on a successor, so r is positive. The value r is the product of three test values, and a product of natural numbers is positive exactly when its factors are, so each test value is positive, and Lemmas K.5 and 20.6 read off what each says: $i < N$, row i is (K, e, n, y), and the row check is positive at every $j < N$. Lemma 20.6 gives each such row a passing justification and Lemma 20.7 its local condition. That is Indexed(N, A, B), and with $i < N$ and row i it is App(e, n, y).

Every step either applies a derived lemma or is logic, equality and arithmetic on supplied witnesses. Every case split eliminates a disjunction that has itself been derived. No EM, LPO or MP rule occurs. □

The universal program does not look for the record that acceptance built. It looks for the first number the test accepts, which may be a different record. Two facts keep that difference harmless.

Lemma 20.9 (The search finds a record)**.** *There is a derivation of: if* $G(p, c, z)$ *and* $\mathrm{App}(T, z, 0)$*, then* $\mathrm{search}_0(T)$ *returns on* p *some* $d \le c$*, and* T *returns* 0 *on the* w *with* $G(p, d, w)$*.*

Proof. Prove more, by induction on h in a formula universal in s: for every gap h and every s, if $s + h = c$ and T returns 0 on $\langle p, c\rangle$, then the search started at $\langle p, s\rangle$ returns some $d \le c$ at which T returns 0. Induct on h. If $h = 0$, then $s = c$ and the search-stop law returns s. For $h + 1$, the test returns 0 or 1 at $\langle p, s\rangle$ (Lemma 20.6). If it returns 0, the search stops at s. If it returns 1, the search-continue law passes to $s + 1$, whose gap is h, and the induction hypothesis gives d. At $s = 0$, the identity and zero laws and the pair law give the input $\langle p, 0\rangle$, and the composition law connects $\mathrm{search}_0(T)$ on p with the search started there. □

Lemma 20.10 (Universal application)**.** *The rules of Chapter 5 give a posit-free derivation, from no hypotheses, of*

$$\forall e, n, y, p\ \big(G(e, n, p) \to \mathrm{App}(e, n, y) \to \mathrm{App}(\mathsf{U}, p, y)\big).$$

If program e *returns* y *on input* n*, then* U *returns* y *on* $\langle e, n\rangle$*.*

Proof. Assume $G(e, n, p)$ and $\mathrm{App}(e, n, y)$, and open the application: an allowance K and a table (N, A, B) with $\mathrm{Indexed}(N, A, B)$, $i < N$ and $\mathrm{Row}(A, B, i; K, e, n, y)$.

1. Acceptance gives c, z with $G(p, c, z)$ and $\mathrm{App}(T, z, 0)$.
2. Lemma 20.9 gives d, w with $\mathrm{App}(\mathrm{search}_0(T), p, d)$, $G(p, d, w)$ and $\mathrm{App}(T, w, 0)$.
3. Record soundness at e, n, p, d, w gives y', q with $G(q, y', d)$ and $\mathrm{App}(e, n, y')$.
4. Functionality gives $y' = y$.
5. The projection law gives $\mathrm{App}(\mathrm{right}, d, y')$.
6. The composition law for $\mathsf{U} = \mathrm{right} \circ \mathrm{search}_0(T)$ combines steps 2 and 5 into $\mathrm{App}(\mathsf{U}, p, y')$.
7. Equality substitution with $y' = y$ gives $\mathrm{App}(\mathsf{U}, p, y)$.

The conclusion contains none of the temporary witnesses, so every existential elimination closes. The derivation never compares the record found by the search with the record built by acceptance: record soundness says that any accepted record describes an actual computation, and functionality says that all such computations have one output. □

20.3.5 Equality that follows the type

A function is represented by the code of a program. Two codes need not be equal numbers to represent the same function, so equality at a function type must compare what the programs do. It must also require the computations to return. Define formulas $e \simeq_A f$ by recursion on the type:

$$\begin{aligned} e \simeq_O f &:= e = f, \\ e \simeq_{A\to B} f &:= \forall x, y \left(x \simeq_A y \to \exists u, v \left(\mathrm{App}(e, x, u) \wedge \mathrm{App}(f, y, v) \wedge u \simeq_B v\right)\right), \end{aligned}$$

and call e *admissible* at A when $H_A(e) := e \simeq_A e$. This is *hereditary extensional equality*: at an arrow type it asks for actual outputs on every pair of related inputs, and relates the outputs at the result type. Every number is admissible at O. At an arrow type a code is admissible only when it returns related outputs on related admissible inputs; there is no blanket assumption that programs terminate. Each formula $e \simeq_A f$ is a formula of the arithmetic language, since its clauses use App and quantifiers over numbers only.

Proposition 20.11 (Symmetry and transitivity)**.** *For every finite type A there are derivations from no hypotheses of*

$$e \simeq_A f \to f \simeq_A e \qquad \text{and} \qquad e \simeq_A f \to f \simeq_A g \to e \simeq_A g.$$

Proof. Recurse on A. At O both are the symmetry and transitivity of equality. At $A \to B$, for symmetry take $x \simeq_A y$; symmetry at A gives $y \simeq_A x$; the hypothesis at y, x gives outputs u of e on y and v of f on x with $u \simeq_B v$; return v and u, related by symmetry at B.

For transitivity at $A \to B$, take $x \simeq_A y$. Symmetry and transitivity at A give $y \simeq_A y$. The first hypothesis at x, y gives outputs u of e on x and v of f on y with $u \simeq_B v$; the second at y, y gives outputs v' of f on y and w of g on y with $v' \simeq_B w$. Functionality, Theorem 20.3(2), gives $v = v'$; equality substitution gives $v \simeq_B w$; transitivity at B gives $u \simeq_B w$. Introduce u, w. □

Transitivity at an arrow type is the first place where the derivation, and not just the truth, of functionality is needed: the two hypotheses supply two outputs of f on y, and only a derivation that they are equal lets the argument continue.

Environments. The values of the free variables of a term are stored in one number, its *environment*, with the newest value on the right: an environment for A, Θ is a number R with $G(r, x, R)$, where x is the value of x_0 and r is an environment for Θ. Define the *context condition* and the *relation of two environments* by recursion on the type context:

$$\begin{aligned} C_{[\,]}(R) &:= (0 = 0), \\ C_{A,\Theta}(R) &:= \exists r, x \left(G(r, x, R) \wedge C_\Theta(r) \wedge H_A(x)\right), \\ R \approx_{[\,]} R' &:= (0 = 0), \\ R \approx_{A,\Theta} R' &:= \exists r, r', x, x' \left(G(r, x, R) \wedge G(r', x', R') \wedge r \approx_\Theta r' \wedge x \simeq_A x'\right). \end{aligned}$$

The number below the oldest declared value is unrestricted. A derivation of $C_\Theta(R)$ gives one of $R \approx_\Theta R$: open each level and use its admissibility $H_A(x)$, which is $x \simeq_A x$. We call this the *diagonal* of the context condition.

The reading of a formula. Let $c(t)$ be the program compiled from the term t, to be defined in the next subsection, and write $E_t(R, y) := \mathrm{App}(c(t), R, y)$, a formula about programs and not the value $E_\rho(t)$ of Definition 5.3: the compiled term returns y at the environment R. The *reading* $\mathrm{Rd}_R(P)$ of a formula P at an environment R is the arithmetic formula defined by

$$\begin{aligned}
\mathrm{Rd}_R(\top) &:= (0 = 0), \qquad \mathrm{Rd}_R(\bot) := \bot,\\
\mathrm{Rd}_R(t =_A u) &:= \exists x, y\,\big(E_t(R, x) \wedge E_u(R, y) \wedge x \simeq_A y\big),\\
\mathrm{Rd}_R(P \wedge Q) &:= \mathrm{Rd}_R(P) \wedge \mathrm{Rd}_R(Q), \qquad \mathrm{Rd}_R(P \to Q) := \mathrm{Rd}_R(P) \to \mathrm{Rd}_R(Q),\\
\mathrm{Rd}_R(\forall x{:}\,A\ P) &:= \forall x\,\big(H_A(x) \to \forall z\,(G(R, x, z) \to \mathrm{Rd}_z(P))\big).
\end{aligned}$$

An equation becomes the statement that the two compiled programs return values and that the values are hereditarily equal. A universal quantifier over a type ranges over the admissible numbers, and the body is read at the environment extended by the new value; the pairing graph supplies that environment, so no pairing symbol is needed. If P has no free variables, $\mathrm{Rd}_0(P)$ is a closed arithmetic formula.

Theorem 20.12 (The reading is exact)**.** *Let* $\mathrm{Holds}(P, R)$ *be read directly in* $\mathbb{N}$*: an equation holds when both compiled terms return values that are hereditarily equal in* $\mathbb{N}$*, the connectives are read as themselves, and* $\forall x{:}\,A\ P$ *holds at* R *when* P *holds at* $\langle R, x\rangle$ *for every admissible* x*. Then* $\mathrm{Rd}_R(P)$ *is true in* $\mathbb{N}$ *exactly when* $\mathrm{Holds}(P, R)$*. Likewise* $C_\Theta(R)$ *is true exactly when every variable declared in* Θ *has an admissible value at its type under lookup from* R*.*

Proof. Induct on P. The equation clause has two existential witnesses, and by Theorem 20.3(1) they are exactly the two returned values. The connective clauses follow from the induction hypotheses. For a universal formula, if the reading holds and x is admissible, take $z = \langle R, x\rangle$; the graph holds, and the induction hypothesis gives the body at $\langle R, x\rangle$. Conversely, any z with $G(R, x, z)$ is $\langle R, x\rangle$. The context condition is the same induction on Θ: a witness pair $\langle r, x\rangle = R$ supplies the newest value and, by the induction hypothesis, the older ones. □

The theorem says what the reading means. A proof translation needs more: for every proof, an actual derivation of the reading, for every environment and every hypothesis list. The statement that a computation returns in $\mathbb{N}$ does not supply such a derivation for arbitrary variables. The rest of the section constructs the derivations, rule by rule.

20.3.6 Compiled terms return admissible values

Every term t receives a fixed program $c(t)$, by recursion on the term:

$$\begin{aligned}
c(x_k) &:= \mathrm{right} \circ d_k, \qquad c(0) := \mathrm{zero}, \qquad c(S(t)) := \mathrm{succ} \circ c(t),\\
c(\lambda A.\, b) &:= \Lambda_{c(b)}, \qquad c(fa) := \mathsf{U} \circ \mathrm{pair}(c(f), c(a)),
\end{aligned}$$

$$\begin{aligned}
c(\mathsf{I}(B, b, g, n)) &:= \mathsf{It} \circ \mathrm{pair}\big(\mathrm{pair}(c(g), c(b)), c(n)\big),\\
c(\mathsf{R}(B, b, g, n)) &:= \mathsf{It}^{\mathrm{ind}} \circ \mathrm{pair}\big(\mathrm{pair}(c(g), c(b)), c(n)\big).
\end{aligned}$$

The fixed programs are these. The *dropping programs* $d_0 := \mathrm{id}$ and $d_{k+1} := d_k \circ \mathrm{left}$ remove k entries from an environment, so $c(x_k)$ reads the kth entry. The *iterator* and *indexed recursor* are

$$\mathsf{It} := \mathrm{rec}(\mathrm{right}, \mathrm{st}), \qquad \mathsf{It}^{\mathrm{ind}} := \mathrm{rec}(\mathrm{right}, \mathrm{st}^{\mathrm{ind}}),$$

with steps $\mathrm{st} := \mathsf{U} \circ \mathrm{pair}(\mathrm{left} \circ \mathrm{left}, \mathrm{right} \circ \mathrm{right})$ and $\mathrm{st}^{\mathrm{ind}} := \mathrm{ap}(\mathrm{ap}(\mathrm{left} \circ \mathrm{left}, \mathrm{left} \circ \mathrm{right}), \mathrm{right} \circ \mathrm{right})$, where $\mathrm{ap}(f, h) := \mathsf{U} \circ \mathrm{pair}(f, h)$. They receive $\langle a, m \rangle$ with $a = \langle g, b \rangle$ storing a step code and a seed, and m the count. At count 0 they return the seed b. At count $m + 1$, with previous value x, the step receives $\langle a, \langle m, x \rangle \rangle$: st runs g on x through U, and $\mathrm{st}^{\mathrm{ind}}$ runs g on m and the resulting code on x. The *closure generator* Λ_c of a program c receives an environment R and returns the code of the program $c \circ \mathrm{pair}(\kappa_R, \mathrm{id})$, where κ_R is a program that returns R on every input; it builds this code without running c. Its definition is in Appendix K.4.

A function value thus returns at once, before its body runs. What a proof needs is the behavior of that value.

Lemma 20.13 (What the closure does)**.** *For every program c there is a derivation of: for every R there is an f with $\mathrm{App}(\Lambda_c, R, f)$ such that, for all x, p, y, if $G(R, x, p)$ and $\mathrm{App}(c, p, y)$, then $\mathrm{App}(f, x, y)$.*

The proof is in Appendix K.4. The generator contains no search, so it returns on every input; the code it returns is that of a composition whose first part pairs a quoted constant with the identity, and the quoted constant is shown to return R by induction on R.

Lemma 20.14 (Iterations of related steps are related)**.** *For every finite type B there are derivations of the following, for all g, h, b, b', a, a' with $G(g, b, a)$ and $G(h, b', a')$:*

1. *if $g \simeq_{B \to B} h$ and $b \simeq_B b'$, then for every m there are p, p', x, x' with $G(a, m, p)$, $G(a', m, p')$, $\mathrm{App}(\mathsf{It}, p, x)$, $\mathrm{App}(\mathsf{It}, p', x')$ and $x \simeq_B x'$;*
2. *if $g \simeq_{O \to (B \to B)} h$ and $b \simeq_B b'$, the same holds with $\mathsf{It}^{\mathrm{ind}}$ in place of It.*

Proof. For the first statement, induct on m in the displayed formula, keeping the parameters and hypotheses. At 0, pairing totality supplies p, p', and the recursion-start law, with $\mathrm{App}(\mathrm{right}, a, b)$ from $G(g, b, a)$, gives $\mathrm{App}(\mathsf{It}, p, b)$; likewise for p'. The seeds are related by hypothesis. At $m + 1$, open the induction hypothesis: outputs $x \simeq_B x'$ of the two iterations at count m. The arrow clause of $g \simeq_{B \to B} h$ at x, x' gives outputs s of g on x and s' of h on x' with $s \simeq_B s'$. Pairing totality supplies the packed inputs $\langle a, m + 1 \rangle$, $\langle m, x \rangle$ and $\langle a, \langle m, x \rangle \rangle$, and their counterparts for the second iteration. On $\langle a, \langle m, x \rangle \rangle$ the projections in st return g and x, Lemma 20.10 carries $\mathrm{App}(g, x, s)$ to $\mathrm{App}(\mathsf{U}, \langle g, x \rangle, s)$, and the composition law gives the step's output s. The recursion-step law then gives $\mathrm{App}(\mathsf{It}, \langle a, m + 1 \rangle, s)$. The same argument for the second iteration gives s', and $s \simeq_B s'$. The indexed case is the same induction with two arrow clauses at each step: $g \simeq h$ at the equal counts m gives related codes, and those codes at x, x' give related outputs; the step $\mathrm{st}^{\mathrm{ind}}$ runs both applications through U. □

The induction formula asserts that computations exist, so it contains quantifiers and the ledger records the induction entry. Taking $h = g$ and $b' = b$, the lemma says that an iteration of an admissible step from an admissible seed returns an admissible value at every count.

Theorem 20.15 (Typed evaluation)**.** *Let t have type A in Θ. Every context that derives $R \approx_\Theta R'$ derives*

$$\exists x, x' \ \big(E_t(R, x) \wedge E_t(R', x') \wedge x \simeq_A x'\big).$$

In particular, every context that derives $C_\Theta(R)$ derives $\exists x\,(E_t(R, x) \wedge H_A(x))$.

Proof. Induct on the typing derivation of t; there are seven cases.

Variable x_k. Open the relation $R \approx_\Theta R'$ level by level, k times on each side: it supplies environments r_j, r'_j with $G(r_{j+1}, v_j, r_j)$ and $G(r'_{j+1}, v'_j, r'_j)$, $r_0 = R$, $r'_0 = R'$, and at level k the related entries $v_k \simeq_A v'_k$. The left-projection law gives $\mathrm{App}(\mathrm{left}, r_j, r_{j+1})$, the composition law assembles $\mathrm{App}(d_k, R, r_k)$, and the right-projection law gives $\mathrm{App}(\mathrm{right} \circ d_k, R, v_k)$; the same on the other side. The written-out induction on k is in Appendix K.5.

Zero. The zero law gives output 0 on both sides, and $0 = 0$.

Successor $S(t)$. The induction hypothesis gives outputs $x \simeq_O x'$, that is $x = x'$, of the compiled t; the successor and composition laws give the output $x + 1$ on both sides.

Application fa with $f : A \to B$. The induction hypotheses give outputs $e \simeq_{A\to B} e'$ of the compiled f and $v \simeq_A v'$ of the compiled a. The arrow clause gives outputs y of e on v and y' of e' on v' with $y \simeq_B y'$. Pairing totality gives p with $G(e, v, p)$; the pair law gives $\mathrm{App}(\mathrm{pair}(c(f), c(a)), R, p)$; universal application gives $\mathrm{App}(\mathsf{U}, p, y)$; and the composition law gives $E_{fa}(R, y)$. The other side is the same.

Iteration $\mathsf{I}(B, b, g, n)$. The induction hypotheses give related outputs of the three parts: $g \simeq_{B\to B} g'$ for the step, $v \simeq_B v'$ for the seed, and equal counts $m = m'$. Pairing totality gives a, a' with $G(g, v, a)$ and $G(g', v', a')$. Lemma 20.14 at the count m gives related outputs $y \simeq_B y'$ of It on $\langle a, m\rangle$ and $\langle a', m\rangle$. The pair law, applied twice, and the composition law assemble $E_t(R, y)$ and $E_t(R', y')$ from these pieces. *Indexed recursion* is the same, with the second part of the lemma.

Abstraction $\lambda A.\, b$ with $b : B$ in A, Θ. Lemma 20.13 gives closure codes f at R and f' at R'. It remains to derive $f \simeq_{A\to B} f'$. Take $x \simeq_A x'$, and let $G(R, x, z)$ and $G(R', x', z')$ by pairing totality. Then $z \approx_{A,\Theta} z'$, with witnesses R, R', x, x'. The induction hypothesis for the body gives outputs $y \simeq_B y'$ of $c(b)$ at z and z', and the closure behavior gives $\mathrm{App}(f, x, y)$ and $\mathrm{App}(f', x', y')$. That is the arrow clause.

For the last statement apply the first to the diagonal $R \approx_\Theta R$. The two outputs $x \simeq_A x''$ give $H_A(x)$ by symmetry and transitivity, Proposition 20.11. □

The two-environment form matters. The abstraction case needs the induction hypothesis at two different extended environments z, z', which agree only up to the relation; a statement about one environment at a time would not give the arrow clause.

20.3.7 Substitution moves with the environment

A quantified statement is used at a particular argument only after the argument has been placed in the environment where the body is read. Suppose $P(x, z)$ is a formula and $t(z)$ a term of the type of x. The usual conclusion from $\forall x\, P(x, z)$ is $P(t(z), z)$. The value of z is still the old one; the new value of x must be the value of t in that old environment. Substituting first

and then reading must agree with extending the environment by that value and then reading the body. This subsection derives that agreement for every formula, in both directions.

A *substitution* σ from Θ into Θ' assigns to each variable x_k of Θ, of type B, a term σ_k of type B in Θ'. The substituted term $t\sigma$ and formula $P\sigma$ replace each x_k by σ_k. Under a binder the substitution is *lifted*: the lifted substitution σ^+ keeps the new variable x_0 and sends x_{k+1} to $\sigma_k\uparrow$, the term σ_k shifted past the new variable. This is the positional substitution of Definition 5.2, and the lifting is what prevents capture. Let R be an environment for Θ' and R' one for Θ. Say that σ is *faithful from R to R'* when every variable is matched: for each x_k of Θ, of type B,

$$\exists p, q\, \big(E_{\sigma_k}(R, p) \wedge E_{x_k}(R', q) \wedge p \simeq_B q\big).$$

The term substituted for x_k, evaluated in the new environment, returns a value related to the entry that R' stores for x_k.

A substitution whose terms are variables is a *renaming*. The simplest is the shift $x_k \mapsto x_{k+1}$, which turns a term t of Θ into $t\uparrow$ of A, Θ.

Lemma 20.16 (Renaming)**.** *Let ρ be a renaming from Θ into Θ''. Say that ρ* matches the slots *of R and R' when, for each variable x_k of Θ, of type B, a context derives that some z, z', r, r', v, v' satisfy*

$$\mathrm{App}(d_{\rho(k)}, R, z), \quad \mathrm{App}(d_k, R', z'), \quad G(r, v, z), \quad G(r', v', z'), \quad v \simeq_B v' :$$

dropping $\rho(k)$ entries from R and k entries from R' leaves environments whose newest entries are related. If ρ matches the slots of R and R' and t has type A in Θ, the context derives $\exists p, q\, (E_{t\rho}(R, p) \wedge E_t(R', q) \wedge p \simeq_A q)$. In particular, if it derives $R \approx_\Theta R'$ and $G(R, X, \hat{R})$, then it derives $\exists p, q\, (E_{t\uparrow}(\hat{R}, p) \wedge E_t(R', q) \wedge p \simeq_A q)$, for an arbitrary number X.

Proof. Induct on the typing of t. For a variable x_k, the right-projection law applied to $G(r, v, z)$ and the composition law give $\mathrm{App}(\mathrm{right} \circ d_{\rho(k)}, R, v)$, which is $E_{x_{\rho(k)}}(R, v)$; likewise $E_{x_k}(R', v')$; and $v \simeq_B v'$. Zero, successor, application, iteration and indexed recursion are the corresponding cases of Theorem 20.15, applied to the outputs that the induction hypotheses relate. For an abstraction $\lambda A.\, b$, take $x \simeq_A x'$, and let $G(R, x, \tilde{R})$ and $G(R', x', \tilde{R}')$. The lifted renaming sends x_0 to x_0 and x_{k+1} to $x_{\rho(k)+1}$, and it matches the slots of $\tilde{R}$ and $\tilde{R}'$. At the new position, the identity law gives $\mathrm{App}(d_0, \tilde{R}, \tilde{R})$, and the graphs $G(R, x, \tilde{R})$ and $G(R', x', \tilde{R}')$ hold the related values x and x'. At an old position, the left-projection law gives $\mathrm{App}(\mathrm{left}, \tilde{R}, R)$, and composition with the given $\mathrm{App}(d_{\rho(k)}, R, z)$ gives $\mathrm{App}(d_{\rho(k)+1}, \tilde{R}, z)$, since $d_{\rho(k)+1} = d_{\rho(k)} \circ \mathrm{left}$; the same on the other side; the graphs and the relation are those of the given slot. Every step runs a law forward. The induction hypothesis for the body and Lemma 20.13 give the arrow clause, as in Theorem 20.15. For the second statement take $\rho(k) = k + 1$. Lemma K.6 turns $R \approx_\Theta R'$ into $\mathrm{App}(d_k, R, z)$ and $\mathrm{App}(d_k, R', z')$ with $z \approx z'$, whose opening supplies the graphs and related values; the left-projection law on $G(R, X, \hat{R})$ and composition move the first to $\mathrm{App}(d_{k+1}, \hat{R}, z)$. The number X is never read. □

Theorem 20.17 (Term transport)**.** *Let t have type A in Θ and let σ be a substitution from Θ into Θ'. If a context derives that σ is faithful from R to R', together with $R \approx_{\Theta'} R$ and $R' \approx_{\Theta} R'$, then it derives*

$$\exists p, q\, \big(E_{t\sigma}(R, p) \wedge E_t(R', q) \wedge p \simeq_A q\big).$$

Proof. Induct on the typing of t. The variable case is the faithfulness hypothesis. The zero, successor, application, iteration and indexed-recursion cases are those of Theorem 20.15, applied to the outputs that the induction hypotheses relate. For an abstraction $\lambda A.\, b$, with $b : B$ in A, Θ, Lemma 20.13 gives closure codes f of $c((\lambda A.\, b)\sigma)$ at R and f' of $c(\lambda A.\, b)$ at R'; we derive $f \simeq_{A\to B} f'$. Take $x \simeq_A x'$, and let $G(R, x, z)$ and $G(R', x', z')$. The lifted substitution is faithful from z to z'. At the new position, x_0 reads x at z and x' at z'. At position $k+1$, the lifted substitution has $\sigma_k{\uparrow}$, and Lemma 20.16, applied to the diagonal $R \approx_{\Theta'} R$ and to $G(R, x, z)$, relates $\sigma_k{\uparrow}$ at z to σ_k at R; faithfulness relates σ_k at R to x_k at R'; functionality identifies the two outputs of σ_k at R; and x_{k+1} at z' reads x_k at R'. Transitivity joins the three relations. The relations $z \approx z$ and $z' \approx z'$ follow from $R \approx R$, $R' \approx R'$ and $H_A(x)$, $H_A(x')$, which symmetry and transitivity give from $x \simeq_A x'$. The induction hypothesis for the body relates the outputs y of $c(b\sigma^+)$ at z and y' of $c(b)$ at z', and the closure behavior sends x to y and x' to y'. □

Theorem 20.18 (Formula substitution)**.** *Let P be formed in Θ and let σ be a substitution from Θ into Θ'. Let a context derive that σ is faithful from R to R', together with $R \approx_{\Theta'} R$ and $R' \approx_{\Theta} R'$. Then it derives $\mathrm{Rd}_{R'}(P) \to \mathrm{Rd}_R(P\sigma)$ and $\mathrm{Rd}_R(P\sigma) \to \mathrm{Rd}_{R'}(P)$.*

Proof. Induct on P, constructing both directions together.

Truth and falsehood read the same in both environments.

Equation $t =_A u$. Suppose the reading at R' supplies outputs p of t and q of u with $p \simeq_A q$. Term transport gives outputs p' of $t\sigma$ and q' of $u\sigma$ at R, related to outputs of t and u at R', and functionality identifies those with p and q. Symmetry and transitivity, Proposition 20.11, give the chain

$$p' \simeq_A p \simeq_A q \simeq_A q',$$

which is the reading of $t\sigma =_A u\sigma$ at R. The reverse direction runs the same chain from the other end.

Conjunction transports each component.

Implication $P \to Q$. Assume $\mathrm{Rd}_{R'}(P) \to \mathrm{Rd}_{R'}(Q)$, and to derive $\mathrm{Rd}_R(P\sigma) \to \mathrm{Rd}_R(Q\sigma)$ assume $\mathrm{Rd}_R(P\sigma)$. Transport it *back* to $\mathrm{Rd}_{R'}(P)$ by the reverse direction for P, apply the assumed implication, and transport $\mathrm{Rd}_{R'}(Q)$ *forward* by the forward direction for Q. Discharge the assumption. The reverse direction swaps the two roles. A one-way transport for the antecedent would not provide the first step; this is why both directions are proved together. The faithfulness and diagonal hypotheses stay available under the temporary assumption, because they are members of the context.

Universal statement $\forall y{:}\, B\, Q$, with Q formed in B, Θ. Forward: assume the reading at R'. Take y with $H_B(y)$ and z with $G(R, y, z)$; pairing totality gives z' with $G(R', y, z')$, the same value placed in the other environment. The lifted substitution is faithful from z to z': at the new

position both environments read y, related to itself by $H_B(y)$, and at the old positions the argument of Theorem 20.17 applies. The diagonals $z \approx z$ and $z' \approx z'$ follow from the given ones and $H_B(y)$. Instantiate the assumed reading at y and z' to get $\mathrm{Rd}_{z'}(Q)$, transport the body forward by the induction hypothesis, and generalize over y and z. The reverse direction begins with an arbitrary y and z' on the other side, builds z by pairing totality, and transports the body back. The temporary pairing witness is eliminated before generalization closes. □

The extended environments are the proof of capture avoidance, not just a place to store values: the lifted substitution can be compared position by position only because both environments grow by the same value.

Corollary 20.19 (Shifted hypotheses and related environments)**.** *Let Q and P be formed in Θ.*

1. *From $C_\Theta(R)$, $H_A(x)$, $G(R, x, \hat{R})$ and $\mathrm{Rd}_R(Q)$, a context derives $C_{A,\Theta}(\hat{R})$ and $\mathrm{Rd}_{\hat{R}}(Q\uparrow)$.*
2. *From $R \approx_\Theta R'$ and $\mathrm{Rd}_R(P)$, a context derives $\mathrm{Rd}_{R'}(P)$.*

Proof. For the first, the three premises are the witnesses of $C_{A,\Theta}(\hat{R})$. The shift $x_k \mapsto x_{k+1}$ is a substitution from Θ into A, Θ, faithful from $\hat{R}$ to R by Lemma 20.16 applied to the diagonal of $C_\Theta(R)$, and $Q\sigma = Q\uparrow$. The forward direction of Theorem 20.18 turns $\mathrm{Rd}_R(Q)$ into $\mathrm{Rd}_{\hat{R}}(Q\uparrow)$.

For the second, induct on P. An equation: Theorem 20.15 relates the outputs of each term at R and at R', and the chain of the preceding proof carries the relation between the two outputs across. An implication uses that $\approx_\Theta$ is symmetric, which follows level by level from Proposition 20.11, to move the antecedent back. A universal statement extends both environments by the same admissible value. □

Lemma 20.20 (An environment for a substitution)**.** *Let σ be a substitution from Θ into Θ'. A context that derives $C_{\Theta'}(R)$ derives that some R' satisfies $C_\Theta(R')$ and that σ is faithful from R to R'.*

Proof. Induct on Θ. For the empty context take $R' = 0$. For A, Θ_0, the induction hypothesis for the tail substitution $k \mapsto \sigma_{k+1}$ gives R_0 with $C_{\Theta_0}(R_0)$, the tail being faithful from R to R_0. Typed evaluation of σ_0 at R gives x with $E_{\sigma_0}(R, x)$ and $H_A(x)$, and pairing totality gives R' with $G(R_0, x, R')$; these three give $C_{A,\Theta_0}(R')$. At the new position σ_0 returns x at R and x_0 returns x at R'. At an old position $k+1$, faithfulness of the tail relates σ_{k+1} at R with x_k at R_0, and Lemma 20.16 relates x_k at R_0 with x_{k+1} at R'; functionality and transitivity join them. □

Proposition 20.21 (Universal elimination)**.** *Let t have type A in Θ and let P be formed in A, Θ. A context that derives $C_\Theta(R)$ and $\mathrm{Rd}_R(\forall x{:}\,A\ P)$ derives $\mathrm{Rd}_R(P[t])$.*

Proof. Typed evaluation gives x with $E_t(R, x)$ and $H_A(x)$; pairing totality gives R'' with $G(R, x, R'')$. The reading of the universal statement, at x and R'', gives $\mathrm{Rd}_{R''}(P)$. The substitution of t for x_0, which sends x_{k+1} to x_k, is a substitution from A, Θ into Θ, faithful from R to R'': at the new position t returns x at R and x_0 returns x at R'', related by $H_A(x)$; at an old position Lemma 20.16 and symmetry relate x_k at R with x_{k+1} at R''. The diagonals $R \approx_\Theta R$ and $R'' \approx_{A,\Theta} R''$ come from $C_\Theta(R)$, $H_A(x)$ and $G(R, x, R'')$. The forward direction of Theorem 20.18 gives $\mathrm{Rd}_R(P[t])$. Neither temporary witness occurs in the conclusion. □

20.3.8 Every rule becomes a derivation

Six rules need constructions of their own: computation, replacement, the two successor laws, extensionality and induction. The others follow from what has been proved.

Theorem 20.22 (Conversion is sound)**.** *Let t, u have type A in Θ with $t \equiv u$. A context that derives $R \approx_\Theta R'$ derives $\exists x, y(E_t(R, x) \wedge E_u(R', y) \wedge x \simeq_A y)$.*

Proof. Lemma 20.1 gives a term v with $t \Rrightarrow^* v$ and $u \Rrightarrow^* v$, every term on the two chains having type A in Θ. It suffices to prove the statement for a single parallel step $t \Rrightarrow t'$ at related environments. A chain then follows by transitivity of $\simeq_A$, using $R' \approx_\Theta R'$, which follows from $R \approx_\Theta R'$ by symmetry and transitivity at each level; and t at R is related to u at R' through the common reduct v at R', using symmetry for the chain from u.

For a single step, induct on its derivation. A congruence step rebuilds a constructor around stepped parts; the case of Theorem 20.15 for that constructor, applied to the outputs related by the induction hypotheses, gives the relation. The five contractions follow both compiled programs to related values. We give two; the other three are in Appendix K.6.

Abstraction, $(\lambda A.\, b)\, s \Rrightarrow b'[s']$ with $b \Rrightarrow b'$ and $s \Rrightarrow s'$. At R, the compiled application evaluates the closure code f of $c(b)$ and the value x of s, and runs U on $\langle f, x\rangle$. Typed evaluation of b at $\langle R, x\rangle$, which is related to itself because $R \approx R$ and $H_A(x)$, gives an output y; the closure behavior gives $\mathrm{App}(f, x, y)$; and universal application gives U the output y. So the left side returns y at R, the value of b at $\langle R, x\rangle$. On the right, the induction hypothesis relates x to the value x' of s' at R', so $\langle R, x\rangle \approx \langle R', x'\rangle$, and relates y to the value y' of b' at $\langle R', x'\rangle$. The single substitution of s' is faithful from R' to $\langle R', x'\rangle$, so term transport relates y' to the value of $b'[s']$ at R'. Transitivity finishes the case.

Iteration at a successor, $\mathsf{I}(B, b, g, S(n)) \Rrightarrow g'\, \mathsf{I}(B, b', g', n')$. At R the parts return γ, v and $m + 1$. Lemma 20.14 gives the output x of It at count m; the arrow clause of $H(\gamma)$ gives an output s of γ on x; universal application and the recursion-step law give It the output s at count $m + 1$; and functionality identifies s with the value of the left side. At R' the right side applies γ', related to γ by the induction hypothesis, to the value x' of $\mathsf{I}(B, b', g', n')$, which the congruence case relates to x. The arrow clause of $\gamma \simeq \gamma'$ at $x \simeq x'$ relates s to the output on the right. □

Proposition 20.23 (Replacement, successor laws, reflexivity)**.** *Let a context derive $C_\Theta(R)$.*

1. *For $t : A$ it derives $\mathrm{Rd}_R(t =_A t)$, and for $t \equiv u$ at A it derives $\mathrm{Rd}_R(t =_A u)$.*
2. *For $t, u : A$ and P formed in A, Θ, if it derives $\mathrm{Rd}_R(t =_A u)$ and $\mathrm{Rd}_R(P[t])$, it derives $\mathrm{Rd}_R(P[u])$.*
3. *For $t : O$ it derives $\mathrm{Rd}_R(S(t) =_O 0 \to \bot)$; and for $t, u : O$, if it derives $\mathrm{Rd}_R(S(t) =_O S(u))$, it derives $\mathrm{Rd}_R(t =_O u)$.*

Proof. (1) Typed evaluation and Theorem 20.22, at the diagonal $R \approx_\Theta R$.

(2) The reading of the equation supplies x, y with $E_t(R, x)$, $E_u(R, y)$ and $x \simeq_A y$; symmetry and transitivity give $H_A(x)$ and $H_A(y)$. Pairing totality gives R_1, R_2 with $G(R, x, R_1)$ and $G(R, y, R_2)$; with $C_\Theta(R)$, $H_A(x)$ and $H_A(y)$ these give the diagonals that Theorem 20.18 needs.

The single substitution of t is faithful from R to R_1, so the reverse direction of Theorem 20.18 turns $\mathrm{Rd}_R(P[t])$ into $\mathrm{Rd}_{R_1}(P)$. The environments R_1 and R_2 are related at A, Θ: their old parts are R, related to itself, and their new entries satisfy $x \simeq_A y$. Corollary 20.19(2) gives $\mathrm{Rd}_{R_2}(P)$, and the forward direction for the substitution of u gives $\mathrm{Rd}_R(P[u])$. At a function type x and y may be different codes of one function; the proof never replaces one by the other, which equality substitution would require, and uses only the relation.

(3) Typed evaluation gives the value x of t at R. Assume the reading of $S(t) =_O 0$: outputs a of $c(S(t))$ and b of $c(0)$ with $a = b$. The successor and zero laws give the outputs $x + 1$ and 0, and functionality gives $a = x + 1$ and $b = 0$. So $x + 1 = 0$, and the separation rule of Chapter 5 gives $\bot$. For injectivity, typed evaluation gives the values a of t and b of u; the reading of $S(t) =_O S(u)$ supplies equal outputs, which functionality identifies with $a + 1$ and $b + 1$; the injectivity rule of Chapter 5 gives $a = b$. □

Each successor law uses the corresponding arithmetic rule once, on numbers. The reading adds only evaluation and functionality.

Theorem 20.24 (Extensionality). *Let f, g have type $A \to B$ in Θ. Suppose the premise $(f\uparrow)\, x_0 =_B (g\uparrow)\, x_0$ compiles at every extended environment: every context that derives $C_{A,\Theta}(R_1)$ and the readings at R_1 of the shifted hypotheses derives its reading at R_1. Then every context that derives $C_\Theta(R)$ and the readings at R of the hypotheses derives $\mathrm{Rd}_R(f =_{A\to B} g)$.*

Proof. Typed evaluation gives admissible values v of f and w of g at R. It remains to derive $v \simeq_{A\to B} w$. Take $x \simeq_A x'$; then $H_A(x)$. Let $G(R, x, R_1)$. Corollary 20.19(1) gives $C_{A,\Theta}(R_1)$ and the shifted hypotheses at R_1, so the compiled premise gives outputs a of $(f\uparrow)\, x_0$ and b of $(g\uparrow)\, x_0$ at R_1 with $a \simeq_B b$.

Connect a with the function value. The compiled $f\uparrow$ at R_1 returns a value v_1 related to v, by Lemma 20.16, and the compiled x_0 returns x. The arrow clause of $v_1 \simeq v$ at $x \simeq x$ gives outputs a_1 of v_1 and a_0 of v on x with $a_1 \simeq_B a_0$. Universal application and the pair and composition laws make a_1 an output of the compiled application $(f\uparrow)\, x_0$ at R_1, and functionality gives $a = a_1$. In the same way the compiled $g\uparrow$ returns a value w_1 related to w; the arrow clause of $w_1 \simeq w$ at $x \simeq x'$ gives outputs b_1 of w_1 on x and b_0 of w on x' with $b_1 \simeq_B b_0$; and $b = b_1$. Symmetry and transitivity give $a_0 \simeq_B b_0$: an output of v on x related to an output of w on x'. Generalizing over x, x' gives the arrow clause for v, w. □

Extensionality adds no principle: the reading of $f =_{A\to B} g$ already states that the two functions agree on related arguments. The work is the link between the compiled application of $f\uparrow$ to the new variable, which the premise mentions, and the application of the value of f to an argument, which the arrow clause mentions. Universal application supplies that link. The proof extends R by x only; the relation with x' enters through the arrow clause of w.

Theorem 20.25 (Induction). *Let P be formed in O, Θ. Suppose the base $P[0]$ compiles at every environment of Θ and the step $P \to P^S$ compiles at every environment of O, Θ, in the sense of Theorem 20.24. Then every context that derives $C_\Theta(R)$ and the readings at R of the hypotheses derives $\mathrm{Rd}_R(\forall x{:}O\ P)$, by a derivation whose ledger records the induction entry and no principle.*

Proof. Since $H_O(x)$ is $x = x$,

$$\mathrm{Rd}_R(\forall x{:}O\ P) = \forall x\big(x = x \to \forall z\,(G(R, x, z) \to \mathrm{Rd}_z(P))\big).$$

Call the formula under the first quantifier $\Phi_R(x)$, and induct on x in $\Phi_R(x)$ with the induction rule (5.2).

Zero. Let $G(R, 0, z_0)$; with $C_\Theta(R)$ and $0 = 0$ it gives the diagonal of z_0. The compiled base gives $\mathrm{Rd}_R(P[0])$. The substitution of 0 is faithful from R to z_0, since the compiled 0 returns 0 at R and z_0 stores 0; the reverse direction of Theorem 20.18 gives $\mathrm{Rd}_{z_0}(P)$.

Successor. Assume $\Phi_R(x)$ and let $G(R, x + 1, z')$. Pairing totality gives z with $G(R, x, z)$, and $\Phi_R(x)$ gives $\mathrm{Rd}_z(P)$. The environment z satisfies $C_{O,\Theta}(z)$ and, by Corollary 20.19(1), the shifted hypotheses, so the compiled step gives $\mathrm{Rd}_z(P) \to \mathrm{Rd}_z(P^S)$ and hence $\mathrm{Rd}_z(P^S)$. The formula P^S is P under the substitution that sends x_0 to $S(x_0)$ and keeps the other variables. It is faithful from z to z': the compiled $S(x_0)$ returns $x + 1$ at z, and z' stores $x + 1$; both environments keep R as their older part, which gives the other positions and the diagonals. The reverse direction of Theorem 20.18 gives $\mathrm{Rd}_{z'}(P)$, which is $\Phi_R(x + 1)$ after discharge.

The induction rule gives $\forall x\,\Phi_R(x)$. The formula $\Phi_R(x)$ contains the quantifier $\forall z$, so the ledger records the induction entry; the premises are posit-free, so it records nothing else. □

The source induction may be on an equation, with no quantifier. Its reading always has one, because the reading of a universal statement quantifies over the extended environment. A compiled induction therefore always records the induction entry.

Theorem 20.26 (Proofs compile to derivations)**.** *For every proof of $\Theta; \Xi \vdash P$ in the language of functions and every environment term R, there is a posit-free derivation of $\mathrm{Rd}_R(P)$ from the hypotheses $C_\Theta(R)$ and $\mathrm{Rd}_R(Q)$ for Q in Ξ. In particular, for every proof of a closed formula P from no hypotheses, the rules of Chapter 5 derive $\mathrm{Rd}_0(P)$ by a posit-free derivation.*

Proof. Prove more: for every list of hypotheses Δ that contains $C_\Theta(R)$ and $\mathrm{Rd}_R(Q)$ for every Q in Ξ, there is a derivation of $\mathrm{Rd}_R(P)$ from Δ. Recurse on the proof, one case for each rule.

(1) *Hypothesis*: $\mathrm{Rd}_R(P)$ is a member of Δ; search the finite list for its position.

(2) *More hypotheses*: Δ also contains the readings of the smaller list; recurse.

(3) *Truth*: $0 = 0$ by reflexivity.

(4) *Falsehood*: $\mathrm{Rd}_R(\bot)$ is $\bot$; apply the rule for an impossible case.

(5–7) *Conjunction*: the reading of a conjunction is the conjunction of the readings; apply the same rule.

(8) *Implication introduction*: recurse with $\mathrm{Rd}_R(P)$ added to Δ, then discharge it.

(9) *Implication elimination*: the same rule.

(10) *Universal introduction*: introduce fresh x and z and assume $H_A(x)$ and $G(R, x, z)$. Corollary 20.19(1) gives $C_{A,\Theta}(z)$ and the readings of the shifted hypotheses at z; recurse on the premise at z; discharge and generalize.

(11) *Universal elimination*: Proposition 20.21.

(12) *Reflexivity*: Proposition 20.23(1).

(13) *Computation*: Proposition 20.23(1), by Theorem 20.22.

(14) *Replacement*: Proposition 20.23(2).

(15) *Successor is not zero*: Proposition 20.23(3).

(16) *Successor injectivity*: Proposition 20.23(3).

(17) *Extensionality*: Theorem 20.24, recursing on the premise at each extended environment.

(18) *Induction*: Theorem 20.25, recursing on the base and the step.

(19) *Substitution*: let σ go from Θ into Θ'. Lemma 20.20 gives R' with $C_\Theta(R')$ to which σ is faithful from R. The reverse direction of Theorem 20.18 turns the readings $\mathrm{Rd}_R(Q\sigma)$ of the hypotheses into $\mathrm{Rd}_{R'}(Q)$; recurse on the premise at R'; the forward direction turns $\mathrm{Rd}_{R'}(P)$ into $\mathrm{Rd}_R(P\sigma)$. The witness R' does not occur in the conclusion.

Every case combines posit-free derivations, so the result is posit-free. For the last assertion take the empty type context, no hypotheses and $R = 0$; the hypothesis $C_{[\,]}(0)$ is $0 = 0$, which reflexivity proves. □

The derivation exists for every proof, including proofs that pass through functions of any finite type. It uses induction on quantified formulas and universal application, and none of EM, LPO and MP.

20.3.9 Recovering the arithmetic sentence

For a sentence about numbers, Theorem 20.26 gives the reading, not yet the sentence. The reading of an equation says that two programs return values and that the values are equal. The sentence says that two terms are equal. For addition and multiplication the gap is real: the compiled programs run the iterator, and every step of the iterator runs U. That a compiled sum returns the actual sum is a theorem, proved by induction along the iteration. In this subsection $+$ and $\cdot$ are the operations of the arithmetic language, governed by the four recursive rules of Chapter 5.

Lemma 20.27 (Counting iterations)**.** *There are derivations of the following.*

1. *If g returns $x + 1$ on every x and $G(g, v, a)$, then for all m, p with $G(a, m, p)$ the iterator It returns $v + m$ on p.*

2. *If g returns $x + k$ on every x and $G(g, 0, a)$, then for all m, p with $G(a, m, p)$ the iterator returns $k \cdot m$ on p.*

Proof. For the first, induct on m in $\forall p\,(G(a,m,p) \to \mathrm{App}(\mathsf{It}, p, v+m))$. At 0 the recursion-start law returns the seed v, and the rule $v + 0 = v$ rewrites the output. At $m + 1$, pairing totality supplies the packed inputs of the previous call and of the step; the induction hypothesis gives the previous output $v + m$; the premise on g and universal application give the step output $(v + m) + 1$; the recursion-step law joins them; and the rule $v + S(m) = S(v + m)$ rewrites the output. The second is the same induction with seed 0, step output $x + k$, and the rules $k \cdot 0 = 0$ and $k \cdot S(m) = k \cdot m + k$. □

The premise on g is met by the compiled step closures. The closure of $\lambda O.\, S(x_0)$ at R sends x to the output of $c(S(x_0))$ at $\langle R, x\rangle$, which the successor law and the right projection give as $x + 1$. So by Lemma 20.13 the step code returns $x + 1$ on every x, and Lemma 20.27 gives:

Proposition 20.28 (Compiled addition and multiplication)**.** *There are derivations of: if the compiled s returns v at R and the compiled t returns m at R, then the compiled* $\mathrm{add}(s,t)$ *returns $v + m$ at R; and if the compiled $s\!\uparrow$ returns k at every one-step extension of R and the compiled t returns m at R, then the compiled* $\mathrm{mul}(s,t)$ *returns $k \cdot m$ at R.*

Proof. For addition, the compiled program evaluates the step closure to a code f that returns $x + 1$ on every x, the seed to v and the count to m, packs $\langle f, v\rangle$ and $\langle\langle f, v\rangle, m\rangle$ by pairing totality, and runs It; Lemma 20.27(1) gives the output $v + m$, and the pair and composition laws assemble the compiled computation. For multiplication, the step closure of $\lambda O.\ \mathrm{add}(x_0, s\!\uparrow)$ sends x to the output of the compiled addition at $\langle R, x\rangle$, where x_0 returns x and, by the premise, $s\!\uparrow$ returns k; by the first part that output is $x + k$. The seed returns 0, and Lemma 20.27(2) gives $k \cdot m$. □

Environments now hold terms of the arithmetic language. For a list $\sigma = (\sigma_0, \sigma_1, \ldots)$ of terms, let $\mathscr{L}_n(\sigma, R)$ say that R lists $\sigma_0, \ldots, \sigma_{n-1}$, newest first: $\mathscr{L}_0(\sigma, R) := (0 = 0)$ and $\mathscr{L}_{n+1}(\sigma, R) := \exists r\,(G(r, \sigma_0, R) \wedge \mathscr{L}_n((\sigma_1, \sigma_2, \ldots), r))$.

Theorem 20.29 (Compiled terms return their values)**.** *For every arithmetic term t with variables below n, and every list σ of terms, there is a derivation of $\mathscr{L}_n(\sigma, R) \to \mathrm{App}(c(t^*), R, t[\sigma])$, where $t[\sigma]$ replaces each x_i by σ_i.*

Proof. Recurse on the size of t, for all n and σ at once. A variable x_i is read by i left projections and one right projection from the graphs inside $\mathscr{L}_n(\sigma, R)$, and returns σ_i. Zero returns 0. For $S(t)$ the successor law applied to the output $t[\sigma]$ gives $S(t[\sigma])$. For $t + u$ the recursive derivations give the two outputs and Proposition 20.28 gives their sum. For $t \cdot u$ the same proposition needs the value of $t^*\!\uparrow$ at every one-step extension of R. An extension lists a new entry X followed by σ, and $t^*\!\uparrow = (t\!\uparrow)^*$. The derivation for $t\!\uparrow$, which has the size of t, at $n + 1$ and the list $(X, \sigma_0, \sigma_1, \ldots)$ gives the value $t\!\uparrow[(X, \sigma_0, \ldots)]$, which is $t[\sigma]$. □

Theorem 20.30 (Recovery and embedding)**.** *For every negative formula A with free variables below n, every list σ of terms and every environment term R, there are derivations of*

$$\mathscr{L}_n(\sigma, R) \to \big(\mathrm{Rd}_R(A^*) \to A[\sigma]\big) \qquad \textit{and} \qquad \mathscr{L}_n(\sigma, R) \to \big(A[\sigma] \to \mathrm{Rd}_R(A^*)\big).$$

Proof. Recurse on A, constructing both together.

Equation $t = u$. The reading supplies outputs a of $c(t^*)$ and b of $c(u^*)$ at R with $a = b$. Theorem 20.29 gives the outputs $t[\sigma]$ and $u[\sigma]$ of the same programs; functionality gives $a = t[\sigma]$ and $b = u[\sigma]$; so $t[\sigma] = u[\sigma]$. Conversely, from $t[\sigma] = u[\sigma]$, Theorem 20.29 supplies the two outputs the reading requires, and the equation relates them.

Falsehood. Both sides are $\bot$.

Implication $A \to B$. Given $\mathrm{Rd}_R(A^*) \to \mathrm{Rd}_R(B^*)$ and $A[\sigma]$, the embedding direction for A gives $\mathrm{Rd}_R(A^*)$, the hypothesis gives $\mathrm{Rd}_R(B^*)$, and the recovery direction for B gives $B[\sigma]$. The converse uses recovery for A and embedding for B. Neither direction for the implication can be built from one direction for its antecedent.

Universal statement $\forall A$. The reading is $\forall x(x = x \to \forall z(G(R, x, z) \to \mathrm{Rd}_z(A^*)))$. For recovery, take x; pairing totality gives z with $G(R, x, z)$, which with $\mathscr{L}_n(\sigma, R)$ gives $\mathscr{L}_{n+1}(x\sigma, z)$ for the list $x\sigma = (x, \sigma_0, \sigma_1, \ldots)$. The reading gives $\mathrm{Rd}_z(A^*)$, recovery for A at $n + 1$ gives $A[x\sigma]$, and generalization gives $(\forall A)[\sigma]$. For embedding, take x and z with $G(R, x, z)$; the same extended list is listed by z, and the hypothesis instantiated at x gives $A[x\sigma]$, which embedding turns into $\mathrm{Rd}_z(A^*)$. □

Theorem 20.31 (Arithmetic is recovered from its reading)**.** *For every closed negative formula A, a posit-free derivation proves that the reading $\mathrm{Rd}_0(A^*)$ implies A.*

Proof. Apply the recovery direction of Theorem 20.30 with $n = 0$, any list σ, which leaves the closed A unchanged, and $R = 0$. The premise $\mathscr{L}_0$ is $0 = 0$. □

Theorem 20.32 (Conservativity for negative sentences)**.** *Let A be a closed formula of the arithmetic language built from $=$, $\bot$, $\to$ and $\forall$. If the language of functions proves A, then the rules of Chapter 5 derive A by a posit-free derivation.*

Proof. Theorem 20.26 gives a posit-free derivation of $\mathrm{Rd}_0(A^*)$, and Theorem 20.31 a posit-free derivation that the reading implies A. Implication elimination combines them. By Proposition 6.4, the combined ledger records none of the three principles. □

The theorem allows full induction on both sides: the proof about functions may induct on any formula, and the derivation records the induction entry when it inducts on a quantified one.

20.3.10 The comparison with Peano arithmetic

The restriction to $=$, $\bot$, $\to$ and $\forall$ loses nothing for classical arithmetic. The *negative translation* φ^N of a formula of Definition 5.1 is defined by

$$(t = u)^N := \neg\neg(t = u), \qquad \bot^N := \bot, \qquad (\varphi \to \psi)^N := \varphi^N \to \psi^N,$$
$$(\varphi \wedge \psi)^N := \neg(\varphi^N \to \neg\psi^N), \qquad (\forall\varphi)^N := \forall\varphi^N, \qquad (\exists\varphi)^N := \neg\forall\neg\varphi^N,$$
$$(\varphi \vee \psi)^N := \neg\neg(\neg\varphi^N \to \neg\neg\psi^N).$$

It doubly negates each equation, replaces $\exists x\psi$ by $\neg\forall x\neg\psi$ and $\psi \vee \chi$ by $\neg(\neg\psi \wedge \neg\chi)$, and writes every conjunction, including the one just introduced, as $\neg(\psi \to \neg\chi)$ [4]. The result is negative, and it keeps every term and every binder in place, so φ^N is closed exactly when φ is.

Lemma 20.33 (The classical bridge)**.** *For every formula φ there are derivations from no hypotheses of $\varphi \to \varphi^N$ and $\varphi^N \to \varphi$ whose ledgers record no principle other than EM, and no induction.*

Proof. Recurse on φ, building both derivations together; write a, b for the components and A, B for their translations.

Equation. From $s = t$ and $\neg(s = t)$ follows $\bot$, so $s = t \to \neg\neg(s = t)$. Conversely, EM gives $s = t$ or $\neg(s = t)$, and the second contradicts $\neg\neg(s = t)$. *Falsehood.* The identity.

Implication. Given $a \to b$ and A: back from A to a, then b, then forward to B. Given $A \to B$ and a: forward to A, then B, then back to b. Both directions of the components are used.

Universal statement. Introduce the fresh variable and apply the component.

Conjunction. From $a \wedge b$ the components give A and B, and a hypothesis $A \to \neg B$ would then give $\bot$. Conversely, from $\neg(A \to \neg B)$, EM on A gives A, since in the case $\neg A$ the implication $A \to \neg B$ holds outright and is refuted; likewise for B; the components give $a \wedge b$.

Disjunction. From $a \vee b$, either case refutes $\neg(\neg A \to \neg\neg B)$: from A the antecedent $\neg A$ is contradictory, and from B the consequent $\neg\neg B$ holds. Conversely, EM on $A \vee B$: in the negative case $\neg A$ and $\neg B$ hold, so $\neg A \to \neg\neg B$ fails, contradicting the hypothesis; in the positive case the components give $a \vee b$.

Existential statement. From $\exists x\, a$ the component gives $\exists x\, A$, which refutes $\forall x \neg A$. Conversely, EM on $\exists x\, A$: in the negative case $\forall x \neg A$ follows, contradicting $\neg\forall x \neg A$; in the positive case the component gives $\exists x\, a$.

No LPO or MP rule and no induction occurs. EM occurs only in the backward directions of the equation, conjunction, disjunction and existential cases, and in the forward direction of an implication through the backward derivation of its antecedent. □

The typed calculus. In the calculus $\mathscr{E}^+$ of Chapter 9, a negative formula A is expressed by a type $\mathrm{Ty}(A)$: an equation $t = u$ by the identity type $\mathrm{Id}_O(t^*, u^*)$, with add and mul written as iterations; $\bot$ by the empty type $\mathbf{0}$; an implication by a function type; and $\forall x$ by a product over O. We say that $\mathscr{E}^+$ *proves* φ^N when it has a closed term of type $\mathrm{Ty}(\varphi^N)$.

The two halves of the comparison go in opposite directions. From $\mathscr{E}^+$ to arithmetic, a closed term is read in the language of functions and then compiled. From arithmetic to $\mathscr{E}^+$, a derivation is translated node by node into a term.

Reading a typed term. A term of the dependent calculus is read through its *erasure*, a term of the language of functions. Erasure sends $\prod_{x:A} B$ to $|A| \to |B|$ and every other type to O. On terms it keeps variables, 0, S, abstraction, application, I and R, and sets

$$|\mathrm{refl}_t| = 0, \qquad |J(A, x, Q, d, y, p)| = |d|, \qquad |\mathsf{E}(P, b, g, t)| = \mathsf{R}(|P|, |b|, |g|, |t|),$$

with the erasure of an empty-type elimination at A the fixed term of type $|A|$ that returns 0 after all its arguments. A type T is read as a formula $\mathrm{Adm}_T(v)$ about a term v of type $|T|$:

$$\begin{aligned} \mathrm{Adm}_O(v) &:= \top, & \mathrm{Adm}_{\mathbf{0}}(v) &:= \bot, \\ \mathrm{Adm}_{\mathrm{Id}_A(t,u)}(v) &:= (v =_O 0) \wedge (|t| =_{|A|} |u|), & \mathrm{Adm}_{D(t)}(v) &:= (|t| =_O 0) \wedge (v =_O 0), \\ \mathrm{Adm}_{\prod_{x:A} B}(v) &:= \forall x{:}|A|\,\big(\mathrm{Adm}_A(x) \to \mathrm{Adm}_B(vx)\big). \end{aligned}$$

A context Γ is read as the type context $|\Gamma|$ together with the hypotheses $\mathrm{Adm}(\Gamma)$, one formula $\mathrm{Adm}_A(x)$ for each entry $x{:}A$.

Lemma 20.34 (Reading the dependent calculus)**.** *With or without the discriminator, and in each fragment, if $\Gamma \vdash t : T$, then $|t|$ has type $|T|$ in $|\Gamma|$, and the language of functions proves $\mathrm{Adm}_T(|t|)$ in $|\Gamma|$ from the hypotheses $\mathrm{Adm}(\Gamma)$.*

Proof. The erased type $|T|$ depends only on the shape of T, so a conversion $A \equiv B$ gives $|A| = |B|$, and every typing rule erases to a typing rule of the language of functions; this gives the first assertion by induction on the derivation. For the readings, induct on the derivation, proving at the same time that a substitution from Γ to Δ sends every entry $x{:}A$ of Γ to a term whose reading is provable from $\mathrm{Adm}(\Delta)$.

- A variable reads its hypothesis. Zero and successor have type O, whose reading is $\top$.
- An abstraction is universal and implication introduction; a computation step $(\lambda x.\, b)\, x \equiv b$ and replacement identify the reading of the body. An application is universal elimination at $|u|$ and implication elimination.
- Reflexivity: $0 =_O 0$ and $|x| =_{|A|} |x|$ by reflexivity.
- Identity elimination $J(A, x, Q, d, y, p)$: the reading of $p : \mathrm{Id}_A(x, y)$ gives $|p| =_O 0$ and $|x| =_{|A|} |y|$. Replacement moves the reading of d from x to y and, by symmetry, from 0 to $|p|$. The erased term is $|d|$.
- Empty-type elimination is the rule for falsehood.
- Iteration and indexed recursion: induct on x for the reading of the erased recursion at x, using its two computation equations, and instantiate at the erased count. The dependent eliminator is the same induction for $\mathrm{Adm}_{P(x)}$; its erasure is an indexed recursion.
- Conversion of a type: the reading moves along each step of a conversion between the two types. The steps inside terms are computations and replacements; the discriminator steps exchange the two conjuncts at $D(0) \equiv \mathrm{Id}_O(0,0)$, and at $D(S(t)) \equiv \mathbf{0}$ use the rule *successor is not zero* forward and falsehood backward. The full argument is in Appendix K.7.
- A substitution substitutes into the proof and cuts its hypotheses against the readings of the substituted terms.

The remaining judgments, about contexts, types and equalities, carry no reading. □

For a negative formula A, the *canonical term* of $|\,\mathrm{Ty}(A)|$ is 0 at O and $\lambda x.\, c$ at an arrow type, with c the canonical term of the codomain.

Lemma 20.35 (Types of formulas read as the formulas)**.** *Let A be a negative formula whose embedding A^* is formed in Θ. In Θ, from any hypotheses:*

(i) a proof of A^* gives a proof of $\mathrm{Adm}_{\mathrm{Ty}(A)}$ of the canonical term;

(ii) for every term r of type $|\mathrm{Ty}(A)|$, a proof of $\mathrm{Adm}_{\mathrm{Ty}(A)}(r)$ gives a proof of A^*.

Proof. Recurse on A, proving both parts together. For an equation the reading is $(v =_O 0) \wedge (t^* =_O u^*)$, since erasure leaves the embedded terms unchanged; (i) pairs reflexivity with the given proof, and (ii) takes the second conjunct. Falsehood is unchanged. For $A \to B$: in (i), assume the reading of the domain at x; part (ii) for A gives A^*, the given proof gives B^*, part (i) for B gives the reading of the canonical term of B, and computation $(\lambda x.\, c)\, x \equiv c$ with replacement moves it to the canonical function applied to x. In (ii), apply the given proof to the canonical term of A, whose reading (i) supplies, and use (ii) for B. For $\forall A$ the reading is $\forall x{:}O\,(\top \to \mathrm{Adm}(r\,x))$; eliminate at a fresh x, apply the part for A, and introduce the quantifier again. □

Theorem 20.36 (From the typed calculus to functions)**.** *With or without the discriminator, and in each fragment, if the calculus has a closed term of type $\mathrm{Ty}(A)$ for a closed negative formula A, then the language of functions proves A.*

Proof. Let t be the closed term. Lemma 20.34 at the empty context gives a proof of $\mathrm{Adm}_{\mathrm{Ty}(A)}(|t|)$ from no hypotheses and gives $|t|$ the type $|\mathrm{Ty}(A)|$; Lemma 20.35(ii) turns it into a proof of A^*. □

From derivations to typed terms. The other direction translates a derivation node by node. The translated formulas are stable under double negation, and that stability absorbs the classical steps.

Lemma 20.37 (Stability)**.** *For every arithmetic formula φ, in each fragment, with or without the discriminator, and in every context in which its free variables are terms of type O, a term of type $\neg\neg\,\mathrm{Ty}(\varphi^N)$ gives a term of type $\mathrm{Ty}(\varphi^N)$.*

Proof. Recurse on φ. For an equation, a conjunction, a disjunction and an existential statement, $\mathrm{Ty}(\varphi^N)$ is a negation $\neg X$, and $\lambda h.\, \lambda x.\, h\,(\lambda k.\, k\,x)$ has type $\neg\neg\neg X \to \neg X$. For falsehood, apply the given term of $\neg\neg\mathbf{0}$ to the identity on $\mathbf{0}$. For an implication and a universal statement the type is a function type; map $\neg\neg(X \to Y)$ to $\neg\neg Y$ by evaluation at the given argument, and apply the case for the consequent. □

Theorem 20.38 (From derivations to typed terms)**.** *In $\mathscr{E}^+$, every derivation of a sentence φ from no hypotheses by the rules of Chapters 5 and 6, whatever its ledger, gives a closed term of type $\mathrm{Ty}(\varphi^N)$.*

Proof. Prove more: for every derivation of φ from hypotheses Ξ, every context Γ of the calculus, every assignment of terms of type O in Γ to the free variables, and terms in Γ of the types of the translated hypotheses, there is a term in Γ of type $\mathrm{Ty}(\varphi^N)$. Induct on the derivation.

Node	Term	Uses
hypothesis	the supplied term	
reflexivity	$\lambda k.\, k$ refl	
equality substitution	identity elimination along $\mathrm{Id}_O(t^*, s^*)$, with the type of the body as motive, under $\neg\neg$, then Lemma 20.37	
$\neg(S(t) = 0)$	reverse the path to $\mathrm{Id}_O(0, S(t^*))$ and eliminate it with motive $D(y)$, from $\mathrm{refl}_0 \,:\, D(0)$ to $D(S(t^*)) \equiv \mathbf{0}$ (Theorem 9.3)	discriminator
successor injectivity	identity elimination with the predecessor of Theorem 9.2	indexed recursion
equations of $+$, $\cdot$	refl by the iteration equations, under $\neg\neg$	
induction	$\lambda x{:}O.\, \mathsf{E}(P, b, g, x)$, with P the type of the translated body	dependent eliminator
$\to$, $\forall$, $\wedge$	abstraction and application; $\lambda h.\, h\, a\, b$ for a conjunction	
introductions of $\vee$, $\exists$; eliminations of $\wedge$, $\vee$, $\exists$	the standard terms for the negative encodings; each elimination yields a doubly negated conclusion, removed by Lemma 20.37	
falsehood	empty-type elimination	
EM	the type is $\neg\neg(\neg X \to \neg\neg\neg X)$, inhabited by $\lambda k.\, k\,(\lambda n.\, \lambda h.\, h\, n)$	
LPO	the type is $Z \to \neg\neg(\neg\neg Y \to \neg\neg Y)$, with Z the type of the translated premise, inhabited by $\lambda d.\, \lambda k.\, k\,(\lambda y.\, y)$	
MP	the type is $\neg\neg\neg Y \to \neg Y$, inhabited by $\lambda h.\, \lambda x.\, h\,(\lambda k.\, k\, x)$	

Table 20.3. Translating derivation nodes into terms of $\mathscr{E}^+$. Here X and Y abbreviate the types of the relevant translated formulas. The last column names the resource of Theorem 9.10 a node needs.

Implication introduction extends Γ by the translated antecedent; universal introduction and existential elimination extend it by a variable of type O. The nodes translate as in Table 20.3. For a sentence take the empty context. □

Theorem 20.39 (Peano arithmetic and the dependent calculus)**.** *Let φ be a sentence of the arithmetic language.*

1. *If $\vdash_{\mathrm{PA}} \varphi$, then $\mathscr{E}^+$ proves φ^N.*
2. *If $\mathscr{E}^+$ proves φ^N, then $\vdash_{\mathrm{PA}} \varphi$.*

Proof. For the first assertion, Theorem 8.11 gives a derivation of φ by the rules of Chapters 5 and 6, and Theorem 20.38 translates it into a closed term of type $\mathrm{Ty}(\varphi^N)$.

For the second, Theorem 20.36 gives a proof of $(\varphi^N)^*$ in the language of functions, and Theorem 20.32 a posit-free derivation of φ^N. Lemma 20.33 adds a derivation of $\varphi^N \to \varphi$ whose ledger records only EM, so the combined derivation of φ records neither LPO nor MP, and Theorem 8.11 converts it into a Peano derivation. □

Each hypothesis has a definite role. The dependent eliminator, the indexed recursor and the discriminator are used only in the first assertion, for induction, successor injectivity and $\neg(S(t) = 0)$; the second holds in each fragment, with or without the discriminator. The discriminator cannot be dropped: with it disabled, the truth-value reading of Theorem 9.8 gives every closed type of the form $\mathrm{Id}_O(t, u) \to \mathbf{0}$ the value false, so $\mathscr{E}^-$ cannot even separate 0 from $S(0)$, while Peano arithmetic can. Together, the two assertions say that $\mathscr{E}^+$ proves the translations of exactly the sentences that Peano arithmetic proves.

20.3.11 Consistency, incompleteness and finite sets

The comparison says that $\mathscr{E}^+$ and Peano arithmetic stand or fall together. It does not by itself say that either stands. This subsection proves that both are consistent, shows that Peano arithmetic does not prove the sentence expressing its own consistency and that $\mathscr{E}^+$ does not prove the negative translation of that sentence, and reads two further theories through the same comparison. Subsection 20.3.12 continues with Löb's theorem, Gödel's second theorem for finite extensions of Peano arithmetic and a tower of consistency statements. From Theorem 20.42 on, the arguments use a classical metatheory: the completeness of first-order calculi for their models, proved by Henkin's construction [11], and, for Theorem 20.44(3), set theory with a universe of sets.

Corollary 20.40 (Equiconsistency)**.** *$\mathscr{E}^+$ has a closed term of the empty type exactly when Peano arithmetic derives $\bot$.*

Proof. Apply Theorem 20.39 to the sentence $\bot$, whose negative translation is $\bot$ and whose type is $\mathbf{0}$. □

Theorem 20.41 (Peano arithmetic and $\mathscr{E}^+$ are consistent)**.** *In a metatheory that grants LPO for the predicates that arithmetic formulas define, and in particular in a classical metatheory, no derivation by the rules of Chapters 5 and 6 proves $\bot$ from no hypotheses, whatever its ledger. Hence Peano arithmetic does not derive $\bot$, and $\mathscr{E}^+$ has no closed term of the empty type. Posit-free derivations need no such principle: none of them proves $\bot$.*

Proof. By Corollary 6.15, under that LPO every derivation from no hypotheses is sound in $\mathbb{N}$, and $\bot$ is satisfied by no environment. A Peano derivation of $\bot$ would give such a derivation, by Theorem 8.11, and a closed term of $\mathbf{0}$ in $\mathscr{E}^+$ would give one, by Corollary 20.40. For posit-free derivations, Corollary 6.7 needs no principle at all. □

Theorem 20.44 below gives a second proof, through a set model of a stronger calculus.

The consistency sentence. To ask whether Peano arithmetic proves its own consistency, consistency must be a sentence of arithmetic. Fix the following finite proof checker. It reads proofs in the language of $0, S, +, \cdot, =, \bot, \to$ and $\forall$, with fourteen axiom schemas: $A \to (B \to A)$; $(A \to (B \to C)) \to ((A \to B) \to (A \to C))$; contraposition $(\neg B \to \neg A) \to (A \to B)$; instantiation and distribution for $\forall$; reflexivity and substitution of equals; the six arithmetic axioms of Definition 8.10; and induction for every formula. Its rules are modus ponens and generalization. It is a Hilbert-style presentation of Peano arithmetic. Terms, formulas and

proofs are coded by numbers through the pairing $(a, b) \mapsto 2^a(2b + 1) - 1$, and finite tables through Gödel's β of Section 20.3.3. This is a second pairing, beside the pairing (10.3) used elsewhere in this section: the checker, and the proof of Theorem 20.44 in Appendix L, are written with it. The clauses below read codes only through the values stored in the tables, and fact (D5) in the proof of Theorem 20.42 builds, from a certificate coded with (10.3), the tables of an accepted proof of this checker. Let Con(PA) be the sentence saying that no finite tables satisfy the finitely many clauses that describe an accepted proof of $\bot$; Definition L.1 writes it out, clause by clause. The fourteen schemas and two rules of the checker are sound in $\mathbb{N}$, but that alone does not make Con(PA) true, since tables that satisfy its clauses need not be the decoding of an accepted proof. Theorem 20.44 shows that it is true: its first part derives the sentence in a calculus whose set model, in part (3), makes every derived arithmetic sentence true.

Theorem 20.42 (Gödel's second incompleteness theorem for this checker)**.** *If Peano arithmetic is consistent, it does not derive* Con(PA)*. Since it is consistent (Theorem 20.41), it does not derive* Con(PA)*.*

Standard theorem; the argument for this checker. This is Gödel's theorem [8, Satz XI, p. 196], with the derivability conditions of Hilbert and Bernays [9] in the form given by Löb [10], here for this presentation and this checker. The steps are stated here and proved in full in Appendix M, Sections M.1–M.5. One change of method makes it manageable: each statement that Peano arithmetic must derive is shown true in an arbitrary model of Peano arithmetic and then read back as a derivation. Peano arithmetic is complete for its models, by Henkin's construction with free variables as witnesses: a formula true in every model under every assignment has a derivation. Inside a model the reasoning is ordinary mathematics about a discretely ordered semiring with induction for every formula.

Let $\mathrm{Pr}(x)$ be the formula "some certificate proves the formula coded by x", with certificates finite lists of records coded by β-tables, each record an axiom, a modus ponens node, a generalization node, or a local check of a substitution, a lifting or a shift of terms, by the clauses the checker uses. Write $\ulcorner\varphi\urcorner$ for the numeral of the code of φ. Appendix M names this formula $\mathrm{Prov}(x)$ and writes $\mathrm{Pr}(\varphi)$ for $\mathrm{Prov}(\ulcorner\varphi\urcorner)$. Five facts are proved.

(D1) If Peano arithmetic derives φ, it derives $\mathrm{Pr}(\ulcorner\varphi\urcorner)$: the derivation becomes a closed Hilbert proof, and in every model each axiom has a certificate while modus ponens and generalization extend certificates.

(D2) Peano arithmetic derives $\mathrm{Pr}(\ulcorner\varphi \to \psi\urcorner) \to \mathrm{Pr}(\ulcorner\varphi\urcorner) \to \mathrm{Pr}(\ulcorner\psi\urcorner)$: two certificates concatenate with one modus ponens record.

(D3) Peano arithmetic derives $\mathrm{Pr}(\ulcorner\varphi\urcorner) \to \mathrm{Pr}(\ulcorner\mathrm{Pr}(\ulcorner\varphi\urcorner)\urcorner)$. In a model every element x has the code of the numeral term $S^x(0)$; codes commute with substitution; every formula true in all models has a certificate at every instance by closed terms; and every true bounded formula has a certificate, by induction on bounded formulas, with a bounded universal quantifier handled by induction on its bound.

(D4) There is a sentence G with $G \leftrightarrow \neg\,\mathrm{Pr}(\ulcorner G\urcorner)$ derivable: with $\mathrm{Dg}(x, y)$ the graph of substituting the numeral of x into the formula coded by x, take $\theta(x) := \forall y(\mathrm{Dg}(x, y) \to \neg\,\mathrm{Pr}(y))$ and $G := \theta(\ulcorner\theta\urcorner)$.

(D5) Peano arithmetic derives $\mathrm{Con(PA)} \to \neg \Pr(\ulcorner \bot \urcorner)$: from a certificate of $\bot$ in a model, comprehension over β-sequences builds the tables of an accepted checker proof of $\bot$, so the model refutes Con(PA).

From (D1)–(D4), Gödel's propositional argument derives $\neg \Pr(\ulcorner \bot \urcorner) \to G$. Write P_G for $\Pr(\ulcorner G \urcorner)$. Assume P_G. By (D3), $\Pr(\ulcorner P_G \urcorner)$. By (D4) Peano arithmetic derives $G \to \neg P_G$, so (D1) and (D2) give $\Pr(\ulcorner \neg P_G \urcorner)$, that is, $\Pr(\ulcorner P_G \to \bot \urcorner)$, and (D2) again gives $\Pr(\ulcorner \bot \urcorner)$. So P_G implies $\Pr(\ulcorner \bot \urcorner)$, and $\neg \Pr(\ulcorner \bot \urcorner)$ implies $\neg P_G$, which is G by (D4). If Peano arithmetic derived Con(PA), it would derive G by (D5); then (D1) gives $\Pr(\ulcorner G \urcorner)$ while G gives its negation, and Peano arithmetic would derive $\bot$. □

Proposition 20.43 (A criterion for strictness)**.** *Let σ be a sentence that Peano arithmetic does not derive. Then $\mathscr{E}^+$ does not prove σ^N, so any extension of $\mathscr{E}^+$ that proves σ^N proves a negative arithmetic sentence that $\mathscr{E}^+$ does not.*

Proof. If $\mathscr{E}^+$ proved σ^N, Theorem 20.39 would give a Peano derivation of σ. □

A universe supplies such an extension. Let $\mathscr{F}_U$ extend $\mathscr{E}^+$ by one universe: a type of codes, with codes for O, the empty type, identity types and products, a decoding that sends each code to the type it names, and the orbit eliminator allowed to produce codes. Section 9.2 excludes universes from $\mathscr{E}^+$. In $\mathscr{F}_U$ the discriminator need not be primitive: $D(t)$ is the decoding of a code defined by recursion on t, and its two equations hold by computation; the derivations of $\mathscr{E}^+$ are translated accordingly.

Theorem 20.44 (One universe proves the consistency of arithmetic)**.**

1. *$\mathscr{F}_U$ proves* $\mathrm{Con(PA)}^N$.
2. *Every derivation of $\mathscr{E}^+$ translates into one of $\mathscr{F}_U$, so $\mathscr{F}_U$ proves the negative translation of every sentence that Peano arithmetic derives.*
3. *In set theory with a universe of sets (a transitive set closed under pairs, unions, power sets and images of its members under maps into it, and containing the set of numerals; the sets of rank below a strongly inaccessible cardinal form one), $\mathscr{F}_U$ is sound for a set model in which U is read as that universe: it has no closed term of the empty type, and every arithmetic sentence whose negative translation it proves is true. In particular, in that metatheory, Peano arithmetic is consistent. In a type-theoretic metatheory the model uses sets built over two type universes, the small sets over the lower one.*
4. *$\mathscr{E}^+$ does not prove* $\mathrm{Con(PA)}^N$*, so $\mathscr{F}_U$ proves a closed negative arithmetic sentence that $\mathscr{E}^+$ does not.*

Proof. The full proof is in Appendix L, Sections L.1–L.8; its route is this. For (1), the universe lets an elimination over the orbit produce codes, so $\mathscr{F}_U$ reads every formula code, under an environment, as a type: an equation as the double negation of an identity, $\bot$ as $\mathbf{0}$, implication as a function type and $\forall$ as a product over O. Given tables that satisfy the clauses of Con(PA), induction on the fuel of the checker shows that every certified line has an inhabited reading,

case by case on the fourteen schemas and the two rules; the induction schema is the case that needs the universe, because its motive varies with a code. A certified proof of $\bot$ would therefore inhabit $\mathbf{0}$. For (2), the discriminator becomes the decoding of a code defined by recursion, and Theorem 20.39 supplies the arithmetic. For (3), types are read as sets and U as the universe of small sets; raw conversion preserves the values of expressions that satisfy a safety condition, by parallel reduction and its confluence, and soundness is by induction on derivations. The metatheory of (3) is stronger than that of Theorem 20.41, which already gives the consistency of Peano arithmetic. Part (4) is Proposition 20.43 with Theorem 20.42. □

Finite sets and bounded arithmetic. The comparison also reads finite set theory. Let $\mathrm{Pow}_2(x, p)$ be a formula with free variables among x and p, and read membership as binary digits:

$$x \,\varepsilon\, y \;:\Longleftrightarrow\; \exists p \le y \exists q \le y \exists r < p \,\big(\mathrm{Pow}_2(x, p) \wedge y = (2q + 1)p + r\big).$$

When Pow_2 defines $p = 2^x$, this says that binary digit x of y is 1. *Bounded arithmetic* $I\Delta_0$ consists of the rules with excluded middle and with induction only on bounded formulas, those whose quantifiers have the form $\forall y \le t$ or $\exists y \le t$; its derivations record neither LPO nor MP. A *standard bounded graph* is a bounded formula $\mathrm{Pow}_2(x, p)$ that defines $p = 2^x$ in $\mathbb{N}$ and for which $I\Delta_0$ derives $\mathrm{Pow}_2(0, 1)$; $\mathrm{Pow}_2(x, p) \to \mathrm{Pow}_2(S(x), 2p)$; $\mathrm{Pow}_2(S(x), q) \to \exists p \le q(q = 2p \wedge \mathrm{Pow}_2(x, p))$; that p is a function of x; that p is positive; and $\mathrm{Pow}_2(x, p) \to \forall y \le x \exists p'\ \mathrm{Pow}_2(y, p')$.

Proposition 20.45 (Pair formation gives exponentiation)**.** *For every formula* $\mathrm{Pow}_2(x, p)$*, the rules derive* $\forall x \exists p\ \mathrm{Pow}_2(x, p)$ *from the pairing axiom* $\forall x \forall y \exists z \forall w(w \,\varepsilon\, z \leftrightarrow (w = x \vee w = y))$*, with the empty ledger.*

Proof. Apply the pairing axiom to x and x: some z satisfies $w \,\varepsilon\, z \leftrightarrow (w = x \vee w = x)$ for every w. At $w = x$ the right side holds by reflexivity, so $x \,\varepsilon\, z$, and the conjunct $\mathrm{Pow}_2(x, p)$ of $x \,\varepsilon\, z$ gives it for some p. The derivation uses the hypothesis, the rules for the connectives and quantifiers and reflexivity, and nothing else. □

Theorem 20.46 (Pair formation and exponentiation)**.** *There is a standard bounded graph* Pow_2 *for which* $I\Delta_0$ *derives the pairing axiom from* $\forall x \exists p\ \mathrm{Pow}_2(x, p)$*. With Proposition 20.45,* $I\Delta_0$ *derives each of pair formation and exponentiation from the other.*

Proof. The full proof is in Appendix L, Sections L.9–L.12; its route is this. The classical rules are complete for their models, by Henkin's construction with fresh free variables as witnesses, and a closed induction axiom for a bounded formula has a derivation with one bounded induction, so $I\Delta_0$ derives a sentence from given sentences exactly when it holds in every model of $I\Delta_0$ that satisfies them. The arithmetic is then done in an arbitrary model. The graph states $p = 2^x$ through a certificate of size polynomial in p: a number $N < 2p$ marks with its binary digits the checkpoints $2^{\lfloor x/2^j \rfloor}$, a number $B < p^2$ records the exponents $\lfloor x/2^j \rfloor$ in its digit blocks, and each checkpoint u steps to u^2 or $2u^2$. Every certificate is a smaller certificate with one new top checkpoint, which proves the six properties by strong induction on p over bounded formulas. For pair formation take $z = 2^x + 2^y$ when $x \neq y$ and $z = 2^x$ when $x = y$, and read off the digits by division by powers of 2. □

Finite set theory $\mathrm{ZF}^*_{\mathrm{fin}}$ is the classical first-order theory of $\in$ with extensionality, empty set, pairing, union, power set, separation and replacement for every formula, foundation, the negation of infinity, and transitive containment, $\forall x\, \exists u\, (x \subseteq u \wedge u \text{ transitive})$. The *Ackermann reading* [12] φ^a of a set-theoretic sentence quantifies over numbers and reads $x \in y$ as $x\ \varepsilon\ y$.

Theorem 20.47 (Finite set theory is Peano arithmetic)**.** *Let* Pow_2 *be a formula for which Peano arithmetic derives* $\mathrm{Pow}_2(0,1)$*, upward recursion and functionality, as it does for a standard bounded graph. Then for every sentence* φ *of set theory,* $\mathrm{ZF}^*_{\mathrm{fin}}$ *derives* φ *exactly when Peano arithmetic derives* φ^a*. For a standard bounded graph this holds exactly when* $\mathscr{E}^+$ *proves* $(\varphi^a)^N$*.*

Standard theorem; the argument for these calculi. The full argument is in Appendix M, Section M.6. The theorem is Kaye and Wong's [13, Theorems 3.1, 6.5 and 6.6, pp. 500–504], where $\mathrm{ZF}^*_{\mathrm{fin}}$ is called ZF−inf*; here it is proved for these calculi and every graph with the three properties. Both directions go through models, with completeness proved by Henkin's construction for Peano arithmetic and for the calculus of $\mathrm{ZF}^*_{\mathrm{fin}}$. If $\mathrm{ZF}^*_{\mathrm{fin}}$ derives φ and M is a model of Peano arithmetic, binary membership in M satisfies every axiom: pairing, union, power set, separation and transitive containment are comprehension over the digits below a bound, replacement is collection followed by comprehension, foundation is the least number principle, and the negation of infinity takes the largest digit. So φ^a holds in M. Conversely, the von Neumann numerals of a nonempty model V of $\mathrm{ZF}^*_{\mathrm{fin}}$ form a model of Peano arithmetic, and the map sending n to the set of the images of the digit places of n, defined by course-of-values recursion, is a bijection onto V under which membership becomes binary membership; it is onto by $\in$-induction, which uses transitive containment [13, Proposition 5.6, p. 502]. The last assertion is Theorem 20.39. □

20.3.12 Self-reference: Löb's theorem and a tower of consistency statements

Theorem 20.42 shows that Peano arithmetic does not derive its own consistency. What can it derive about its own provability? Take a sentence H that says of itself that it is provable: $H \leftrightarrow \mathrm{Pr}(\ulcorner H \urcorner)$. Henkin asked whether such a sentence is a theorem. Löb's answer is yes, and his theorem settles a wider question: Peano arithmetic certifies the soundness of its proof of φ, in the form $\mathrm{Pr}(\ulcorner \varphi \urcorner) \to \varphi$, only when it proves φ outright. A second question follows. Peano arithmetic is consistent, so the sentence $\neg\, \mathrm{Pr}(\ulcorner \bot \urcorner)$, which says so, is true, and we may add it as an axiom. The stronger theory proves the consistency of Peano arithmetic. Does it prove its own?

The metatheory is classical, as from Theorem 20.42 on. $\mathrm{Prov}(x)$ is the provability formula of Appendix M.2, written $\mathrm{Pr}(x)$ in the proof of Theorem 20.42. As in that proof, $\ulcorner \varphi \urcorner$ is the code of φ (inside a formula, its numeral), and $\mathrm{Pr}(\ulcorner \varphi \urcorner)$ is the sentence $\mathrm{Prov}(\ulcorner \varphi \urcorner)$, which Appendix M writes $\mathrm{Pr}(\varphi)$. The derivability conditions (D1)–(D5) are those of that proof, proved in Appendix M (Propositions M.4, M.5, M.9, M.6 and M.7). A Σ_1 *sentence* is a sentence $\exists x_1 \cdots \exists x_k\, B$ whose matrix B is bounded: built from equations and $\bot$ by $\wedge$, $\vee$, $\to$ and the bounded quantifiers $\forall y \le t$ and $\exists y \le t$, as in Section L.9. Each $\mathrm{Pr}(\ulcorner \varphi \urcorner)$ is one, since Prov is twelve existential quantifiers over a bounded formula (Appendix M.2).

Finite extensions. For a finite list $\Gamma = (\gamma_1, \dots, \gamma_n)$ of sentences, write $\Gamma \Rightarrow \varphi$ for $\gamma_1 \to (\gamma_2 \to \cdots \to (\gamma_n \to \varphi))$. Say that PA + Γ *derives* φ when Peano arithmetic derives $\Gamma \Rightarrow \varphi$; by implication introduction and elimination this is the same as $\Gamma \vdash_{\mathrm{PA}} \varphi$. Put

$$\mathrm{Pr}_\Gamma(\ulcorner\varphi\urcorner) := \mathrm{Pr}(\ulcorner\Gamma \Rightarrow \varphi\urcorner), \qquad \mathrm{Con}(\mathrm{PA}+\Gamma) := \neg\,\mathrm{Pr}_\Gamma(\ulcorner\bot\urcorner).$$

PA + Γ is *consistent* when it does not derive $\bot$. For Γ empty, Con(PA + Γ) is $\neg\,\mathrm{Pr}(\ulcorner\bot\urcorner)$, which (D5) derives from Con(PA).

Theorem 20.48 (The diagonal lemma)**.** *For every formula $\psi(y)$, whose other free variables are parameters, there is a formula D with the same parameters, a sentence when ψ has no other free variable, such that Peano arithmetic derives $D \to \psi(\ulcorner D\urcorner)$ and $\psi(\ulcorner D\urcorner) \to D$.*

Proof. This is the proof of Proposition M.6 with $\neg\,\mathrm{Prov}$ replaced by ψ. Let $\mathrm{Dg}(x, y)$ be the formula of that proof, put $\theta(x) := \forall y(\mathrm{Dg}(x, y) \to \psi(y))$, and let $D := \theta(\ulcorner\theta\urcorner)$. In every model of Peano arithmetic, $\mathrm{Dg}(\ulcorner\theta\urcorner, y)$ holds exactly for $y = \ulcorner D\urcorner$, by Lemma M.2(c) and (d). So at every assignment of the parameters, D holds exactly when $\psi(\ulcorner D\urcorner)$ does, and Theorem M.1 gives both implications. □

Theorem 20.49 (Löb's theorem)**.** *For every formula φ: if Peano arithmetic derives $\mathrm{Pr}(\ulcorner\varphi\urcorner) \to \varphi$, it derives φ. Hence it derives $\mathrm{Pr}(\ulcorner\varphi\urcorner) \to \varphi$ exactly when it derives φ. The diagonal sentence H of $\mathrm{Prov}(y)$, for which Peano arithmetic derives $H \leftrightarrow \mathrm{Pr}(\ulcorner H\urcorner)$, is a theorem of Peano arithmetic.*

Proof. Apply Theorem 20.48 to $\mathrm{Prov}(y) \to \varphi$: some L has $L \leftrightarrow (\mathrm{Pr}(\ulcorner L\urcorner) \to \varphi)$ derivable. Write P for $\mathrm{Pr}(\ulcorner L\urcorner)$. From $L \to (P \to \varphi)$, (D1) and (D2) twice give $P \to (\mathrm{Pr}(\ulcorner P\urcorner) \to \mathrm{Pr}(\ulcorner\varphi\urcorner))$, and (D3) gives $P \to \mathrm{Pr}(\ulcorner P\urcorner)$; so $P \to \mathrm{Pr}(\ulcorner\varphi\urcorner)$. With the hypothesis $\mathrm{Pr}(\ulcorner\varphi\urcorner) \to \varphi$ this gives $P \to \varphi$, which is L by the diagonal property. Then (D1) gives P, and so φ. If Peano arithmetic derives φ, it derives $\mathrm{Pr}(\ulcorner\varphi\urcorner) \to \varphi$ trivially. For H, the diagonal property gives $\mathrm{Pr}(\ulcorner H\urcorner) \to H$, and the first assertion gives H. □

The theorem is Löb's [10]. At $\varphi = \bot$ it is Gödel's second theorem again: $\mathrm{Pr}(\ulcorner\bot\urcorner) \to \bot$ is $\neg\,\mathrm{Pr}(\ulcorner\bot\urcorner)$, so a derivation of it would give a derivation of $\bot$.

Theorem 20.50 (Gödel's second theorem for finite extensions)**.** *Let Γ be a finite list of sentences.*

1. *If* PA + Γ *is consistent, it does not derive* Con(PA + Γ).
2. *If* PA + Γ *derives* $\mathrm{Pr}_\Gamma(\ulcorner\varphi\urcorner) \to \varphi$*, it derives φ.*

Proof. The proofs of Theorems 20.49 and 20.42 use only these facts about the theory and its provability formula: the theory contains Peano arithmetic and is closed under modus ponens, (D1), (D2) and (D3) hold, and the needed diagonal sentences exist. We check them for PA+Γ and Pr_Γ. The theory is closed under modus ponens, since $(\Gamma \Rightarrow (\varphi \to \psi)) \to ((\Gamma \Rightarrow \varphi) \to (\Gamma \Rightarrow \psi))$ is a tautology, and it contains every theorem of Peano arithmetic, since $A \to (\Gamma \Rightarrow A)$ is one. (D1): if PA + Γ derives φ, then (D1) gives $\mathrm{Pr}(\ulcorner\Gamma \Rightarrow \varphi\urcorner)$. (D2): (D1) and (D2) at the first tautology give $\mathrm{Pr}_\Gamma(\ulcorner\varphi \to \psi\urcorner) \to (\mathrm{Pr}_\Gamma(\ulcorner\varphi\urcorner) \to \mathrm{Pr}_\Gamma(\ulcorner\psi\urcorner))$. (D3): (D3) gives $\mathrm{Pr}(\ulcorner A\urcorner) \to \mathrm{Pr}(\ulcorner\mathrm{Pr}(\ulcorner A\urcorner)\urcorner)$ for $A := \Gamma \Rightarrow \varphi$, and (D1) and (D2) at the second tautology turn $\mathrm{Pr}(\ulcorner\mathrm{Pr}(\ulcorner A\urcorner)\urcorner)$ into $\mathrm{Pr}_\Gamma(\ulcorner\mathrm{Pr}_\Gamma(\ulcorner\varphi\urcorner)\urcorner)$.

Diagonal sentences: let $\mathrm{Prov}_\Gamma(y)$ say that Prov holds at the code of $\Gamma \Rightarrow \eta$, for η the formula coded by y; the code of an implication is computed from the codes of its parts by the pairing of Appendix M.2, which a formula defines. In every model, at the numeral of $\ulcorner \eta \urcorner$ this formula holds exactly when $\mathrm{Pr}_\Gamma(\ulcorner \eta \urcorner)$ does, so Theorem 20.48 at $\neg\,\mathrm{Prov}_\Gamma(y)$ and at $\mathrm{Prov}_\Gamma(y) \to \varphi$, with Theorem M.1, gives a sentence G_Γ, and a formula L with the free variables of φ, such that Peano arithmetic derives $G_\Gamma \leftrightarrow \neg\,\mathrm{Pr}_\Gamma(\ulcorner G_\Gamma \urcorner)$ and $L \leftrightarrow (\mathrm{Pr}_\Gamma(\ulcorner L \urcorner) \to \varphi)$.

Now (2) is the proof of Theorem 20.49 read in PA + Γ. For (1), the propositional argument of Theorem 20.42, read in PA + Γ, derives $\neg\,\mathrm{Pr}_\Gamma(\ulcorner \bot \urcorner) \to G_\Gamma$. If PA + Γ derived $\mathrm{Con}(\mathrm{PA} + \Gamma)$, which is $\neg\,\mathrm{Pr}_\Gamma(\ulcorner \bot \urcorner)$ literally, it would derive G_Γ, then $\mathrm{Pr}_\Gamma(\ulcorner G_\Gamma \urcorner)$ by (D1), while G_Γ gives its negation; so it would derive $\bot$. No counterpart of (D5) is needed. □

For Γ empty, part (1) says that Peano arithmetic does not derive $\neg\,\mathrm{Pr}(\ulcorner \bot \urcorner)$; with (D5) this gives Theorem 20.42 again. To use the theorem we need to know which extensions are consistent. The provability formula answers that in $\mathbb{N}$.

Theorem 20.51 (The provability formula reads correctly in $\mathbb{N}$)**.** *For every formula X and every finite list Γ of sentences:*

1. $\mathrm{Pr}(\ulcorner X \urcorner)$ *is true in* $\mathbb{N}$ *exactly when Peano arithmetic derives X;*
2. $\mathrm{Con}(\mathrm{PA} + \Gamma)$ *is true in* $\mathbb{N}$ *exactly when* PA + Γ *is consistent;*
3. *the reflection instance* $\mathrm{Pr}(\ulcorner X \urcorner) \to X$ *is true in* $\mathbb{N}$ *at every assignment, and Peano arithmetic derives it only if it derives X.*

Proof. (1) If Peano arithmetic derives X, Lemma M.3(d) gives a closed Hilbert derivation of a formula with the code $\ulcorner X \urcorner$, and the construction in the proof of Proposition M.4, carried out in $\mathbb{N}$, gives a certificate. Conversely, take a certificate in $\mathbb{N}$. Decode every number as an expression: tags 2 to 6 as a variable, 0, a successor, a sum and a product, tags 7 to 10 as an equation, $\bot$, an implication and a universal statement, and any other number as the term 0 in a term position and as $\bot$ in a formula position. The decoding is total; no well-formedness is assumed. By strong induction on codes, each locally correct record of kinds 1 to 4 computes its operation on the decoded expressions. Hence the conclusion of each axiom record decodes to an instance of its schema, whatever its parameters, and each schema instance is true in every model of Peano arithmetic. Modus ponens and generalization preserve truth in every model. The premises of a proof node are its children, hence smaller, so strong induction on the code of proof nodes shows that every proof record's conclusion decodes to a formula true in every model. The root's conclusion $\ulcorner X \urcorner$ decodes to $X^\star$, the formula of Lemma M.3 with $\wedge$, $\vee$ and $\exists$ written classically, which is true in exactly the same structures as X. Theorem M.1 gives a derivation of X.

(2) Apply (1) to $X := \Gamma \Rightarrow \bot$.

(3) If $\mathrm{Pr}(\ulcorner X \urcorner)$ is true, Peano arithmetic derives X by (1), and X is true at every assignment, since every derivation of Peano arithmetic is sound in $\mathbb{N}$ in a classical metatheory (Corollary 6.15 and Theorem 8.11). The second assertion is Theorem 20.49. □

So every reflection instance is true, and Peano arithmetic proves exactly those it needs no reflection for. The next fact is the internal form of part (1) for Σ_1 sentences.

Proposition 20.52 (Σ_1 completeness inside Peano arithmetic)**.** *For every Σ_1 sentence σ, Peano arithmetic derives $\sigma \to \mathrm{Pr}(\ulcorner \sigma \urcorner)$.*

Proof. Let σ be $\exists x_1 \cdots \exists x_k\, B$, and let σ hold in a model M with witnesses $a_1, \ldots, a_k$. By Lemma M.8(d), the code of B with the numeral codes of the a_i plugged in has a certificate in M. Existential introduction is an instance of a propositional and quantifier law, so Lemma M.8(b) and modus ponens add the k quantifiers one at a time, as in the proof of Proposition M.9, and give a certificate for $\ulcorner \sigma \urcorner$. Theorem M.1 gives the derivation. □

The tower. Put $\Gamma_0 := ()$ and $\Gamma_{k+1} := (\mathrm{Con}(\mathrm{PA} + \Gamma_k), \Gamma_k)$, and write T_k for $\mathrm{PA} + \Gamma_k$, Pr_{T_k} for Pr_{Γ_k} and $\mathrm{Con}(T_k)$ for $\mathrm{Con}(\mathrm{PA} + \Gamma_k)$. So T_0 is Peano arithmetic and $T_{k+1} = T_k + \mathrm{Con}(T_k)$. Such progressions of theories go back to Turing [71].

Theorem 20.53 (A tower of consistency statements)**.** *For every k:*

1. *T_k is consistent;*
2. *T_{k+1} derives $\mathrm{Con}(T_k)$;*
3. *for every Σ_1 sentence σ, T_{k+1} derives $\mathrm{Pr}_{T_k}(\ulcorner \neg\sigma \urcorner) \to \neg\sigma$;*
4. *T_k does not derive $\mathrm{Con}(T_k)$;*
5. *T_k does not derive $\mathrm{Pr}_{T_k}(\ulcorner \neg(0 = 0) \urcorner) \to \neg(0 = 0)$.*

Proof. (1) Prove by induction on k that every member of Γ_k is true in $\mathbb{N}$ and that T_k is consistent. For $k = 0$ there is no member, and Peano arithmetic is consistent (Theorem 20.41). For the step, $\mathrm{Con}(T_k)$ is true by Theorem 20.51(2) and the induction hypothesis, so every member of Γ_{k+1} is true. If Peano arithmetic derived $\Gamma_{k+1} \Rightarrow \bot$, that formula would be true in $\mathbb{N}$, by soundness as in the proof of Theorem 20.51(3), and its premises are true, so $\bot$ would be true.

(2) $\mathrm{Con}(T_k)$ is the first member of Γ_{k+1}.

(3) Argue in T_{k+1}. Assume $\mathrm{Pr}_{T_k}(\ulcorner \neg\sigma \urcorner)$ and σ. Proposition 20.52 gives $\mathrm{Pr}(\ulcorner \sigma \urcorner)$, and (D1) and (D2) at the tautology $\sigma \to (\Gamma_k \Rightarrow \sigma)$ give $\mathrm{Pr}_{T_k}(\ulcorner \sigma \urcorner)$. (D1) and (D2) at the tautology $(\Gamma_k \Rightarrow \sigma) \to ((\Gamma_k \Rightarrow \neg\sigma) \to (\Gamma_k \Rightarrow \bot))$ give $\mathrm{Pr}_{T_k}(\ulcorner \bot \urcorner)$, against $\mathrm{Con}(T_k)$. So $\neg\sigma$.

(4) Theorem 20.50(1) with (1).

(5) By Theorem 20.50(2), a derivation of the instance would give a derivation of $\neg(0 = 0)$ in T_k, and with reflexivity a derivation of $\bot$, against (1). □

Each level certifies the consistency of the level below and more: by (3), whenever T_k refutes a Σ_1 sentence, T_{k+1} certifies that the refutation is correct. No level certifies either fact about itself, and by (5) not even the single reflection instance at $0 = 0$. Reflection for Σ_1 sentences themselves, rather than their negations, lies higher: the instance at A_k two levels up (Theorem 20.54(3)), and the whole Σ_1 schema for T_k at no level of the tower (Theorem 20.54(4)).

Theorem 20.54 (Reflection at A_k lies two levels up). *For every k, let $A_k := \mathrm{Pr}_{T_k}(\ulcorner \bot \urcorner)$, a Σ_1 sentence, and let $\rho_k := \mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner) \to A_k$ be the Σ_1 reflection instance for T_k at A_k.*

1. *ρ_k is true in $\mathbb{N}$.*
2. *T_{k+1} derives ρ_k exactly when it derives $\mathrm{Con}(T_{k+1})$; so it does not derive ρ_k.*
3. *T_{k+2} derives ρ_k.*
4. *For all k and j, let $\sigma_{k,j}$ be $\mathrm{Con}(T_{k+j-1}) \to (\cdots \to (\mathrm{Con}(T_k) \to A_{k+j}))$, with $\sigma_{k,0} = A_k$. The instance $\mathrm{Pr}_{T_k}(\ulcorner \sigma_{k,j} \urcorner) \to \sigma_{k,j}$ is true in $\mathbb{N}$, and T_j does not derive it.*

Proof. Since $\Gamma_{k+1} \Rightarrow \bot$ is $\neg A_k \to (\Gamma_k \Rightarrow \bot)$, (D1) and (D2) at the two classical tautologies $(\neg A \to (\Gamma \Rightarrow \bot)) \to (\Gamma \Rightarrow A)$ and $(\Gamma \Rightarrow A) \to (\neg A \to (\Gamma \Rightarrow \bot))$ give

$$\vdash_{\mathrm{PA}} A_{k+1} \to \mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner) \qquad \text{and} \qquad \vdash_{\mathrm{PA}} \mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner) \to A_{k+1}. \tag{20.3}$$

(1) If $\mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner)$ is true, Peano arithmetic derives $\Gamma_k \Rightarrow A_k$ (Theorem 20.51(1)); that formula is then true, and the members of Γ_k are true (proof of Theorem 20.53(1)), so A_k is true.

(2) Suppose T_{k+1} derives ρ_k. Argue in T_{k+1}: from A_{k+1}, (20.3) gives $\mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner)$ and ρ_k gives A_k, against the member $\mathrm{Con}(T_k) = \neg A_k$; so $\neg A_{k+1}$, which is $\mathrm{Con}(T_{k+1})$. Conversely, if T_{k+1} derives $\neg A_{k+1}$, then by (20.3) it refutes $\mathrm{Pr}_{T_k}(\ulcorner A_k \urcorner)$, and ρ_k holds. By Theorems 20.50(1) and 20.53(1), T_{k+1} does not derive $\mathrm{Con}(T_{k+1})$.

(3) T_{k+2} has the member $\mathrm{Con}(T_{k+1}) = \neg A_{k+1}$, and the converse direction of (2) applies in T_{k+2}.

(4) Truth is as in (1). For the rest, let Δ list the members of Γ_{k+i} above Γ_k, so that $\Gamma_{k+i} \Rightarrow \varphi$ is $\Delta \Rightarrow (\Gamma_k \Rightarrow \varphi)$, and $\sigma_{k,i}$ is $\Delta \Rightarrow A_{k+i}$. The first half of (20.3) at $k+i$, followed by (D1) and (D2) at the tautology that moves the premises Δ past Γ_k, gives

$$\vdash_{\mathrm{PA}} A_{k+i+1} \to \mathrm{Pr}_{T_k}(\ulcorner \sigma_{k,i} \urcorner).$$

In T_{k+i+1} every member of Δ holds and $\neg A_{k+i}$ holds, so $\neg \sigma_{k,i}$. A derivation of the instance at $\sigma_{k,i}$ in T_{k+i+1} would therefore give $\neg \mathrm{Pr}_{T_k}(\ulcorner \sigma_{k,i} \urcorner)$, hence $\neg A_{k+i+1}$, which is $\mathrm{Con}(T_{k+i+1})$; by Theorems 20.50(1) and 20.53(1) there is none. Take $i := j$. Every member of Γ_j is a member of Γ_{k+j+1}, so T_j derives only what T_{k+j+1} derives, and T_j does not derive the instance. □

Consistency gives reflection for negations of Σ_1 sentences, by the proof of Theorem 20.53(3), and it climbs one level per step. Reflection at the Σ_1 sentence A_k is two steps away. Each $\sigma_{k,j}$ is equivalent in Peano arithmetic to $A_k \vee \cdots \vee A_{k+j}$, since $\mathrm{Con}(T_m)$ is $\neg A_m$, and so to a Σ_1 sentence, obtained by merging the existential quantifiers; and by (D1) and (D2), sentences that Peano arithmetic proves equivalent have equivalent reflection instances. So no level of the tower derives every Σ_1 reflection instance for any level. That Σ_1 reflection, already in this local form, and a fortiori uniform Σ_1 reflection, is stronger than consistency is a classical theme of reflection principles [72].

A true sentence about finite sets. Theorem 20.47 turns the second theorem into a statement about finite sets. Let θ be the set-theoretic sentence that reads $\neg \mathrm{Pr}(\ulcorner \bot \urcorner)$ in the von Neumann natural numbers, with addition and multiplication defined by recursion as in Lemma M.11. The *hereditarily finite sets* are the sets obtained from the empty set by finitely many steps of forming finite sets of sets already obtained; under binary membership they are the natural numbers [12].

Proposition 20.55 (A true sentence of finite set theory)**.** *The sentence θ is true in the hereditarily finite sets and is not derivable in* $\mathrm{ZF}^*_{\mathrm{fin}}$. *For every formula* Pow_2 *as in Theorem 20.47, Peano arithmetic derives $\theta^a \leftrightarrow \neg \mathrm{Pr}(\ulcorner \bot \urcorner)$.*

Proof. Let M be a model of Peano arithmetic. Read through binary membership, it is a model of $\mathrm{ZF}^*_{\mathrm{fin}}$ (Lemma M.10). Define $g(0) := 0$ and $g(n+1) := g(n) + 2^{g(n)}$, the number whose binary digits are those of $g(n)$ together with digit $g(n)$, that is, $g(n) \cup \{g(n)\}$. By induction in M, g is injective and each $g(n)$ is a von Neumann natural; every von Neumann natural u is some $g(n)$, by induction along membership, since a nonzero natural is $v \cup \{v\}$ for a natural v; and the recursive addition and multiplication of the set model satisfy, under g, the recursion equations of $+$ and $\cdot$ in M, so g carries them to $+$ and $\cdot$, again by induction. Hence M satisfies θ^a exactly when it satisfies $\neg \mathrm{Pr}(\ulcorner \bot \urcorner)$, and Theorem M.1 gives derivations of both implications. For $\mathbb{N}$ with a standard bounded graph (Theorem 20.46), binary membership is the membership of the hereditarily finite sets, and $\neg \mathrm{Pr}(\ulcorner \bot \urcorner)$ is true there by Theorem 20.51(2) and Theorem 20.41; so θ is true in the hereditarily finite sets. If $\mathrm{ZF}^*_{\mathrm{fin}}$ derived θ, Peano arithmetic would derive θ^a, by Theorem 20.47, and so $\neg \mathrm{Pr}(\ulcorner \bot \urcorner)$, against Theorem 20.50(1) for Γ empty. □

20.3.13 A small case

What does conservativity say in practice? Consider a proof that passes through all functions on O. In the language of functions, prove

$$L: \qquad \forall f{:}O \to O \;\; \forall x{:}O \;\; \forall n{:}O \quad \mathsf{I}\big(O, fx, f, n\big) =_O f\big(\mathsf{I}(O, x, f, n)\big).$$

Starting one step later is the same as taking one more step at the end. Induct on n. At 0, both sides compute to fx. If the equation holds at n, then

$$\mathsf{I}\big(O, fx, f, S(n)\big) \equiv f\big(\mathsf{I}(O, fx, f, n)\big) = f\big(f(\mathsf{I}(O, x, f, n))\big) \equiv f\big(\mathsf{I}(O, x, f, S(n))\big),$$

by computation, replacement with the induction hypothesis, and computation. Now instantiate f by the successor function $\lambda O.\, S(x_0)$. Addition is iteration of that function, so computation turns the instance into

$$B: \qquad \forall x \;\; \forall n \quad S(x) + n = S(x + n).$$

One induction proved a fact about every function, and the arithmetic fact is one of its instances. The sentence B is built from $=$ and $\forall$.

Theorem 20.32 says that this kind of route never reaches a closed negative sentence beyond the posit-free derivations. For B the direct derivation is visible: Lemma 3.2 proved B by induction on n, and the same induction, written with the rules of Chapter 5, uses the quantifier-free formula $S(x) + n = S(x + n)$ and has an empty ledger.

The compiled proof takes a different path. Its reading of L says: for every number f admissible at $O \to O$, and for all numbers x and n, the programs compiled from the two sides return values at the environment that lists f, x, n, and those values are equal. The source induction was on an equation. The compiled induction, Theorem 20.25, is on the reading of that equation, which asserts that values exist, so it inducts on a formula with quantifiers and the ledger records the induction entry. The instantiation, Proposition 20.21, must show that the code of $\lambda O.\, S(x_0)$ is admissible at $O \to O$; that is the abstraction case of Theorem 20.15, and applying that code runs through U, which is where universal application enters. Recovery, Theorem 20.30, then shows that the programs compiled from $S(x) + n$ and $S(x + n)$ return the actual numbers, and so turns the reading of B into B.

The point generalizes. A proof about numbers may pass through functions. The passage never yields a closed negative statement about numbers that the arithmetic rules could not already derive without an added principle.

20.4 What a classical proof gives without excluded middle

Here is a classical proof that every number is even or odd, that is, of

$$\forall x \exists y \big(x = y + y \ \vee \ x = S(y + y) \big).$$

Suppose some number is neither. Then there is a least such number m, by the least number principle, which excluded middle and induction provide. It is not 0, since $0 = 0 + 0$, so $m = S(k)$ for some k. Being smaller, k is even or odd: $k = y + y$ gives $m = S(y + y)$, and $k = S(y + y)$ gives $m = S(y) + S(y)$. Either way m is even or odd, which is a contradiction.

The argument never names the y that belongs to a given x. Does the proof contain one anyway? And does the theorem have a derivation that avoids excluded middle? Section 20.3 compared Peano arithmetic with a richer typed language through the negative translation. This section answers the two questions inside arithmetic, for each shape of statement. For a statement $\forall x \exists y\, A$ with a quantifier-free matrix A, which in this language has no bounded quantifiers, a classical proof always yields a derivation without excluded middle and a program that computes y from x. For $\forall x \exists y \forall z\, A$ it yields, in general, a strategy against every proposed counterexample, and when A mentions only x, y and z it yields the statement itself. For an arbitrary theorem the price is at most LPO, and one theorem pays it.

Notation. Peano arithmetic is the calculus of Definition 8.10, and $\Gamma \vdash_{\mathrm{PA}} \varphi$ says that it derives φ from the finite list Γ. We write $\Gamma \vdash_{\mathrm{HA}} \varphi$ when φ has a posit-free derivation from Γ; by Corollary 8.12 this is the same as a derivation in Heyting arithmetic, the calculus of Definition 8.10 without excluded middle. Formulas may have free variables. The negative translation φ^N is that of Section 20.3.10, and Γ^N lists the translations of the members of Γ. Negation abbreviates implication to $\bot$, so $(\neg\varphi)^N$ is $\neg\varphi^N$.

20.4.1 Translating a classical derivation step by step

Lemma 20.33 proves $\varphi \leftrightarrow \varphi^N$ with excluded middle. The point of the translation is that φ^N needs no excluded middle once φ has a classical proof. Every atom of φ^N is negated, and

negated formulas obey a law that excluded middle is usually invoked for.

Lemma 20.56 (Translated formulas are stable)**.** *For every formula φ:*

1. *the translation commutes with lifting, with substitution of a term, and with the replacement of x_0 by $S(x_0)$ in the induction rule: $(\varphi\uparrow)^N = \varphi^N\uparrow$ and $(\varphi(t))^N = \varphi^N(t)$;*
2. *$\vdash_{\mathrm{HA}} \neg\neg\varphi^N \to \varphi^N$, by a derivation that uses the rules for the connectives and quantifiers only.*

Proof. (1) The translation keeps every term and every binder in place and changes only connectives. Lifting, substitution and the step act on terms and pass through binders by the same clauses, so each commutes with the translation, by recursion on φ.

(2) Recurse on φ. When φ is an equation, a conjunction, a disjunction or an existential statement, φ^N is a negation $\neg X$, and $\neg\neg\neg X \to \neg X$ is derivable: under $\neg\neg\neg X$ and X, the hypothesis X refutes $\neg X$, which gives $\neg\neg X$, and $\neg\neg\neg X$ turns that into $\bot$. For $\bot$, apply $\neg\neg\bot$ to the identity $\bot \to \bot$. For an implication, from $\neg\neg(\varphi^N \to \psi^N)$ and φ^N derive $\neg\neg\psi^N$: a hypothesis $\neg\psi^N$ refutes $\varphi^N \to \psi^N$, against its double negation; the case for ψ then gives ψ^N. For $\forall\varphi$, from $\neg\neg\forall\varphi^N$ derive, at a fresh variable, $\neg\neg\varphi^N$: a hypothesis $\neg\varphi^N$ refutes $\forall\varphi^N$ by universal elimination at that variable. The case for φ gives φ^N, and universal introduction gives $\forall\varphi^N$. □

The lemma is the arithmetic form of Lemma 20.37. No axiom and no induction occurs in these derivations. In particular, the equations of φ^N need no decision procedure, because each occurs doubly negated.

Theorem 20.57 (The negative translation of a derivation)**.** *For every finite list Γ and every formula φ, free variables allowed: if $\Gamma \vdash_{\mathrm{PA}} \varphi$, then $\Gamma^N \vdash_{\mathrm{HA}} \varphi^N$. In particular every theorem φ of Peano arithmetic has $\vdash_{\mathrm{HA}} \varphi^N$.*

Proof. Recurse on the Peano derivation. In each case the induction hypotheses give derivations, in Heyting arithmetic, of the translated premises from the translated context, and we derive the translated conclusion. Write A, B and C for the translations of the formulas the rule mentions. Lemma 20.56(1) identifies the translation of a lifted context with the lifted translated context, and the translation of an instance with the instance of the translation; so the quantifier rules and induction keep their eigenvariable conditions. Lemma 20.56(2) is cited as *stability*: to derive C, it suffices to derive $\bot$ from the further hypothesis $\neg C$.

Hypotheses are the translated hypotheses. *Axioms.* The translation of $\neg(S(t) = 0)$ is $\neg\neg(S(t) = 0) \to \bot$, and the axiom $\neg(S(t) = 0)$ itself refutes the antecedent. The translation of $S(t) = S(u) \to t = u$ is $\neg\neg(S(t) = S(u)) \to \neg\neg(t = u)$: under $\neg(t = u)$ the axiom gives $\neg(S(t) = S(u))$, against the antecedent. Each equational axiom E gives $\neg\neg E$. *Reflexivity* gives $\neg\neg(t = t)$. *Equality substitution*, from $\neg\neg(t = u)$ and $A(t)$ to $A(u)$: by stability assume $\neg A(u)$; then $t = u$ would give $A(u)$ by substitution, so $\neg(t = u)$, against $\neg\neg(t = u)$.

Implication, the universal quantifier, the impossible case and induction translate to the same rule at the translated formulas. For induction the premises become $A(0)$ and $\forall x(A \to A(S(x)))$ and the conclusion $\forall x\, A$, by Lemma 20.56(1).

Conjunction. The translation of $\varphi \wedge \psi$ is $\neg(A \to \neg B)$. Introduction: A and B refute $A \to \neg B$. Elimination to A: by stability assume $\neg A$; then $A \to \neg B$ holds, because its antecedent is refuted, against the premise. Elimination to B: under $\neg B$ the implication $A \to \neg B$ holds outright.

Disjunction. The translation of $\varphi \vee \psi$ is $\neg\neg(\neg A \to \neg\neg B)$; any derivable formula yields its own double negation. From A, the implication $\neg A \to \neg\neg B$ holds, because A refutes its antecedent. From B, it holds because $\neg\neg B$ follows from B. Elimination with conclusion C: by stability assume $\neg C$. The two branches, discharged, give $A \to C$ and $B \to C$, hence $\neg A$ and $\neg B$. Then $\neg A \to \neg\neg B$ would give $\neg\neg B$ and so $\bot$; this refutes the implication, against the premise.

Existential quantifier. The translation of $\exists\varphi$ is $\neg\forall\neg A$. Introduction from $A(t)$: a hypothesis $\forall\neg A$, instantiated at t, gives $\neg A(t)$ and so $\bot$. Elimination with conclusion C: by stability assume $\neg C$. In the lifted context the branch turns A into the lifted C, hence into $\bot$; implication and universal introduction give $\forall\neg A$, against $\neg\forall\neg A$.

Excluded middle. The translation of $\varphi \vee \neg\varphi$ is $\neg\neg(\neg A \to \neg\neg\neg A)$. The implication inside is an instance of $P \to \neg\neg P$, which is derivable, and so is its double negation.

The construction is a recursion on the finite derivation tree and uses no principle in the metatheory. The derivation it produces inducts on A exactly where the Peano derivation inducts on the formula translated as A, and on no other: stability adds none. □

The translation is due to Gödel [65] and Gentzen [67], who used it in his consistency proof for arithmetic [66]. For a sentence, the conclusion $\vdash_{\mathrm{HA}} \varphi^N$ also follows from Theorem 20.39(1), Theorem 20.36 and Theorem 20.32, through the calculus $\mathscr{E}^+$ and the language of functions. The proof above stays in arithmetic, and it allows hypotheses and free variables. Conversely, a derivation in Heyting arithmetic is a Peano derivation, and Lemma 20.33 returns φ from φ^N with excluded middle. So $\Gamma \vdash_{\mathrm{PA}} \varphi$ holds exactly when $\Gamma^N \vdash_{\mathrm{HA}} \varphi^N$ does.

20.4.2 Two quantifiers: a witness and a program

The translation of $\exists y\, A$ is $\neg\forall y\neg A^N$. It says that a witness cannot be ruled out, not that one is at hand. For a quantifier-free matrix and one searched variable the gap is closed by the restricted Markov rule: every object-language instance $\neg\neg\exists y\, A \to \exists y\, A$ has a posit-free derivation once induction on every formula is allowed (Theorem 6.9(3)). Markov's principle for arbitrary decidable predicates is a different matter (Chapter 7). In this language a quantifier-free formula is built from equations between polynomial terms by $\bot$, $\wedge$, $\vee$ and $\to$; a bounded quantifier is a quantifier.

Lemma 20.58 (Quantifier-free translations)**.** *For every quantifier-free formula A, $\vdash_{\mathrm{HA}} A^N \to \neg\neg A$ and $\vdash_{\mathrm{HA}} \neg\neg A \to A^N$.*

Proof. Recurse on A, deriving both implications together; every step is propositional. For an equation, A^N is $\neg\neg A$. For $\bot$, the formulas $\bot$ and $\neg\neg\bot$ imply each other. For the connectives, write a and b for the components; by the induction hypotheses a^N may be replaced by $\neg\neg a$ and b^N by $\neg\neg b$ inside the translation, and $\neg\neg\neg a$ by $\neg a$. It remains to derive three equivalences. First, $\neg(\neg\neg a \to \neg b)$ is equivalent to $\neg\neg(a \wedge b)$: under $\neg(a \wedge b)$ and $\neg\neg a$, a proof of b would give $\neg a$, so $\neg b$, and the implication holds; conversely, under $\neg\neg(a \wedge b)$ and the implication,

$a \wedge b$ gives $\neg\neg a$, hence $\neg b$, a contradiction. Second, $\neg\neg a \to \neg\neg b$ is equivalent to $\neg\neg(a \to b)$: a refutation of $a \to b$ gives both $\neg b$ and $\neg\neg a$; conversely, under $\neg\neg(a \to b)$, $\neg\neg a$ and $\neg b$, the implication $a \to b$ would give $\neg a$. Third, $\neg(\neg a \to \neg\neg b)$ is equivalent to $\neg a \wedge \neg b$, hence to $\neg(a \vee b)$; negating both sides gives the equivalence of $\neg\neg(\neg a \to \neg\neg b)$ with $\neg\neg(a \vee b)$. □

Theorem 20.59 (Two quantifiers convert at no price)**.** *Let A be quantifier-free, without bounded quantifiers; its free variables other than x and y are parameters.*

1. *If $\vdash_{\mathrm{PA}} \exists y\, A$, then $\vdash_{\mathrm{HA}} \exists y\, A$.*
2. *If $\vdash_{\mathrm{PA}} \forall x\, A$, then $\vdash_{\mathrm{HA}} \forall x\, A$.*
3. *If $\vdash_{\mathrm{PA}} \forall x \exists y\, A$, then $\vdash_{\mathrm{HA}} \forall x \exists y\, A$.*

Proof. For (2), Theorem 20.57 gives $\vdash_{\mathrm{HA}} \forall x\, A^N$, and Lemma 20.58 gives $\forall x \neg\neg A$. Heyting arithmetic decides the quantifier-free A (Lemma E.1(2)); in the case $\neg A$ the impossible case applies, so $\neg\neg A \to A$, and universal introduction gives $\forall x\, A$.

For (1), Theorem 20.57 gives $\vdash_{\mathrm{HA}} \neg\forall y \neg A^N$. We derive $\neg\neg\exists y\, A$ from it. Assume $\neg\exists y\, A$. At a fresh y, a proof of A would give $\exists y\, A$, so $\neg A$; and A^N gives $\neg\neg A$ by the lemma, so $\neg A^N$. Universal introduction yields $\forall y \neg A^N$, a contradiction. By Theorem 6.9(3), the instance $\neg\neg\exists y\, A \to \exists y\, A$ of the restricted Markov rule, with y searched and every other variable a parameter, has a posit-free derivation. Implication elimination gives $\exists y\, A$.

For (3), apply the argument of (1) to the translation $\neg\forall y \neg A^N$ at a fresh x, obtained from $\forall x \neg\forall y \neg A^N$ by universal elimination, and finish with universal introduction. □

No principle is recorded, and none is used in the metatheory. The induction entry is true: the decision of quantifier-free formulas and the derivation of the Markov instance induct on formulas with quantifiers. The third assertion is the case of one searched variable of the standard Π_2 conservativity of Peano arithmetic over Heyting arithmetic [4]; with one variable, Lemma 6.8 bounds the search. Friedman's translation, in the next subsection, gives it a second proof [68], by the argument of Theorem 20.63(1) with $G := \exists y\, A$.

For the parity statement, the third assertion says that Heyting arithmetic proves

$$\forall x \exists y \big(x = y + y \;\vee\; x = S(y + y) \big).$$

The derivation it builds also computes.

Theorem 20.60 (A program for the witness)**.** *Let A be quantifier-free, and suppose $\vdash_{\mathrm{PA}} \forall x \exists y\, A$. There is a program that returns, on every input n, a number whose first component y satisfies A at $x = n$, every parameter of A being read as 0. The proof uses the classical metatheory of Appendix E.3.*

Proof. Theorem 20.59 gives a posit-free derivation d of $\forall x \exists y\, A$ from no hypotheses. Theorem E.9, applied to d, gives a program c_d; let r be its value on $\langle \ulcorner() \urcorner, \ulcorner() \urcorner \rangle$, a realizer of $\forall x \exists y\, A$ at the environment $\rho_{()}$, which gives every variable the value 0. By the clause for the universal quantifier, $\{r\}(n)\!\downarrow v$ for some v that realizes $\exists y\, A$ at $[n, \rho_{()}]$. By the clause for the existential

quantifier, $v = \langle y, q\rangle$ with q realizing A at $[y, [n, \rho_{()}]]$, and by Lemma E.7 A is then true there. The program sought runs r on its input, through the universal program; its code is computed from r by fixing part of an input. □

For the parity statement the witness is unique, so the program returns, on n, a pair whose first component is the integer part of $n/2$. Nothing in the classical proof mentioned halving. The program is assembled from the derivation, node by node, as in the proof of Theorem E.9.

20.4.3 Friedman's translation

For three quantifiers the restricted Markov rule no longer closes the gap. The translation of $\exists y\,\forall z\,A$ is $\neg\forall y\neg\forall z\,A^N$, and the rule removes a double negation only in front of an existential statement with a quantifier-free body. Friedman's idea is to keep the double negations and change the meaning of $\bot$: read it as the goal G we want to prove. A double negation $\neg\neg P$ then becomes $(P^G \to G) \to G$, and it yields G as soon as P^G is shown to imply G.

Definition 20.61 (Friedman's translation)**.** Let G be a formula. The translation φ^G of a formula φ is defined by recursion:

$$(t = u)^G := (t = u) \vee G, \qquad \bot^G := G, \qquad (\varphi \circ \psi)^G := \varphi^G \circ \psi^G \ \text{ for } \circ \in \{\wedge, \vee, \to\},$$
$$(\forall\varphi)^G := \forall\,\varphi^{G\uparrow}, \qquad (\exists\varphi)^G := \exists\,\varphi^{G\uparrow}.$$

Under a binder G is lifted, so no free variable of G is captured; in named notation, the bound variables of φ are kept apart from the free variables of G. For a list Γ, Γ^G lists the translations of its members. In particular $(\neg\varphi)^G$ is $\varphi^G \to G$.

Lemma 20.62 (Friedman's translation preserves derivations)**.** *Let G be a formula and Γ a finite list of formulas.*

1. *If $\Gamma \vdash_{\mathrm{HA}} G$, then $\Gamma \vdash_{\mathrm{HA}} \varphi^G$ for every formula φ.*
2. *If $\Gamma \vdash_{\mathrm{HA}} \varphi$, then $\Gamma^G \vdash_{\mathrm{HA}} \varphi^G$.*
3. *For every quantifier-free A: $A \vdash_{\mathrm{HA}} (A^N)^G$ and $\neg A, (A^N)^G \vdash_{\mathrm{HA}} G$.*

Proof. Like the negative translation, φ^G changes atoms only and keeps terms and binders in place. Lifting and substitution therefore commute with it, provided G is lifted with them: $(\varphi\uparrow)^{G\uparrow} = \varphi^G\uparrow$, and $(\varphi(t))^G = \varphi^{G\uparrow}(t)$, because $G\uparrow$ does not contain x_0; the same holds for the step $x_0 \mapsto S(x_0)$.

(1) Recurse on φ, for every G, every context and every substitution instance of φ at once. An equation becomes $(t = u) \vee G$, given by its right side; $\bot$ becomes G; a conjunction follows from its two components, a disjunction from its left component, and an implication from its consequent. For $\forall\varphi$, lift the context: the lifted context derives $G\uparrow$, the induction hypothesis at $G\uparrow$ gives $\varphi^{G\uparrow}$, and universal introduction concludes. For $\exists\varphi$, the induction hypothesis for the instance $\varphi(0)$ gives $\varphi(0)^G$, which is $\varphi^{G\uparrow}(0)$, and existential introduction at 0 concludes.

(2) Recurse on the derivation, for every G at once. Rules that lift the context use the induction hypothesis at $G\uparrow$, together with the commutation just stated; so universal introduction,

existential elimination and induction translate to the same rule at the translated formulas, with the same eigenvariable conditions. The connective rules, universal elimination and existential introduction are the same rule. The remaining cases use the translation of atoms. Reflexivity becomes $(t = t) \vee G$. An equational axiom E becomes $E \vee G$. The axiom $\neg(S(t) = 0)$ becomes $(S(t) = 0 \vee G) \to G$: in the first case the axiom gives $\bot$ and the impossible case gives G. Injectivity becomes $(S(t) = S(u) \vee G) \to (t = u \vee G)$, by cases. Equality substitution, from $t = u \vee G$ and $\varphi(t)^G$: in the first case substitute, and in the second (1) gives $\varphi(u)^G$. The impossible case, from G to φ^G, is (1).

(3) Recurse on A, proving both statements together and writing a^* for $(a^N)^G$. An equation $t = s$ gives $((t = s \vee G) \to G) \to G$. From $t = s$: a hypothesis $(t = s \vee G) \to G$, applied to the left side, gives G. From $\neg(t = s)$: the map $(t = s \vee G) \to G$ exists, since its first case is impossible and its second is the identity, and the translated formula turns it into G. For $\bot$, $\bot^*$ is G, and both statements are immediate. A conjunction $a \wedge b$ gives $(a^* \to (b^* \to G)) \to G$. From $a \wedge b$ the induction hypotheses supply a^* and b^*. Under $\neg(a \wedge b)$, decide a (Lemma E.1(2)): if $\neg a$, then $a^* \to G$, and if a, then $\neg b$ and $b^* \to G$; either way $a^* \to (b^* \to G)$ holds, and the hypothesis gives G. A disjunction $a \vee b$ gives $(P \to G) \to G$ with $P := (a^* \to G) \to ((b^* \to G) \to G)$. From a, the term $k \mapsto (m \mapsto k\,a^*)$ proves P, and a hypothesis $P \to G$ then gives G; from b, use $k \mapsto (m \mapsto m\,b^*)$. Under $\neg(a \vee b)$ we have $\neg a$ and $\neg b$, hence $a^* \to G$ and $b^* \to G$; applying a proof of P to these two gives G, so $P \to G$ holds, and the translated formula gives G. An implication $a \to b$ gives $a^* \to b^*$. From $a \to b$, decide a: if a, then b and b^*; if $\neg a$, then a^* gives G, and G gives b^* by (1). Under $\neg(a \to b)$, the decision of a gives a, since $\neg a$ would prove $a \to b$; so a^* holds, and with it b^*, while $\neg b$ gives $b^* \to G$. □

The translation is Friedman's [68]. Nothing in the proof uses a principle, in the derivations or in the metatheory.

20.4.4 Three quantifiers: a strategy against counterexamples

What does a classical proof of $\forall x\,\exists y\,\forall z\,A$ provide? Kreisel's answer is a game. A challenger who doubts the statement at x must answer every candidate y with a proposed counterexample z. The statement then promises that some candidate survives its own counterexample. That promise can be met without excluded middle.

Theorem 20.63 (Kreisel's no-counterexample form)**.** *Let $A(x, y, z)$ be quantifier-free with no free variable other than x, y and z, and suppose $\vdash_{\mathrm{PA}} \forall x\,\exists y\,\forall z\,A$.*

1. *For every formula $F(x, y, z)$, which may have further free variables,*

$$\vdash_{\mathrm{HA}} \ \forall x\Big[\forall y\exists z\,F(x,y,z) \ \to \ \exists y\exists z\big(F(x,y,z) \wedge A(x,y,z)\big)\Big].$$

2. *In the classical metatheory of Appendix E.3, there is a program that, on input x, returns a program that turns every realizer of $\forall y\,\exists z\,F$ at x into numbers y and z with $A(x, y, z)$ true, together with a realizer of $F(x, y, z)$; the further free variables of F are read as 0.*

Proof. (1) Theorem 20.57 gives $\vdash_{\mathrm{HA}} \forall x \neg\forall y \neg\forall z\, A^N$, and universal elimination at the variable x gives $\neg\forall y \neg\forall z\, A^N$. Put $G := \exists y \exists z\,(F \wedge A)$. By Lemma 20.62(2), Heyting arithmetic derives the translation of that formula by G:

$$\Big[\forall y\big(\forall z\,(A^N)^G \to G\big)\Big] \to G.$$

It remains to derive the premise from the hypothesis $\forall y \exists z\, F$. Fix y and assume $\forall z\,(A^N)^G$. The hypothesis gives a z with $F(x, y, z)$. Decide the quantifier-free $A(x, y, z)$ (Lemma E.1(2)). If it holds, y and z witness G. If not, instantiate the assumption at this z; Lemma 20.62(3) turns $(A^N)^G$ and $\neg A$ into G. Either way G follows, and implication and universal introduction give the claim.

(2) By (1), the formula of (1) has a posit-free derivation d from no hypotheses. As in the proof of Theorem 20.60, Theorem E.9 gives a realizer r of it at $\rho_{()}$. On x, $\{r\}(x)\!\downarrow v$ with v realizing the implication at $[x, \rho_{()}]$; so for every realizer s of $\forall y \exists z\, F$ there, $\{v\}(s)\!\downarrow w$ with w realizing $\exists y \exists z\,(F \wedge A)$. Then $w = \langle y, \langle z, \langle q_F, q_A\rangle\rangle\rangle$ with q_F realizing F and q_A realizing A at those values, and A is true by Lemma E.7. □

The only decision in the proof is the decision of a quantifier-free formula; no Markov principle and no excluded middle is used. The theorem is Kreisel's no-counterexample interpretation [55, 69], here proved inside Heyting arithmetic through Friedman's translation. Read with F the graph of a function f, it says that for every f defined by a formula some y satisfies $A(x, y, f(y))$. A first-order formula can define only some functions. The same reading in $\mathbb{N}$ reaches all of them, and it allows blocks of variables and parameters.

Theorem 20.64 (The no-counterexample form for every function)**.** *Let A be quantifier-free, with free variables x, y, a block $\bar z = (z_1, \dots, z_n)$ and any further parameters, and suppose $\vdash_{\mathrm{PA}} \forall x \exists y \forall \bar z\, A$. For every assignment of numbers to the parameters, every number x and every function f that sends each number y to an n-tuple $f(y)$, some y satisfies $A(x, y, f(y))$. Hence the least such y, found by testing $y = 0, 1, 2, \dots$ in turn, defines a functional $\Phi(x, f)$ with $A(x, \Phi(x, f), f(\Phi(x, f)))$. The proof uses no excluded middle, no omniscience principle and no choice in the metatheory.*

Proof. For a proposition G of the metatheory, read formulas in $\mathbb{N}$ as in Definition 5.3, except that an equation $t = s$ is read as "t and s have the same value, or G" and $\bot$ is read as G. Write $\rho \Vdash_G \varphi$ for this reading. It is Friedman's translation read in $\mathbb{N}$.

Soundness. If $\Gamma \vdash_{\mathrm{HA}} \varphi$, then every environment that satisfies Γ in this reading satisfies φ, for every G. Induct on the derivation as in Theorem 5.5. The connective and quantifier rules are sound for any such reading, and induction is induction in $\mathbb{N}$. The axiom $\neg(S(t) = 0)$ reads "if $S(t)$ and 0 have the same value, or G, then G", true because the values differ. Injectivity and the equational axioms are true casewise. The reading respects lifting and substitution as satisfaction does; the proof of Lemma 5.4 applies word for word. For equality substitution this settles the case of equal values; in the case G, note that G makes the reading of every formula true, by induction on the formula, which also gives the impossible case.

The reading. Fix the parameters, x and f, and let G be "some y satisfies $A(x, y, f(y))$". By Theorem 20.57 Heyting arithmetic derives $\forall x \neg\forall y \neg\forall \bar z\, A^N$, and by Lemma 20.58 it derives

$A^N \to \neg\neg A$. Read at G, the first says: if every y has the property that $\forall \bar{z}\, A^N$ in this reading implies G, then G. We check that property. Fix y and assume the reading of $\forall \bar{z}\, A^N$. At $\bar{z} := f(y)$ it gives the reading of A^N, hence that of $\neg\neg A$, which is: if the reading of A implies G, then G. For a quantifier-free A the reading of A holds exactly when A is true or G holds, by induction on A, deciding each quantifier-free component by Lemma 6.2. And the reading of A does imply G: it gives "$A(x, y, f(y))$ is true, or G", and in the first case y witnesses G. So G holds.

Every step is a construction or a decision of a quantifier-free formula. The search for the least y terminates because some y succeeds, and each test decides a quantifier-free formula. □

A small case shows the game. For a quantifier-free $B(x, z)$, consider

$$\forall x \exists y \forall z \big(B(x, z) \to B(x, y)\big) :$$

if anything has the property $B(x, \cdot)$, then y has it. A classical proof takes y to be such a thing if there is one, and anything otherwise, without saying which case holds. The no-counterexample form asks less: given, for each candidate y, a proposed counterexample $f(y)$, find a y with $B(x, f(y)) \to B(x, y)$. Two candidates suffice. Decide whether $B(x, f(0)) \to B(x, 0)$ holds. If it does, $y = 0$ wins. If not, $B(x, f(0))$ holds, and $y = f(0)$ wins, since then $B(x, y)$ holds whatever $f(y)$ is. The strategy uses the challenger's own answer and one decision of a quantifier-free formula.

More is true: by Gödel's functional interpretation, the functional Φ can be given by a closed term of Gödel's system T of primitive recursive functionals of finite type. Since Definition 8.10 is the usual presentation of Peano arithmetic, the standard result applies (Gödel [70]; see Kohlenbach [56]); it is not proved here, and nothing below depends on it.

When the matrix mentions only x, y and z, as in the small case, the game can be won outright: a single y defeats every challenger.

Corollary 20.65 (Single-variable statements with three quantifiers)**.** *Let A be quantifier-free with no free variable other than x, y and z.*

1. *If $\vdash_{\mathrm{PA}} \forall x \exists y \forall z\, A$, then $\vdash_{\mathrm{HA}} \forall x \exists y \forall z\, A$. The sentence is true in $\mathbb{N}$, with no principle used in the metatheory. In the classical metatheory of Appendix E.3, a program returns on every input x a number whose first component y satisfies $A(x, y, z)$ for every z.*
2. *If A has no free variable other than y and z, and $\vdash_{\mathrm{PA}} \exists y \forall z\, A$, then $\vdash_{\mathrm{HA}} \exists y \forall z\, A$.*

So no sentence of either shape is a theorem of Peano arithmetic and not of Heyting arithmetic.

Proof. Step 1: one searched variable. For every quantifier-free φ with a searched variable z and any parameters, $\vdash_{\mathrm{HA}} \exists z\, \varphi \vee \forall z\, \neg\varphi$. This is the alternative derived in the proof of Theorem 6.9: by the constancy (6.8), a quantifier-free formula in one variable does not change beyond the bound T, and a bounded search below T decides it.

Step 2: a test formula. Put $F(x, y, z) := \neg A(x, y, z) \vee \forall w\, A(x, y, w)$. Then $\vdash_{\mathrm{HA}} \forall x \forall y \exists z\, F$. Apply Step 1 to $\neg A$, with x and y as parameters. If some z has $\neg A$, it witnesses the left side of

F. If every z has $\neg\neg A$, then every z has A, by the decision of A, and $z := 0$ witnesses the right side.

Step 3. Theorem 20.63(1) at this *F*, with Step 2, gives $\vdash_{\mathrm{HA}} \forall x \exists y \exists z\,(F \wedge A)$.

Step 4. In $F \wedge A$ the conjunct A refutes the left side of *F*, so $\forall w\, A(x, y, w)$ holds. Hence $\vdash_{\mathrm{HA}} \forall x \exists y \forall z\, A$.

Truth in $\mathbb{N}$ follows from Corollary 6.7, which needs no principle. The program comes from Theorem E.9 as in the proof of Theorem 20.60: the realizer at x carries y as its first component, and at each z it realizes the quantifier-free $A(x, y, z)$, which is then true by Lemma E.7. For (2), universal introduction over a variable x that does not occur gives $\vdash_{\mathrm{PA}} \forall x \exists y \forall z\, A$; apply (1) and instantiate x at 0. □

Step 1 needs the innermost quantifier to bind a single variable, because Lemma 6.8 concerns one searched variable. For a block of variables the general form, Theorem 20.64, remains.

20.4.5 What each shape of classical theorem costs

The results of this section fix the price of converting a classical theorem, shape by shape, for the shapes of this language. As in Section 6.7, the price of a derivation is the set of principles its ledger records.

Theorem 20.66 (The conversion prices)**.** *Allow induction on every formula, and let φ be a theorem of Peano arithmetic. Quantifier-free formulas are those of Section 20.4.2, without bounded quantifiers.*

1. *If φ is $\exists y\, A$, $\forall x\, A$ or $\forall x \exists y\, A$ with A quantifier-free, or $\forall x \exists y \forall z\, A$ or $\exists y \forall z\, A$ with A quantifier-free in the variables shown only, then φ has a posit-free derivation. For $\forall x \exists y \forall z\, A$ so does, for every formula F, the no-counterexample form of Theorem 20.63.*
2. *φ has a derivation whose ledger records no principle other than LPO.*
3. *The sentence Λ of the proof of Theorem 6.11 is a theorem of Peano arithmetic. For every set $\mathcal{S}$ of the three principles, Λ has a derivation whose ledger records only principles in $\mathcal{S}$ exactly when $\mathcal{S}$ contains EM or LPO.*

Proof. (1) is Theorems 20.59 and 20.63 and Corollary 20.65. (2) Theorem 8.11 gives a derivation whose ledger records no principle other than EM. Replace each EM leaf by a derivation of the same instance from the base rules and the LPO rule (Theorem 6.10), as in Section 6.7. (3) One LPO rule and universal introduction derive Λ; by Theorem 6.10 the LPO leaf has a derivation from the base rules and the EM rule, and Theorem 8.11 turns that derivation into a Peano derivation. So Λ has a derivation recording only LPO and one recording only EM. If $\mathcal{S}$ contains neither, it is contained in {MP}, and the proof of Theorem 6.11(3) shows that no derivation whose additional rules are MP rules proves Λ: every such derivation is realized, and Λ has no realizer. That argument uses a classical metatheory. □

Table 20.4 collects the rows. Together with Remark 6.12 they say where the step from Heyting to Peano arithmetic is paid for. With neither EM nor LPO, the rules derive exactly the theorems

Theorem of Peano arithmetic	What is derived	Price	Proved in
$\exists y\, A$, $\forall x\, A$	the same formula	none	Theorem 20.59
$\forall x \exists y\, A$	the same formula, and a program for y	none	Theorems 20.59, 20.60
$\forall x \exists y \forall z\, A$, with A in x, y, z only	the same formula and a program for y; the no-counterexample form for every formula F	none	Corollary 20.65, Theorem 20.63
$\exists y \forall z\, A$, with A in y, z only	the same formula	none	Corollary 20.65
$\forall x \exists y \forall \bar{z}\, A$, any block and parameters	the no-counterexample form, read in $\mathbb{N}$, for every function	none	Theorem 20.64
any sentence	the same sentence	LPO alone, or EM alone	Theorems 8.11, 6.10
Λ, the LPO instance at the halting matrix	the same sentence, only with EM or LPO	LPO, attained	Theorem 6.11

Table 20.4. The price of converting a theorem of Peano arithmetic, by shape; A is quantifier-free throughout, with no bounded quantifiers, so that a search over one of its variables is bounded in advance (Lemma 6.8). The rows concern this class, not matrices with bounded quantifiers; the row for $\forall x \exists y\, A$ is the case of one searched variable of the standard Π_2 conservativity. "None" means a posit-free derivation: no EM, LPO or MP rule, with induction on every formula allowed. In the row read in $\mathbb{N}$ it means that the proof uses no principle in the metatheory. The programs for y in the second and third rows are obtained in the classical metatheory of Appendix E.3.

of Heyting arithmetic; with either, exactly those of Peano arithmetic. The difference never shows in the shapes of part (1) of Theorem 20.66. It shows at Λ, whose matrix describes a computation and so needs quantifiers, as the discussion after Theorem 6.9 explains.

20.5 Finite access and a uniform construction differ

Every finite tally has its own finite stage. Compatible readings of these stages assemble into one reading of the whole orbit, uniquely. For a given input, the proof uses only that input's stage. The compatibility hypothesis ensures that increasing the budget cannot change an answer already given.

A program is also a finite object. Chapter 10 stores its expression as a tally and recovers the identical expression. Execution is therefore preserved, including the inputs on which execution is undefined. The recovery law does not require a termination claim.

For an interval protocol, a uniform name has a further obligation: one program must return the correct endpoint pair at every precision. The existence of such a name is equivalent to computability of that endpoint function. A supplied finite table of endpoints always has a lookup program, but the table may change with the requested budget. The quantifiers are different:

$$\forall N \exists c\, \forall n < N \qquad \text{and} \qquad \exists c\, \forall n.$$

Here the suppressed conclusion is the same correct endpoint response in both expressions. Theorem 11.11 proves, in the stated classical real display, that the first requirement does not imply the second. Each finite program determines at most one protocol and hence at most one displayed value. Countably many finite programs cannot name every value in that display.

This leaves the enclosure construction intact. Nested rational intervals with the given width bound determine a unique classical value; overlapping at every precision is exactly equality of that value. The distinction is between this mathematical family and an effective rule producing its members. The completeness and classical comparison used for the display are stated where they enter the construction. Chapter 12 prices that completeness on a line that does not presuppose it.

Exact decisions reveal another boundary. For the regular dyadic presentations of Chapter 12, deciding exact zero is equivalent to WLPO. A witnessed positive-or-zero-or-negative answer is equivalent to LPO. The weaker nonnegative-or-nonpositive answer is equivalent to LLPO. Turning a proof that a quantity is not zero into a sign is equivalent to the binary form $\mathrm{MP}_{\mathrm{bin}}$ of Markov's principle (Definition 7.8), and the comparisons themselves recover LPO as WLPO together with that principle. These principles already priced the recognition catalogue in Chapter 7. The same prices hold on the line built from the ratios of Chapter 4, which is one continuum with the dyadic presentations. Its completeness comes apart in the same way. The limit of a Cauchy sequence costs only a choice of representatives, and nothing at all as a located cut. That choice decides nothing: intuitionistic arithmetic with variables for sequences and countable choice for numbers and for sequences proves none of LPO, WLPO, LLPO and $\mathrm{MP}_{\mathrm{bin}}$ (Theorem 12.22). Excluded middle cannot replace it: with excluded middle and choice only for relations whose witnesses a search can find, and without unique choice, neither the Cauchy limit nor the passage from a located cut to a point is provable (Theorem 12.63). Monotone convergence costs LPO, a least upper bound of a bounded sequence WLPO, and an exact root or an attained maximum of a uniformly continuous function LLPO, while the approximate versions cost nothing. The proofs give explicit encodings in both directions. A sequence of increasingly accurate rational answers does not erase these distinctions.

20.6 The physical bridge has a construction and a constraint

The first physical question is about the information a reader actually receives. If two situations produce the same record, an exact reader must give them the same required answer. This collision argument gives the capacity bound in Chapter 17. A bounded adaptive test tree still produces a bounded transcript, because its branches and stopping rules are included in the construction of that transcript. Allowing an error tolerance changes exact distinction into separation by more than twice that tolerance.

These bounds identify what a record must retain. Chapter 18 constructs an operation that returns a quantum system together with its mark. Positivity and normalization supply branch matrices. Stacking those matrices gives an isometry, and the explicit block dilation extends it to a unitary on the whole stated space. A complete reader retains both the intended rows and their complement. The error estimate includes any finite retained reference, so correlations with a system outside the apparatus are part of the comparison.

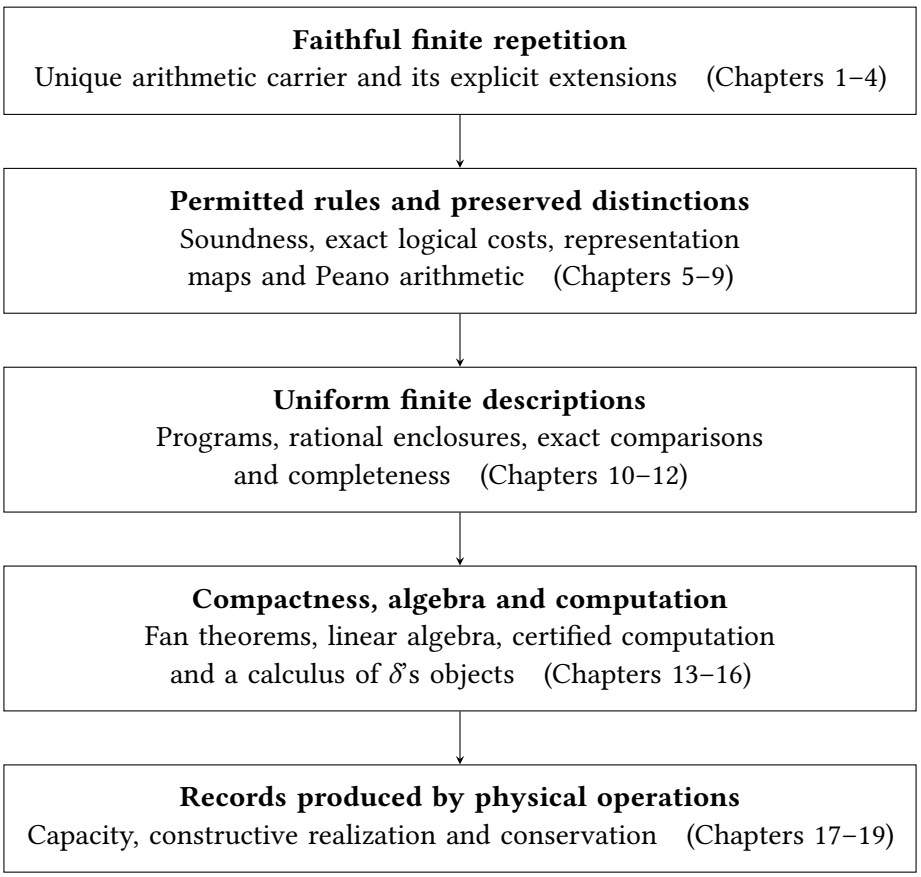

Figure 20.1. A route through the argument. At each stage, the next question requires additional specified objects: a language and its rules, an effective description, or a physical apparatus. The arrows organize the reading; they do not discharge those additional hypotheses.

Two results then connect the descriptions to finite operations. First, ordinary effective matrix names and effective operation-word names can be translated uniformly for fixed dimensions. The search accepts a rational certificate with a strict margin; density ensures that an acceptable word eventually appears. Second, native controls realize the required approximation with positive full energy operators and an explicit scalar action contribution. Input preparation, selectable control pulses, the fixed background holding and the complete reader are all retained in the construction.

The recorder theorem supplies a complementary restriction. For the two-cell event specified in Chapter 19, a whole unitary that conserves both native charges and is followed by a neutral sharp pointer obeys

$$e \geq \frac{1}{2(r^2+3)}.$$

Here r counts the recorder's native charge-carrying cells. Its internal correlations are allowed, while its fixed initial preparation is separate from the unknown source. The proof derives the count conservation from the two native charges, bounds noise by uniform event error, and evaluates an explicit source vector. The size of neutral memory cannot remove the charge bound.

Both results concern actual operations under their stated physical conditions. Supplied

controls and a closed conserving recorder impose different requirements. An apparatus meeting both descriptions would have to include its control supply in the conserving account. The construction does not assert such an autonomous implementation, and the lower bound does not construct an apparatus attaining it. Those are specific tasks left to further construction. Figure 20.1 traces the route of the whole argument.

20.7 What a further claim must show

The book gives several ways to make a necessity claim checkable. Construct the map and prove it unique. Classify every allowed identification. Recover the proposed additional principle from the claim itself. Exhibit a model that satisfies the weaker rules but cannot satisfy the stronger judgment. Compile the proofs of one system into another, then translate their conclusions back. Build the physical operation, then carry its errors and resources through the complete reader.

These methods specify the next work as well. A broader representation claim needs translations preserving the additional structure it names. The comparison with Peano arithmetic in Chapter 8 is one such translation, for a second proof system over the same language. Section 20.3 carries the method to a language of functions, where even the test that runs the compiled programs has its correctness derived by the rules. A uniform construction needs one procedure with the required behavior on every input. A stronger physical realization needs the preparation, controller and reader it assumes to be constructed within the same resource account. Each question can be pursued without replacing the arithmetic, classification and resource results already proved.

The results of this book hold together, about one orbit, with no hypotheses beyond those stated with each theorem. A physical claim that goes further needs an identification of a mathematical object with a physical one, and the book keeps such identifications apart from its theorems. Two concern the results here directly. The identification of *access* says that the physically real collections are exactly those whose members each leave an exact finite record from which a reader recovers them, as in the conditions of Theorem 17.11. That theorem says that such a collection injects into the natural numbers. So access would make every physically real collection inject into the natural numbers, and the classical line of Chapter 11 would not be among them. The converse is not claimed: an injection gives each member the binary numeral of its image, from which the member is read back, but that numeral is a mathematical code, not a record that an apparatus acquires (Section 17.1). The identification of *carrier closure* says that the physically possible finite processes are exactly the valid finite instruments of Chapter 18; with Theorem 18.11 it would give every physically possible finite process an approximation to any tolerance, on every retained reference, by externally switched positive native pulses, with its scalar action recorded. Neither is a theorem, and no theorem of this book assumes either. Further physical consequences are developed in the companion volume under these and other identifications. Parts VI to VIII restate the mathematical content of several of them in this book's own words and prove it, on the line where it holds there and in classical mathematics where they say so, beginning with the cost of a comparison (Chapter 21), and keep each physical identification named beside the theorem it concerns.

The first tally therefore remains visible at the end of the argument. Its start and step determine

a finite construction. Faithfulness determines what must remain distinct. A reader determines what can be identified. A proof exposes the rules needed to pass from those objects to a conclusion. A physical apparatus must enact the required transformation and retain its record. The resulting structure can be followed, checked and used at each of those levels.

Questions to work through

1. Follow the map in Theorem 2.7. Which hypothesis gives injectivity, and which gives surjectivity?

2. Compare the WLPO, LPO and LLPO forms of the recognition catalogue in Theorem 7.9 with Theorems 12.6–12.8, and its Markov form, Theorem 7.7, with Theorem 12.11. For each principle, name the data supplied to the forward construction and the object used in the reverse implication in both settings.

3. Explain how a program can have faithful finite storage while failing to halt on an input. Then explain why a uniform interval name must halt at every precision request.

4. Locate one retained premise in each of the three physical chapters: a condition on the record, a condition on supplied controls, and a condition on conservation. Describe the exact proof step that uses each one.

5. In the small case at the end of Section 20.3, the proof of L inducts on an equation, while its compiled form inducts on the reading of that equation. Identify the quantifiers in that reading, and state which ledger entries the compiled derivation records.

6. Why are the comparison theorems stated for formulas built from $=$, $\bot$, $\to$ and $\forall$? Suppose the finite-type logic had an existential quantifier, read in the same way as the other connectives. Describe what the reading of $\exists y \psi(y)$ would ask a compiled proof to supply, and compare it with what Theorem 20.31 has to recover.

7. Show that the first assertion of Theorem 20.39 fails for $\mathscr{E}^{-}$. Write the type that expresses the translation of $\forall x \neg(S(x) = 0)$, and compute its value under the valuation of Theorem 9.8.

Part VI

The comparison cost and its forcing chain

Part VI turns from what a proof may use to what a physical derivation costs. Recognition Science, as this book restates it, derives the structure of physics from distinction: a cost of comparing two positive quantities, the golden ratio, three spatial dimensions, which it reads off a kept pair of records linked in space, and the constants that follow from them. Each of its steps can be restated on the line $\mathbb{R}_\delta$, where every number is a construction and nothing is decided for free, and then proved or priced.

Chapter 21 proves that the composition law and its calibration leave exactly one cost, $J(x) = \frac{1}{2}(x + x^{-1}) - 1$, with no omniscience principle and no choice, and supplies the functions, the data forms of the omniscience principles and the ledger that the later chapters use. Chapter 22 restates the steps of the forcing chain in the book's own words, in the second column of its price table, and prices each restated step on the line: of the 130 rows of that table (the steps, the second rung's groups of consequences and the constants), 119 hold with no omniscience principle and no choice, ten have an exact price, one is bracketed (below a named principle), and none is open. Chapter 23 proves natively the topological fact on which the dimension step rests: a circle embedded in a sphere can be linked exactly when the sphere has dimension three. Reading a kept pair of records as a linked circle is an identification, which the chain takes as a premise; it is not a theorem of the chapter. Chapter 24 reads the records of a ledger: one account's debits and credits fill a light cone, and one coherently carried binary distinction has the record cone of special relativity; its Section 24.11 climbs from posting toward a clock, the square law, conserved charges and a space of cells, proving what posting forces and naming the premise at each step it does not decide. The last sections of these chapters prove that one bit of calibration with one regularity condition already forces J; that the verdict of the chain holds with no cited premise, and that three of its four brackets are exact prices; that, with the code's hypothesis in its free form, every conclusion of the moral code's main theorem is free on the line; and which values the world's records keep physically real, with the eight-tick comparison at its exact scope.

Parts VI to VIII read maps as rules given with their data, without unique choice (Section 21.1). Each result says whether it is free, what it costs, or whether it is proved in classical mathematics. Physical readings of the objects, such as debit and credit as time and position, are identifications: a theorem states what follows from them and does not supply them.

Chapter 21

The cost of a comparison

Compare a positive quantity with a reference and write $x > 0$ for the ratio. A cost of the comparison is a number $F(x)$ with $F(1) = 0$: comparing a quantity with itself costs nothing. What can such a cost be, if comparing in two steps must cost what the steps cost together? Recognition Science states the requirement as one equation. Composing a comparison x with a comparison y can go forward, to xy, or backward, to x/y, and the two composites together must cost

$$F(xy) + F(x/y) = 2F(x)F(y) + 2F(x) + 2F(y) \qquad \text{for all } x, y > 0. \tag{21.1}$$

In the variables $M = 1 + F$ the requirement reads $M(xy) + M(x/y) = 2M(x)M(y)$: on average over the two directions, composing multiplies the excesses.

Here is a small case. Put $J(x) = \frac{1}{2}(x + x^{-1}) - 1$. Then $J(1) = 0$, $J(2) = \frac{1}{4}$ and $J(4) = \frac{9}{8}$, and at $x = y = 2$ the two sides of (21.1) are $J(4) + J(1) = \frac{9}{8}$ and $2 \cdot \frac{1}{16} + \frac{1}{2} + \frac{1}{2} = \frac{9}{8}$. The quadratic $F(x) = \frac{1}{2}(x-1)^2$ has the same value 0 and the same curvature at $x = 1$, but it fails the law at the same pair: $F(4) + F(1) = \frac{9}{2}$, while $2F(2)^2 + 4F(2) = \frac{5}{2}$. The law at $y = x$ gives the squaring rule $F(x^2) = 2F(x)^2 + 4F(x)$, so the value at 2 fixes the values at 4, 16, 256, ... : from $J(2) = \frac{1}{4}$ it gives $J(16) = 2 \cdot \frac{81}{64} + \frac{9}{2} = \frac{225}{32}$, which is $(16 + \frac{1}{16})/2 - 1$. Squaring moves every ratio toward the reference when it is run backward, and near the reference the cost is fixed by its curvature. This chapter turns that observation into a proof: on the line $\mathbb{R}_\delta$ the composition law and the unit curvature at the reference leave exactly one cost, J, and the proof uses no omniscience principle and no choice principle (Theorem 21.14).

The chapter opens Part VI and provides what Chapters 22 to 30 use. Section 21.1 fixes how maps are read in Parts VI to VIII, without unique choice, and defines the data forms of the omniscience principles that this reading separates from the principles. Section 21.2 builds the logarithm, the sine and the cosine on $\mathbb{R}_\delta$ and proves that the sine's period is 2π, with δ's own π and no choice principle. Section 21.3 proves the forcing theorem, separates the two families that are both called gauges of J, restricts the theorem to the golden orbit and prices the decision of the law for constant costs. Section 21.4 proves, in classical mathematics, that J is the cost of one fair binary distinction. Section 21.5 shows that the recognition ledger is the ring $\mathbb{Z}[\varphi]$, whose prices are compared by an integer sign test, that its history is a sigma-delta encoder of φ^{-3}, and that ledger balances and rates are δ's integers and ratios. Section 21.6 prices the decision whether a given cost obeys the law, and Section 21.7 shows, in classical mathematics, that a comparison which changes a record with certainty costs $J \geq \frac{1}{4}$, less a drift from the holding of the register, when the reference action is one cycle. The last five sections return to the forcing theorem. Section 21.8 shows that one binary distinction, with any one of four mild conditions, fixes the cost, and what the bit alone cannot do. Section 21.9 shows that bounds near the reference give the curvature. Section 21.10 shows that the ratio law is the logarithmic law and prices naming the branch of a cost, deciding its sign and

comparing two costs. Section 21.11 proves the exact values of J that later chapters use, the golden ladders among them, with no principle. Section 21.12 states the cost on ratio records and sorts Recognition Science's five premises for it into the redundant and the independent.

21.1 Reading maps without unique choice

In the first five parts of this book a map is a relation with exactly one output for each input (Appendix C). That reading contains the principle of unique choice: once each input is known to have exactly one output, the outputs form a map (Section 12.9). Section 14.9 and Chapter 16 also worked with a narrower reading, and Parts VI to VIII use that narrower reading throughout.

Here a map is a rule given as data. A map on the points of $\mathbb{R}_\delta$ computes its value from a regular sequence naming the point, and gives the same point for any two sequences that name the same point. A search that is proved to terminate counts as an explicit rule. A proof that every input has exactly one output does not, by itself, produce a map. Every theorem of Parts VI to VIII is proved under this reading. The proofs use a map only by evaluating it, and a rule given as data is also a map under the default reading; so a proof under the narrower reading is also a proof under the default reading, and each theorem stays true there. A statement that quantifies over all maps ranges over more maps under the default reading, and it stays true for the same reason: its proof only evaluates the map it is given, and every map it builds is a rule given as data, hence a map under either reading.

The reading matters for prices. WLPO says of each binary sequence that it is all zero or not. Under the narrower reading this does not give one map that returns the answer for every sequence. We therefore name the data forms.

Definition 21.1 (Data forms of the principles)**.** We use five data forms.

1. *The LPO function* exists when some map d from binary sequences to $\{0,1\}$ satisfies $d(\alpha) = 1$ exactly when $\alpha(n) = 1$ for some n.
2. *The WLPO function* exists when some map d from binary sequences to $\{0,1\}$ satisfies $d(\alpha) = 1$ exactly when $\alpha(n) = 0$ for every n.
3. *The WEM function*, a double-negation decision, exists when some map d from propositions to $\{0,1\}$ satisfies $d(P) = 1$ exactly when $\neg\neg P$.
4. *A zero test on the line* is a map z from $\mathbb{R}_\delta$ to $\{0,1\}$ with $z(x) = 1$ exactly when $x = 0$.
5. *An apartness test on the line* is a map a from $\mathbb{R}_\delta$ to $\{0,1\}$ with $a(x) = 1$ exactly when $x \# 0$, that is, when $x < 0$ or $x > 0$.

Each data form gives its principle with no choice: evaluate the map. The LPO function gives LPO, the WLPO function gives WLPO, the WEM function gives weak excluded middle, WEM, which states $\neg P \vee \neg\neg P$ for every proposition P; a zero test decides $x = 0 \vee x \neq 0$ for every point, which is WLPO by Corollary 12.18; and an apartness test decides $x \# 0 \vee \neg(x \# 0)$, that is, $x > 0 \vee x = 0 \vee x < 0$, for every point, which is LPO by Corollary 12.18. Chapter 28 proves that a zero test exists exactly when the WLPO function does and an apartness test exactly when the LPO function does.

Remark 21.2 (Under unique choice the data forms are the principles)**.** Assume unique choice. Each principle then gives its data form by the same argument: the principle gives every input exactly one bit, since two bits with the same defining property are equal, and unique choice turns that relation between inputs and bits into a map.

1. *WLPO gives the WLPO function.* WLPO says that each binary sequence α is all zero or not, so exactly one bit b has $b = 1$ exactly when $\alpha(n) = 0$ for every n. Unique choice turns this relation into a map d with $d(\alpha) = 1$ exactly when α is all zero.

2. *WLPO gives a zero test.* By Corollary 12.18, WLPO decides $x = 0 \vee x \neq 0$ for each point x, so exactly one bit b has $b = 1$ exactly when $x = 0$. Unique choice turns this relation into a map z on $\mathbb{R}_\delta$, a zero test.

3. *LPO gives an apartness test.* By Corollary 12.18, LPO gives $x > 0 \vee x = 0 \vee x < 0$ for each point x; the outer cases give $x \# 0$ and the middle case excludes it, so exactly one bit b has $b = 1$ exactly when $x \# 0$. Unique choice turns this relation into a map a on $\mathbb{R}_\delta$, an apartness test.

In the same way LPO gives the LPO function and WEM gives the WEM function. Under the default reading of this book each data form is therefore equivalent to its principle, and every theorem of Parts VI to VIII that names a data form is, under that reading, a theorem about the principle. The separations between a principle and its data form, where we state them, are statements about the narrower reading.

Three words recur. A result is *free* when its proof uses no omniscience principle and no choice principle, neither countable nor unique choice. A proof *with no choice principle* may use an omniscience principle that is named as a hypothesis; "T costs exactly P" means that T and P imply each other with no choice principle, and "at most" and "at least" name one of the two directions. A result *proved in classical mathematics* is a theorem about the classical real numbers, or about complex matrices or measures, with excluded middle and the axiom of choice available. Such a result carries no price on $\mathbb{R}_\delta$, and we say so before its statement. A *reading* is a map ρ from $\mathbb{R}_\delta$ to the classical real numbers that preserves sums, products and 1 and satisfies $x < y$ exactly when $\rho(x) < \rho(y)$; statements about readings are classical. Physical readings of the mathematics are named as identifications and kept apart from what is proved.

21.2 Logarithm, sine, cosine and π on the line

Proposition 12.88 constructs the exponential function on $\mathbb{R}_\delta$ at no price. The cost J needs its inverse, and the physics of the later chapters needs the circle functions and π. We construct them as maps in the sense of Section 21.1. We write e^x for $\exp(x)$ and use the facts of Proposition 12.19 without comment.

Lemma 21.3 (Order facts of the exponential)**.** *For all points a, b, c, u, x of $\mathbb{R}_\delta$:*

1. *$e^x > 0$ and $e^x e^{-x} = 1$;*
2. *$1 + u \le e^u$;*
3. *$e^b(a - b) \le e^a - e^b$;*
4. *if $a \le c$ then $e^a \le e^c$, and if $a \le c$ and $b \le c$ then $|e^a - e^b| \le e^c|a - b|$;*
5. *$a < b$ exactly when $e^a < e^b$; in particular $e^a = e^b$ implies $a = b$.*

The proofs are free.

Proof. 1. $e^x e^{-x} = e^0 = 1$, so e^x has an inverse and is positive or negative. It is not negative, since $e^x = (e^{x/2})^2 \ge 0$.

2. For $|h| \le 1$, Proposition 12.88 gives $e^h \ge 1+h-h^2$. If $e^v \ge 1+v-\varepsilon$, then $e^{2v} = (e^v)^2 \ge 2e^v - 1 \ge 1 + 2v - 2\varepsilon$, because $(e^v - 1)^2 \ge 0$. Let $V \ge |u|$ be a natural number and $2^K \ge V$. Applying the doubling step K times to $h = u/2^K$ gives $e^u \ge 1 + u - 2^K h^2 = 1 + u - u^2/2^K \ge 1 + u - V^2/2^K$. This holds for every such K, so $e^u \ge 1 + u$ by Lemma 12.52, item 2.

3. $e^a - e^b = e^b(e^{a-b} - 1) \ge e^b(a - b)$, by item 2 and $e^b > 0$.

4. Suppose $a \le c$ and $e^c < e^a$. Item 3 at the pair (c, a) gives $e^a(c - a) \le e^c - e^a < 0$, so $c - a < 0$ because $e^a > 0$; this denies $a \le c$. Now let $a, b \le c$. Item 3 at (b, a) gives $e^a - e^b \le e^a(a - b) \le e^c|a - b|$, and exchanging a and b gives the other half.

5. If $a < b$, item 3 gives $e^b - e^a \ge e^a(b - a) > 0$. Conversely let $e^a < e^b$, and take a natural number c above a and b. By item 4, $0 < e^b - e^a \le e^c|a - b|$, so $|a - b| > 0$, and Lemma 12.52, item 6, gives $a < b$ or $b < a$; the second would give $e^b < e^a$. If $e^a = e^b$, neither $a < b$ nor $b < a$, so $a = b$. □

A positive point has exactly one logarithm, by item 5. Turning that fact into a map would be unique choice, so we compute the logarithm.

Definition 21.4 (The logarithm)**.** Let $y > 0$, and let s be a regular sequence naming y. Search for the first stage N with $s_N > 2/(N + 1)$; it exists because $y > 0$. By Lemma 12.16, $y \ge 1/(2N + 2)$, and Proposition 12.19, item 4, gives a natural number K_s with $y \le K_s$. Put $c = 2N + K_s + 2$, so that $e^{-c} \le 1/(1 + c) \le y \le 1 + c \le e^c$ by Lemma 21.3, and let

$$f(t) = e^{c(2t-1)} - y \qquad (0 \le t \le 1).$$

Theorem 12.92 computes a root t^* of f in $[0, 1]$ from the data listed below, and we put $\log y = c(2t^* - 1)$.

The data are these. $f(0) \le 0 \le f(1)$. Let A be a natural number with $e^c \le A$. By Lemma 21.3, item 4, $|f(t) - f(t')| \le 2cA|t - t'|$, a modulus of uniform continuity given as a function. If $|f(t)|$ and $|f(t')|$ are at most $1/(\mu + 1)$, then $|e^a - e^{a'}| \le 2/(\mu + 1)$ for $a = c(2t - 1)$ and $a' = c(2t' - 1)$, both at least $-c$. Item 3 of the lemma gives $|e^a - e^{a'}| \ge e^{-c}|a - a'|$: if the right side were larger,

$|a - a'| > 0$, and in the case $a < a'$ we would have $e^{a'} - e^{a} \geq e^{a}(a' - a) \geq e^{-c}(a' - a)$, and symmetrically in the other case. So $|t - t'| \leq A/(c(\mu + 1))$, and $\mu(k) = A(k + 1)$ is a modulus of uniqueness. Finally, the value of f at each point $j/3^n$ is named by a regular sequence computed from n, j and s: the exponential of a ratio is computed from its constant sequence. Every step is a computation from s or a terminating search.

Proposition 21.5 (The logarithm is free)**.** *The logarithm of Definition 21.4 is a map on the positive points of $\mathbb{R}_\delta$: the point* $\log y$ *does not depend on the regular sequence used. For all positive x, y and every point t:*

1. $e^{\log y} = y$*, so every positive point is an exponential;*
2. $\log e^{t} = t$*;*
3. $\log(xy) = \log x + \log y$*;*
4. $x < y$ *exactly when* $\log x < \log y$*.*

No omniscience principle and no choice principle is used.

Proof. Item 1 holds by construction: $f(t^*) = 0$. Two sequences naming y give points with the same exponential, and these are equal by Lemma 21.3, item 5; so log is a map on the points. For item 2, $\log e^{t}$ and t have the same exponential. For item 3, $e^{\log x + \log y} = e^{\log x} e^{\log y} = xy = e^{\log(xy)}$. Item 4 is item 5 of the lemma applied to $\log x$ and $\log y$. □

For $x > 0$ and a point c we write $x^{c} = e^{c \log x}$; for an integer c this is the ordinary power. The circle functions are built from two power series in $s = \theta^2$, exactly as the exponential is built in Proposition 12.88.

Definition 21.6 (Cosine, sine and π_δ)**.** For a point s let

$$\mathrm{C}(s) = \sum_{j \geq 0} \frac{(-s)^{j}}{(2j)!}, \qquad \mathrm{S}(s) = \sum_{j \geq 0} \frac{(-s)^{j}}{(2j+1)!},$$

each the limit of its partial sums, computed on a regular sequence naming s with the modulus given by a natural bound $V \geq |s|$ and the diagonal limit of Theorem 12.25. Put $\cos\theta = \mathrm{C}(\theta^2)$ and $\sin\theta = \theta\,\mathrm{S}(\theta^2)$. For a natural number $m \geq 2$ put

$$\arctan\frac{1}{m} = \sum_{j \geq 0} \frac{(-1)^{j}}{(2j+1)\,m^{2j+1}}, \qquad \pi_\delta = 4\Big(\arctan\frac{1}{2} + \arctan\frac{1}{3}\Big).$$

A *quarter period* is a point q with $0 \leq q \leq 2$ and $\cos q = 0$.

The jth term of each series in s is at most $V^{j}/(2j)!$, and the terms of the arctangent series are at most $2^{-(2j+1)}$, so all three limits come with explicit moduli, and limits are unique, so the values depend only on the point. Theorem 21.8 below shows that there is exactly one quarter period and that it is $\pi_\delta/2$.

Lemma 21.7 (Identities and small-angle bounds)**.** *For all points α, β, θ:*

1. $\cos(-\theta) = \cos\theta$, $\sin(-\theta) = -\sin\theta$, $\cos 0 = 1$ *and* $\sin 0 = 0$;
2. $\cos(\alpha+\beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta$ *and* $\sin(\alpha+\beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta$;
3. $\cos^2\theta + \sin^2\theta = 1$, *so* $|\cos\theta| \le 1$ *and* $|\sin\theta| \le 1$;
4. *if* $|\theta| \le 1$, *then* $|\cos\theta - 1| \le \theta^2$, $|\sin\theta - \theta| \le |\theta|^3$ *and* $|\cos\theta - 1 + \theta^2/2| \le \theta^4$;
5. *if* $0 \le \theta \le 2$, *then* $\sin\theta \ge \theta/3$.

The proofs are free.

Proof. 1. The series depend on θ^2 only, and $\theta\,\mathrm{S}(\theta^2)$ is odd.

2. The partial sums $c_N(\theta)$ and $s_N(\theta)$ of the cosine and sine series are the two components of $\sum_{k<2N}(\mathrm{i}\theta)^k/k!$ in pairs of points multiplied by $(a,b)(a',b') = (aa'-bb', ab'+ba')$. As in the proof of Proposition 12.88, part 1, the binomial theorem shows that the product of the sums at α and at β differs from the sum at $\alpha+\beta$ by terms $\alpha^i\beta^j/(i!\,j!)$ with $i,j < 2N \le i+j$, at most a tail of the exponential series at $|\alpha|+|\beta|$ in absolute value. The defect tends to 0, and the two components of the limit are the two formulas.

3. Item 2 at $\alpha = \theta$, $\beta = -\theta$, with item 1.

4. $\cos\theta - 1 = \sum_{j\ge1}(-\theta^2)^j/(2j)!$ has absolute value at most $\theta^2\sum_{j\ge1}1/(2j)! \le \theta^2$, and the same bound for the partial sums passes to the limit (Lemma 12.52, item 2). Likewise $|\sin\theta - \theta| \le |\theta|^3\sum_{j\ge1}1/(2j+1)! \le |\theta|^3$ and $|\cos\theta - 1 + \theta^2/2| \le \theta^4\sum_{j\ge2}1/(2j)! \le \theta^4$.

5. For $0 \le s \le 6$ we have $\mathrm{S}(s) - 1 + s/6 = \sum_{i\ge1}\big(s^{2i}/(4i+1)! - s^{2i+1}/(4i+3)!\big)$, and each bracket is nonnegative because $s \le (4i+2)(4i+3)$. So $\mathrm{S}(s) \ge 1 - s/6$, and for $s = \theta^2 \le 4$ this gives $\mathrm{S}(\theta^2) \ge \frac{1}{3}$ and $\sin\theta = \theta\,\mathrm{S}(\theta^2) \ge \theta/3$. □

Theorem 21.8 (The sine's period is $2\pi_\delta$, with no choice)**.**

1. *For every natural number $m \ge 2$, the point $A = \arctan(1/m)$ satisfies $m\sin A = \cos A$, and $4/(5m) \le A \le 1/m$.*
2. *The point $\pi_\delta/2$ lies in $[\frac{4}{3}, \frac{5}{3}]$ and satisfies $\cos(\pi_\delta/2) = 0$ and $\sin(\pi_\delta/2) = 1$.*
3. *If $0 \le q \le 2$ and $\cos q = 0$, then $4q = 2\pi_\delta$.*

No omniscience principle and no choice principle is used.

Proof. 1, a grid of angles. Fix $m \ge 2$ and $N \ge 1$, and put $h = 1/(mN)$, $t_k = kh$ for $0 \le k \le N$, $\phi_k = h/(1+t_k^2)$ and $\Phi_n = \sum_{k<n}\phi_k$. These are ratios, $0 \le t_k \le 1/m \le \frac{1}{2}$ and $\frac{4}{5}h \le \phi_k \le h$. For $M \ge 1$ let $P_M(t) = \sum_{j<M}(-1)^j t^{2j+1}/(2j+1)$ and $Q_M(t) = \sum_{j<M}(-t^2)^j$, so that $(1+t^2)Q_M(t) =$

$1-(-t^2)^M$. For ratios $t,h\ge 0$ and $n\ge 2$ the binomial expansion and $\binom{n}{i}\le\binom{n}{2}\binom{n-2}{i-2}$ give $|(t+h)^n-t^n-nt^{n-1}h|\le\binom{n}{2}h^2(t+h)^{n-2}$. Hence, for $0\le t\le t+h\le\frac12$,

$$|P_M(t+h)-P_M(t)-hQ_M(t)|\le h^2\sum_{j\ge1} j\,2^{-(2j-1)}=\tfrac89 h^2,$$

since $\binom{2j+1}{2}/(2j+1)=j$. Also $hQ_M(t_k)=\phi_k\bigl(1-(-t_k^2)^M\bigr)$ differs from ϕ_k by at most $h4^{-M}$. Summing over $k<N$, the telescoping sum $P_M(1/m)=\sum_{k<N}\bigl(P_M(t_{k+1})-P_M(t_k)\bigr)$ satisfies $|P_M(1/m)-\Phi_N|\le\frac89 Nh^2+Nh4^{-M}\le 1/N+4^{-M}$. The tail of the arctangent series beyond M terms is at most $\sum_{j\ge M}2^{-(2j+1)}\le 4^{-M}$, so $|A-\Phi_N|\le 1/N+2\cdot4^{-M}$ for every M, and therefore $|A-\Phi_N|\le 1/N$. Since $\frac45 Nh\le\Phi_N\le Nh$, this gives $4/(5m)-1/N\le A\le 1/m+1/N$ for every N, hence the bounds on A.

1, the ray defect. Put $D_k=\sin\Phi_k-t_k\cos\Phi_k$, so $D_0=0$. Fix $k<N$ and write $S=\sin\Phi_k$, $C=\cos\Phi_k$, $t=t_k$, $\phi=\phi_k$, $\cos\phi=1+\gamma$ and $\sin\phi=\phi+\sigma$, with $|\gamma|,|\sigma|\le\phi^2$ by Lemma 21.7, item 4. By the addition formulas,

$$D_{k+1}=Sc'+Cs'-(t+h)(Cc'-Ss'),\qquad c'=\cos\phi,\ s'=\sin\phi.$$

Replacing c' by 1 and s' by ϕ leaves $S-tC+(\phi C+t\phi S-hC)+h\phi S$, and since $h=(1+t^2)\phi$,

$$\phi C+t\phi S-hC=t\phi(S-tC)=t\phi D_k.$$

The replaced terms contribute at most $(1+t+h)(|\gamma|+|\sigma|)\le 4h^2$, and $|h\phi S|\le h^2$. So $|D_{k+1}|\le(1+h)|D_k|+5h^2$. By induction, $|D_k|\le 5kh^2(1+h)^k$: the step is $(1+h)\,5kh^2(1+h)^k+5h^2\le 5(k+1)h^2(1+h)^{k+1}$. With $(1+h)^N\le e^{Nh}=e^{1/m}\le e^{1/2}\le 2$ (because $e\le 3$), $|D_N|\le 10Nh^2=10/(m^2N)\le 3/N$.

1, conclusion. For $|d|\le 1$ the addition formula gives $\sin(b+d)-\sin b=\sin b(\cos d-1)+\cos b\sin d$, so $|\sin(b+d)-\sin b|\le d^2+|d|+|d|^3\le 3|d|$, and likewise for the cosine. With $b=\Phi_N$, $b+d=A$ and $t_N=1/m$,

$$\Bigl|\sin A-\frac1m\cos A\Bigr|\le\frac3N+\frac{3}{2N}+|D_N|<\frac8N.$$

This holds for every N, so $m\sin A=\cos A$.

2. Let $\alpha=\arctan\frac12$ and $\beta=\arctan\frac13$, so $\cos\alpha=2\sin\alpha$ and $\cos\beta=3\sin\beta$. The addition formulas give

$$\sin(\alpha+\beta)=3\sin\alpha\sin\beta+2\sin\alpha\sin\beta=5\sin\alpha\sin\beta,$$
$$\cos(\alpha+\beta)=6\sin\alpha\sin\beta-\sin\alpha\sin\beta=5\sin\alpha\sin\beta,$$

the identity $(2+\mathrm{i})(3+\mathrm{i})=5(1+\mathrm{i})$ in disguise. With $p=\alpha+\beta$, $\pi_\delta/2=2p$ and $\cos 2p=\cos^2p-\sin^2p=0$. By part 1, $\frac25\le\alpha\le\frac12$ and $\frac{4}{15}\le\beta\le\frac13$, so $\frac43\le 2p\le\frac53$. Finally $\sin 2p=2\sin p\cos p=50\sin^2\alpha\sin^2\beta\ge 0$ and $\sin^2 2p=1$, so $(\sin 2p-1)(\sin 2p+1)=0$ with $\sin 2p+1\ge 1$ invertible, and $\sin 2p=1$.

3. Let $0\le a,b\le 2$ with $\cos a=\cos b=0$, and suppose $a<b$. With $u=(a+b)/2$ and $v=(b-a)/2$, the addition formulas give $\cos a-\cos b=\cos(u-v)-\cos(u+v)=2\sin u\sin v$. Here $0<v\le 1$ and $0<u\le 2$, so $\sin u$ and $\sin v$ are positive by Lemma 21.7, item 5, and $\cos a-\cos b>0$, a contradiction. So $\neg(a<b)$, likewise $\neg(b<a)$, and $a=b$. Taking $b=\pi_\delta/2$ from part 2 gives $q=\pi_\delta/2$. Every step is a ratio computation, a stage estimate or an inequality proved by refuting its negation; nothing is chosen. $\square$

Conditions and scope.

Base and premises
The line $\mathbb{R}_\delta$ with its free field operations, and the series of Definition 21.6; nothing else.

Conclusion
Exactly one zero of the cosine lies in $[0, 2]$, it is $\pi_\delta/2$, and four quarter periods make $2\pi_\delta$. Since $\cos q = 0$ and $\sin q = 1$, the addition formulas give $\sin(\theta + q) = \cos\theta$ and $\cos(\theta + q) = -\sin\theta$, so $\sin(\theta + 2\pi_\delta) = \sin\theta$ and $\cos(\theta + 2\pi_\delta) = \cos\theta$.

Not claimed
That π_δ is the least period; no property of the classical number π is used.

Gregory's series for the arctangent and Euler's identity $\pi/4 = \arctan\frac{1}{2} + \arctan\frac{1}{3}$ are classical. What the theorem adds is that both the identity and the quarter period are reached on $\mathbb{R}_\delta$ by explicit estimates, with no limit taken by choice and no decision about a point. The same tool proves Machin's identity (Question 3).

Proposition 21.9 (The classical reading)**.** *In classical mathematics there is exactly one reading* $\rho : \mathbb{R}_\delta \to \mathbb{R}$. *It sends* π_δ *to* π, *the positive root of* $x^2 = x + 1$ *to the golden ratio, and* $\log y$ *to* $\log \rho(y)$ *for every* $y > 0$.

Proof. For a regular sequence s, its stages converge classically; let ρ send the point of s to the limit. Sequences naming the same point have the same limit, sums and products of sequences converge to sums and products, and a positive stage gives a positive limit by Lemma 12.16, while a positive limit gives a positive stage. So ρ is a reading. Any reading fixes the integers, hence the ratios, and for integers a and natural numbers b it satisfies $a < (b+1)\rho(x)$ exactly when $a < (b+1)x$; so $\rho(x)$ is determined by the ratios below x, and the reading is unique. A reading preserves limits with a modulus, because it preserves the bounds $|x - y| \le 1/(k+1)$. So it sends each series of this section to the classical series, π_δ to $4(\arctan\frac{1}{2} + \arctan\frac{1}{3}) = \pi$, and $\log y$ to the classical number whose exponential is $\rho(y)$. The positive root of $x^2 = x + 1$ goes to a positive root of the same equation. □

21.3 The composition law forces J

We now state the law of the opening on $\mathbb{R}_\delta$ and prove that it leaves one cost. It is convenient to work in logarithmic coordinates: a ratio $x > 0$ is e^t with $t = \log x$, the reference $x = 1$ is $t = 0$, and the two composites xy and x/y are $s + t$ and $s - t$.

Definition 21.10 (Comparison costs, the composition law and calibration)**.**

1. A *comparison cost* is any function C from $\mathbb{R}_\delta$ to $\mathbb{R}_\delta$, the cost of the comparison at $t = \log x$. No continuity, monotonicity or other property is assumed.

2. C obeys the *composition law* when

$$C(s + t) + C(s - t) = 2C(s)C(t) + 2C(s) + 2C(t) \qquad \text{for all points } s, t. \tag{21.2}$$

3. C is *calibrated* when $C(0) = 0$ and for every k there is a j such that

$$\left|C(t) - \frac{t^2}{2}\right| \le \frac{t^2}{k+1} \qquad \text{whenever } |t| \le \frac{1}{j+1}. \tag{21.3}$$

   For a point c, C has *curvature* c^2 *at* 0 when $C(0) = 0$ and the same holds with $c^2t^2/2$ in place of $t^2/2$, and *curvature* $-c^2$ with $-c^2t^2/2$.

4. In multiplicative form, a function F on $\mathbb{R}_\delta$ obeys the *multiplicative law* when

$$F(xy) + F(xz) = 2F(x)F(y) + 2F(x) + 2F(y) \quad \text{whenever } x > 0,\ y > 0,\ yz = 1,$$

   and is *calibrated at* 1 when $F(1) = 0$ and for every k there is a j with $|F(x) - (x-1)^2/2| \le (x-1)^2/(k+1)$ whenever $|x-1| \le 1/(j+1)$.

The quotient x/y is written xz with $yz = 1$, so no division map is needed. With $H = 1 + C$ the law (21.2) is d'Alembert's equation $H(s+t) + H(s-t) = 2H(s)H(t)$. On the classical real line its continuous solutions are 0, $\cosh(ct)$ and $\cos(ct)$, and without a regularity condition there are wild solutions [97, 98]. On $\mathbb{R}_\delta$ a function carries no continuity unless it is stated, and the calibration (21.3) is the only regularity we assume: a uniform second-order expansion at the single point 0, with a modulus.

Definition 21.11 (The cost J)**.** For a positive point x put $J(x) = \frac{1}{2}(x + x^{-1}) - 1$, and for every point t put

$$G(t) = \cosh t - 1 = \frac{e^t + e^{-t}}{2} - 1, \qquad \sinh t = \frac{e^t - e^{-t}}{2}.$$

Then $J(e^t) = G(t)$, $J(x) = (x-1)^2/(2x) = J(x^{-1}) \ge 0$, and $x^c = e^{c \log x}$ gives $J(x^c) = G(c \log x)$.

Proposition 21.12 (Facts about $\cosh - 1$)**.** *For every point c:*

1. *$t \mapsto G(ct)$ obeys the composition law;*
2. *$|G(u) - u^2/2| \le 6|u|^3$ and $|G(u)| \le 7u^2$ whenever $|u| \le 1$;*
3. *$G(2w) = 2\sinh^2 w$, so $G \ge 0$;*
4. *G is calibrated, with $j = 6(k+1)$ in* (21.3)*;*
5. *$t \mapsto G(ct)$ has curvature c^2 at 0, and if $M \ge |c|$ is a natural number, $|G(ct)| \le 7M^2t^2$ whenever $|t| \le 1/(M+1)$.*

The proofs are free.

Proof. 1. Put $a = cs$ and $b = ct$, and $A = \cosh a$, $B = \cosh b$. Since $e^{a \pm b} = e^a e^{\pm b}$, $\cosh(a+b) + \cosh(a-b) = 2AB$. The left side of the law is therefore $2AB - 2$, and so is the right side, $2(A-1)(B-1) + 2(A-1) + 2(B-1)$. Only $2 \cdot \frac{1}{2} = 1$ is used.

2. Put $w = u/2$ and $r = \sinh w - w$. Expanding the squares, $\cosh 2w - 1 = 2\sinh^2 w$, so $G(u) - u^2/2 = 2(w+r)^2 - 2w^2 = 4wr + 2r^2$. Next $2r = (e^w - 1 - w) - (e^{-w} - 1 + w)$, and

Proposition 12.88, item 2, bounds each bracket by w^2, so $|r| \le w^2 \le u^2$. Hence $|G(u) - u^2/2| \le 4|u|^3 + 2u^4 \le 6|u|^3$, since $|u| \le 1$, and $|G(u)| \le 6|u|^3 + u^2/2 \le 7u^2$.

3. Shown in item 2.

4. If $|t| \le 1/(6k+7)$, then $6|t|^3 \le 6t^2/(6k+7) \le t^2/(k+1)$.

5. For $|t| \le 1/(M+1)$ we have $|ct| \le 1$, so item 2 gives $|G(ct) - c^2t^2/2| \le 6M^3|t|\,t^2$ and $|G(ct)| \le 7M^2t^2$. Given k, put $j = M + 6M^3(k+1)$; then $|t| \le 1/(j+1)$ gives $6M^3|t| \le 1/(k+1)$. No case distinction on $c = 0$ is made. □

Setting $s = t$ in the law, and using $C(0) = 0$, gives the *duplication law*

$$C(2s) = 2C(s)^2 + 4C(s) \qquad \text{for every point } s. \tag{21.4}$$

The opening used it to pass from $J(2)$ to $J(4)$ and $J(16)$. Run backward, it lets the values near 0 decide everything, and the next theorem makes this exact. Its proof contains the one estimate of the chapter that is not routine: errors that double at every halving step must not compound.

Theorem 21.13 (Duplication determines a cost)**.** *Let f and g be functions on $\mathbb{R}_\delta$ that both obey the duplication law* (21.4)*. Suppose*

(i) for every k there is a j with $|f(t) - g(t)| \le t^2/(k+1)$ whenever $|t| \le 1/(j+1)$, and

(ii) there are natural numbers j_0 and B with $|g(t)| \le Bt^2$ whenever $|t| \le 1/(j_0+1)$.

Then $f(t) = g(t)$ for every point t. The proof is free.

Proof. Put $D = f - g$. Subtracting the two duplication laws,

$$D(2v) = 2D(v)\big(2 + f(v) + g(v)\big). \tag{21.5}$$

A small interval. Take j_1 from (i) at $k = 0$, so that $|D(v)| \le v^2$ for $|v| \le 1/(j_1+1)$. Put $\gamma = 2B+1$, $M = j_0 + j_1 + \gamma$ and $\varepsilon = 1/(M+1)$. For $|v| \le \varepsilon$ we have $v^2 \le \varepsilon$, so $\gamma v^2 \le 1$, and

$$|2 + f(v) + g(v)| = |2 + D(v) + 2g(v)| \le 2 + v^2 + 2Bv^2 = 2 + \gamma v^2 \le 2(1 + \gamma v^2).$$

The bounded product. We claim that for every n and every u with $|2^n u| \le \varepsilon$,

$$|D(2^n u)| \le \big(1 + \gamma(2^n u)^2\big)\, 4^n\, |D(u)|.$$

For $n = 0$ this is clear. For the step put $w = 2^n u$ with $|2w| \le \varepsilon$. By (21.5), the bound on $|2 + f + g|$ and the claim at n, $|D(2w)| \le 4^{n+1}(1 + \gamma w^2)^2 |D(u)|$, and $(1+a)^2 \le 1 + 4a$ for $0 \le a \le 2$ gives $(1 + \gamma w^2)^2 \le 1 + \gamma(2w)^2$. The factors $1 + \gamma(2^i u)^2$ do not multiply up along the doublings: a single factor $1 + \gamma t^2$ covers them all.

Equality near 0. Let $|t| \le \varepsilon$ and fix k. Take j from (i) at $2k+1$, and put $u = t/2^j$. Since $j + 1 \le 2^j$ and $|t| \le 1$, $|u| \le 1/(j+1)$, so $|D(u)| \le u^2/(2k+2)$. The claim with $n = j$ gives

$$|D(t)| \le (1 + \gamma t^2)\, 4^j u^2\, \frac{1}{2k+2} = (1 + \gamma t^2)\frac{t^2}{2k+2} \le \frac{1}{k+1},$$

because $4^j u^2 = t^2$ exactly, $\gamma t^2 \le 1$ and $t^2 \le 1$. As k is arbitrary, $D(t) = 0$ by Corollary 12.24.

The whole line. If $f(u) = g(u)$, the duplication laws give $f(2u) = g(2u)$. For any t take a natural number $A \ge 1$ with $|t| \le A$ and $n = A(M+1)$; then $|t/2^n| \le A/(n+1) < \varepsilon$, so f and g agree at $t/2^n$, and n doublings give $f(t) = g(t)$.

Every inequality above is a closed bound proved from closed bounds, and the only numbers produced are computed from j_0, j_1, B and the given moduli. No comparison of points is decided. □

Theorem 21.14 (The composition law and the calibration force J)**.**

1. *A comparison cost C obeys the composition law and is calibrated if and only if $C(t) = \cosh t - 1$ for every point t.*
2. *Let c be a point. A comparison cost C obeys the composition law and has curvature c^2 at 0 if and only if $C(t) = \cosh(ct) - 1$ for every t.*
3. *A function F obeys the multiplicative law and is calibrated at 1 if and only if $F(x) = J(x)$ for every positive point x.*

No omniscience principle and no choice principle is used. In classical mathematics, moreover: for every reading ρ, every C as in part 1 and all points $x > 0$ and y with $e^y = x$, $\rho(C(y)) = J(\rho(x))$; and for every F as in part 3, $\rho(F(x)) = J(\rho(x))$.

Proof. Part 1 is part 2 at $c = 1$. In part 2, the cost $t \mapsto \cosh(ct) - 1$ obeys the law and has curvature c^2 by Proposition 21.12. Conversely let C obey the law with curvature c^2, and put $g(t) = \cosh(ct) - 1$. Both C and g vanish at 0 and obey the law, so both obey the duplication law. For hypothesis (i) of Theorem 21.13, take the moduli of C and of g at $2k+1$; below both, $|C(t) - g(t)| \le |C(t) - c^2t^2/2| + |c^2t^2/2 - g(t)| \le t^2/(k+1)$. Hypothesis (ii) is Proposition 21.12, item 5, with $B = 7M^2$. So $C = g$.

For part 3 let F obey the multiplicative law and be calibrated at 1, and put $C(t) = F(e^t)$. At $x = e^s$, $y = e^t$ and $z = e^{-t}$ the multiplicative law is the composition law for C, since $e^s e^{\pm t} = e^{s \pm t}$. For the calibration, $C(0) = F(1) = 0$, and for $|t| \le 1$, $|e^t - 1| \le |e^t - 1 - t| + |t| \le 2|t|$. Given k, let j_2 be the modulus of F at $8k+8$, and let $|t| \le 1/(j+1)$ with $j = 2j_2 + 6k + 7$. Then $|e^t - 1| \le 1/(j_2+1)$, so

$$\left| F(e^t) - \frac{(e^t-1)^2}{2} \right| \le \frac{(e^t-1)^2}{8k+9} \le \frac{4t^2}{8k+9} \le \frac{t^2}{2k+2},$$

and $|(e^t-1)^2 - t^2| = |e^t - 1 - t|\,|e^t - 1 + t| \le 3|t|^3$, so $|(e^t-1)^2/2 - t^2/2| \le \frac{3}{2}|t|\,t^2 \le t^2/(2k+2)$. Adding, $|C(t) - t^2/2| \le t^2/(k+1)$. By part 1, $C = \cosh - 1$. For $x > 0$ put $\ell = \log x$ (Proposition 21.5); then $F(x) = C(\ell) = (x + e^{-\ell})/2 - 1$, and $e^{-\ell} = x^{-1}$. So $F(x) = J(x)$.

Conversely, J is calibrated at 1: $J(x) - (x-1)^2/2 = (x-1)^2(1-x)/(2x)$, and for $|x-1| \le \frac{1}{2}$ we have $x \ge \frac{1}{2}$, so $|J(x) - (x-1)^2/2| \le (x-1)^2|x-1| \le (x-1)^2/(k+1)$ when $|x-1| \le 1/(k+2)$. J obeys the multiplicative law: with $yz = 1$, both sides plus 2 equal $\frac{1}{2}(x + x^{-1})(y + z)$, because $(xy)^{-1} = x^{-1}z$ and $(xz)^{-1} = x^{-1}y$.

For the classical statements, a reading ρ preserves products, so $\rho(e^y)\rho(e^{-y}) = 1$ and $\rho(e^{-y}) = \rho(x)^{-1}$; with $\rho(\frac{1}{2}) = \frac{1}{2}$ this gives $\rho(\cosh y - 1) = J(\rho(x))$, and part 1 or part 3 identifies $C(y)$ or $F(x)$. □

Conditions and scope.

Base and premises
The line $\mathbb{R}_\delta$; a cost C that is an arbitrary function, with the composition law (21.2) at all pairs of points and the calibration (21.3) with a modulus.

Conclusion
$C = \cosh - 1$, equivalently $F = J$ on the positive points, with no omniscience principle and no choice principle. The two premises hold for exactly one function.

Identification
That the cost of a physical comparison obeys the law and the calibration is the premise of Recognition Science's derivation of J (Chapter 22). The theorem derives the cost from that premise; it does not supply the premise, and no observation is used.

Not claimed
Any price for deciding whether a given cost obeys the premises; Section 21.6 computes it.

On the classical real line, Recognition Science reaches the same conclusion from the law and the curvature limit $2C(t)/t^2 \to 1$ through the regularity theory of d'Alembert's equation. Theorem 21.14 replaces that theory by the duplication estimate, and the uniform form of the calibration is what the estimate needs. Two remarks fix its scope.

Remark 21.15 (The normalisation is needed and is implied)**.** The constant cost $C \equiv -1$ obeys the law, since $-2 = 2 - 2 - 2$, so some normalisation must exclude it. The second-order clause already implies $C(0) = 0$: at $t = 0$ it reads $|C(0)| \le 0$. Section 21.6 shows that a cost obeying the law has $C(0) = 0$ or $C(0) = -1$, with no omniscience, and that $C(0) = -1$ forces $C \equiv -1$.

The curvature parameter c of part 2 is easily confused with a different family.

Proposition 21.16 (Two gauges, and only one keeps the law)**.**

1. *For every point c, the cost $t \mapsto \cosh(ct) - 1$ obeys the composition law; at $t = \log x$ it equals $J(x^c)$. This is the* exponent family.
2. *For a point λ, the cost $\lambda(\cosh t - 1)$ obeys the composition law if and only if $\lambda^2 = \lambda$.*
3. *If $\kappa\lambda = 2$, then $C = \lambda(\cosh - 1)$ obeys $C(s+t) + C(s-t) = \kappa C(s)C(t) + 2C(s) + 2C(t)$ for all s, t; if it also obeys the composition law, then $\kappa = 2$ and $\lambda = 1$.*

The proofs are free.

Proof. 1. Proposition 21.12, item 1, and $J(x^c) = \cosh(c \log x) - 1$.

2. If $\lambda^2 = \lambda$, multiply the law for $G = \cosh - 1$ by λ and use $2\lambda^2 G(s)G(t) = 2\lambda G(s)G(t)$. Conversely, write the law for λG at $s = t = 1$ and subtract λ times the law for G there: what

remains is $2(\lambda^2-\lambda)G(1)^2=0$. Since $e\geq 2$ by Lemma 21.3, $G(1)\geq \frac{1}{2}e^{-1}>0$, so $G(1)^2$ is invertible and $\lambda^2=\lambda$.

3. $\lambda G(s\pm t)$ summed is $\lambda\big(2G(s)G(t)+2G(s)+2G(t)\big)$, and $2\lambda=\kappa\lambda^2$. If moreover $\lambda^2=\lambda$, then $2\lambda=\kappa\lambda^2=\kappa\lambda=2$, so $\lambda=1$ and $\kappa=2$. □

The *amplitude family* λJ belongs to the law with product coefficient $\kappa=2/\lambda$. Scaling the cost by $\kappa/2$, as in the relation $(\kappa/2)F=J$, leaves the composition law of this chapter unless $\kappa=2$. The family that stays inside the law is the exponent family $J(x^c)$, whose parameter is the curvature c^2 at the reference. The sign of the curvature selects the branch.

Proposition 21.17 (The curvature selects the branch)**.** *Let c be a point. The cost $t\mapsto\cos(ct)-1$ obeys the composition law, has curvature $-c^2$ at 0 and is at most 0. A cost that obeys the law and has curvature $-c^2$ at 0 equals $\cos(ct)-1$ at every point. The proofs are free.*

Proof. By Lemma 21.7, $\cos(a+b)+\cos(a-b)=2\cos a\cos b$, and the computation of Proposition 21.12, item 1, gives the law. Also $\cos u-1=-2\sin^2(u/2)\leq 0$. For a natural number $M\geq|c|$ and $|t|\leq 1/(M+1)$, Lemma 21.7, item 4, gives $|\cos(ct)-1+c^2t^2/2|\leq(ct)^4\leq M^3|t|\,t^2$ and $|\cos(ct)-1|\leq M^2t^2$; the modulus is chosen as in Proposition 21.12, item 5, and Theorem 21.13 applies as in Theorem 21.14. □

Recognition Science's calibration is $+1$, so the oscillating branch is excluded by the sign of a premise, not by an additional assumption.

The golden orbit

The ring $\mathbb{Z}[\varphi]$ carries the ledger of Section 21.5 and the discrete form of the forcing theorem.

Definition 21.18 (The golden ratio and its ring)**.** Let $\varphi=(1+\sqrt{5})/2$ in $\mathbb{R}_\delta$, with $\sqrt{5}$ the nonnegative square root of Proposition 12.19, and $\psi=1-\varphi$. The ring $\mathbb{Z}[\varphi]$ consists of the formal sums $a+b\varphi$ with integers a,b, multiplied by $(a+b\varphi)(a'+b'\varphi)=(aa'+bb')+(ab'+ba'+bb')\varphi$, that is, with $\varphi^2=\varphi+1$; each such sum also names a point of $\mathbb{R}_\delta$. The element $a+b\varphi$ *passes the sign test* when, with $s=2a+b$ and $t=b$ (so that $a+b\varphi=(s+t\sqrt{5})/2$),

$$s\geq 0,\ t\geq 0,\ (s,t)\neq(0,0),\quad\text{or}\quad s<0<t,\ s^2<5t^2,\quad\text{or}\quad t<0<s,\ 5t^2<s^2.$$

The point φ is positive, $\varphi^2=\varphi+1$, $\varphi\psi=-1$, so $\varphi^{-1}=\varphi-1$ and every integer power φ^n lies in $\mathbb{Z}[\varphi]$; also $\varphi^{-3}=2\varphi-3=\sqrt{5}-2$. It is the only positive solution of $x^2=x+1$: if $x>0$ solves it, then $(x-\varphi)(x+\varphi-1)=0$ with $x+\varphi-1>0$.

Lemma 21.19 (The sign test decides the order of $\mathbb{Z}[\varphi]$)**.** *For integers a,b, the point $a+b\varphi$ is positive exactly when $a+b\varphi$ passes the sign test. For every $d\in\mathbb{Z}[\varphi]$ exactly one of the following holds: d passes the sign test, $d=0$, or $-d$ passes the sign test. These are decided by integer arithmetic, and no principle is used.*

Proof. Since $\sqrt{5}$ is irrational, $s^2=5t^2$ holds for integers only at $s=t=0$: otherwise 5 divides s, then t, and the pair can be divided by 5 indefinitely. If $s,t\geq 0$, not both 0, then $s+t\sqrt{5}>0$. If $s<0<t$, then $s+t\sqrt{5}>0$ exactly when $t\sqrt{5}>-s$, and for positive points $u<v$ exactly when

$u^2 < v^2$; so exactly when $5t^2 > s^2$. The third case is symmetric, and if $s, t \le 0$ the point is not positive. The trichotomy follows from integer trichotomy for s, t and $s^2 - 5t^2$. □

For an arbitrary point, deciding $x > 0 \vee x = 0 \vee x < 0$ costs LPO (Corollary 12.18). The lemma says that on $\mathbb{Z}[\varphi]$ it costs nothing.

Proposition 21.20 (J on the golden orbit)**.**

1. *For every integer n, $e^{n \log \varphi} = \varphi^n$.*
2. *Every comparison cost C that obeys the composition law and is calibrated satisfies $2C(n \log \varphi) = \varphi^n + \varphi^{-n} - 2 = 2J(\varphi^n)$, an element of $\mathbb{Z}[\varphi]$, for every integer n.*
3. *A function g on the integers, with values in $\mathbb{Z}[\varphi]$ or in $\mathbb{R}_\delta$, that satisfies*

$$g(m+n) + g(m-n) = g(m)g(n) + 2g(m) + 2g(n), \qquad g(0) = 0, \qquad g(1) = \sqrt{5} - 2, \tag{21.6}$$

is $g(n) = \varphi^n + \varphi^{-n} - 2$.

The proofs are free.

Proof. 1. $e^{\log \varphi} = \varphi$ and $e^{a+b} = e^a e^b$. 2. By Theorem 21.14, $C(n \log \varphi) = \cosh(n \log \varphi) - 1$. 3. The function $\varphi^n + \varphi^{-n} - 2 = 2G(n \log \varphi)$ satisfies (21.6), because $2G$ obeys the law with product coefficient 1 and $\varphi + \varphi^{-1} = 2\varphi - 1 = \sqrt{5}$. Conversely, $m = 0$ gives $g(-n) = g(n)$, and the law at the pair $(k+1, 1)$ gives $g(k+2) = g(k+1)g(1) + 2g(k+1) + 2g(1) - g(k)$ for every $k \ge 0$, so $g(0)$ and $g(1)$ determine g. □

Recognition Science proves part 3 for functions into $\mathbb{Z}[\varphi]$: the discrete composition law with the unit value $\sqrt{5} - 2$ at one golden step has exactly one solution. Part 2 shows that this discrete theorem is Theorem 21.14 restricted to the orbit $\{n \log \varphi\}$, the logarithms of the powers of the golden ratio.

Deciding the law for a constant

The forcing theorem takes the law as a premise. Whether a given cost obeys it is a separate question with a price. The smallest case already costs WLPO.

Proposition 21.21 (Constant costs: deciding the law is WLPO)**.**

1. *The constant cost $C \equiv a$ obeys the composition law exactly when $a^2 + a = 0$.*
2. *The assertion that for every point a the constant cost a obeys the law or does not is equivalent to WLPO, with no choice principle.*
3. *For every point c the law for $t \mapsto \cosh(ct) - 1$ is a free theorem.*

Proof. 1. At $s = t = 0$ the law reads $2a = 2a^2 + 4a$, that is $a^2 + a = 0$; conversely $a^2 + a = 0$ gives $a + a = 2a^2 + 2a + 2a$ at every pair.

2. WLPO decides $x = 0 \vee x \neq 0$ for every point (Corollary 12.18); apply it to $x = a^2 + a$. Conversely, given a point r, decide the law for the constant r^2. It holds exactly when $r^4 + r^2 = 0$, that is when $r^2 = 0$, since both terms are at least 0; and $r^2 = 0$ exactly when $r = 0$. So $r = 0 \vee r \neq 0$ is decided for every r, which is WLPO by Corollary 12.18.

3. Proposition 21.12, item 1. □

21.4 J is the cost of one fair binary distinction

The forcing theorem starts from an arbitrary function. A second route starts from a mechanism. Read a comparison $x > 0$ through one record increment K, an integer drawn from some law, as the power x^K, and take as the cost the expected excess $\mathbb{E}[x^K] - 1$. Which laws give a cost that obeys the composition law? The answer is: exactly the fair choice between two opposite steps, and the unit calibration picks the step ± 1. For the fair sign $S = \pm 1$ with probability $\frac{1}{2}$ each, $1 + J(x) = \mathbb{E}[x^S]$, and the law says $\mathbb{E}[x^S]\,\mathbb{E}[y^{S'}] = \frac{1}{2}\big(\mathbb{E}[(xy)^S] + \mathbb{E}[(x/y)^S]\big)$ for independent fair signs S, S'.

This section is proved in classical mathematics, over the classical real numbers and, for the second theorem, with measure theory. It is a characterisation of J among costs of a stated form, not a result priced on $\mathbb{R}_\delta$. Reading a comparison through an increment as a power is an identification; the theorems say what follows from it. Throughout, the composition law is (21.1) for all classical $x, y > 0$.

Theorem 21.22 (One fair binary distinction, finite support)**.** *In classical mathematics: let S be a finite set of integers and a_k, for $k \in S$, real numbers of any sign with $\sum_k a_k = 1$, and put $C(x) = \sum_{k\in S} a_k x^k - 1$ for $x > 0$.*

1. *C obeys the composition law if and only if there is a natural number c with $C(x) = J(x^c)$ for every $x > 0$.*
2. *In that case $a_k = \frac{1}{2}$ for $k = \pm c$ and $a_k = 0$ for every other $k \in S$ when $c \geq 1$, and $a_0 = 1$, $a_k = 0$ otherwise, when $c = 0$. The weights are nonnegative and the law is the fair choice between c and $-c$.*
3. *For a natural number c, $J(2^c) = \frac{1}{4}$ if and only if $c = 1$. Hence if C obeys the law and $C(2) = \frac{1}{4}$, then $C = J$ on $x > 0$ and the law is the fair step ± 1.*

Proof. Laurent monomials are independent. If $\sum_{k\in S} b_k x^k = 0$ for every $x > 0$, then every $b_k = 0$: with $N = \sum_{k\in S} |k|$ the polynomial $\sum_k b_k X^{k+N}$ vanishes at infinitely many points, so it is 0, and its exponents $k + N$ are distinct.

The law on coefficients. Put $M(x) = 1 + C(x) = \sum_k a_k x^k$. The law for C is equivalent to $M(xy) + M(x/y) = 2M(x)M(y)$. Fix $y > 0$; as a Laurent polynomial in x,

$$M(xy) + M(x/y) - 2M(x)M(y) = \sum_{k\in S} a_k\big(y^k + y^{-k} - 2M(y)\big)x^k,$$

so the law gives $a_k(y^k + y^{-k} - 2M(y)) = 0$ for every $k \in S$ and $y > 0$.

One profile. The weights sum to 1, so some $a_{k_0} \neq 0$, and then $M(y) = \frac{1}{2}(y^{k_0} + y^{-k_0})$ for every $y > 0$. With $c = |k_0|$ this is $C(y) = J(y^c)$. *The weights.* The fair weights w_k of part 2 satisfy $\sum_k w_k x^k = \frac{1}{2}(x^c + x^{-c}) = M(x)$; independence on $S \cup \{c, -c\}$ gives $a_k = w_k$ for $k \in S$. Positivity and fairness are conclusions.

The converse. J obeys the law at all $u, v \neq 0$: both sides plus 2 equal $\frac{1}{2}(u+u^{-1})(v+v^{-1})$. Apply this at $u = x^c$, $v = y^c$.

Part 3. Put $z = 2^c \geq 1$. Then $J(z) = \frac{1}{4}$ exactly when $2z^2 - 5z + 2 = 0$, that is $(2z-1)(z-2) = 0$; $z \geq 1$ excludes $z = \frac{1}{2}$, so $z = 2$ and $c = 1$. Conversely $J(2) = \frac{5}{4} - 1 = \frac{1}{4}$. If $C(2) = \frac{1}{4}$, part 1 gives $C(2) = J(2^c)$, so $c = 1$. □

Theorem 21.23 (One fair binary distinction, beyond finite support)**.** *In classical mathematics: let μ be a probability measure on the real line with $\int e^{st}\, d\mu(t) < \infty$ for every real s, and put $C_\mu(x) = \int x^t\, d\mu(t) - 1$ for $x > 0$.*

1. *C_μ obeys the composition law if and only if $\mu = \frac{1}{2}\delta_c + \frac{1}{2}\delta_{-c}$ for some $c \geq 0$.*
2. *For every real c and every $x > 0$, the law $\frac{1}{2}\delta_c + \frac{1}{2}\delta_{-c}$ has cost $J(x^c)$.*
3. *For real $c \geq 0$, $J(2^c) = \frac{1}{4}$ if and only if $c = 1$.*

Proof. Put $E(s) = \int e^{st}\, d\mu(t)$, so that $C_\mu(e^s) = E(s) - 1$ and $E(0) = 1$. At $x = e^a$, $y = e^b$ the law becomes $E(a+b) + E(a-b) = 2E(a)E(b)$ for all real a, b. At $a = 0$ it gives $E(-b) = E(b)$, and at $a = b = 1$ it gives $E(2) = 2m^2 - 1$ with $m = E(1)$.

The variance argument. Since $e^t e^{-t} = 1$,

$$\left(e^t + e^{-t} - 2m\right)^2 = e^{2t} + e^{-2t} + 2 + 4m^2 - 4me^t - 4me^{-t},$$

and every term is integrable. Integrating, $2(2m^2 - 1) + 2 + 4m^2 - 8m^2 = 0$. A nonnegative function with integral 0 vanishes almost everywhere, so $\cosh t = m$ for μ-almost every t.

Two points. The almost-sure set is not empty; pick t_0 in it and put $c = |t_0|$. Since cosh is even and injective on $[0, \infty)$, μ is carried by $\{c, -c\}$. If $c = 0$, $\mu = \delta_0$. If $c > 0$, write $\mu = p\delta_c + q\delta_{-c}$; then $E(-1) = E(1)$ reads $(p - q)(e^c - e^{-c}) = 0$, so $p = q = \frac{1}{2}$.

Parts 2 and 3. $\int f d\mu = \frac{1}{2}(f(c) + f(-c))$ gives $C_\mu(x) = \frac{1}{2}(x^c + x^{-c}) - 1 = J(x^c)$, and the law follows from the law for J at $u = x^c$, $v = y^c$. Part 3 is the computation of Theorem 21.22 with $z = 2^c \geq 1$, followed by $c \log 2 = \log 2$. □

The hypothesis $c \geq 0$ in part 3 is needed: $J(2^{-1}) = J(\frac{1}{2}) = \frac{1}{4}$, since $J(x) = J(x^{-1})$. Theorem 21.22 assumes no positivity of the weights, and neither theorem assumes symmetry of the law, continuity or a calibration at the reference; the only reference value used is $J(2) = \frac{1}{4}$. Where Theorem 21.14 classifies functions, these theorems classify mechanisms, and both routes end at the same function.

Conditions and scope.

Base and premises
Classical real numbers and, in Theorem 21.23, a probability measure with all exponential moments finite. Proved in classical mathematics.

Conclusion
Among costs $\mathbb{E}[x^K] - 1$, the composition law holds exactly for the fair law on $\pm c$, and the value $\frac{1}{4}$ at $x = 2$ fixes $c = 1$, the cost J.

Identification
Reading a comparison through one increment as a power of the ratio, and the cost as the expected excess.

Not claimed
A version priced on $\mathbb{R}_\delta$.

21.5 The ledger is $\mathbb{Z}[\varphi]$

Recognition Science records recognitions in a ledger. A recognition is summarised by its census: how many independent steps it took and how many closures. Joining a recognition to the one before it is the step that Chapter 22 shows forces the golden ratio. This section proves what that bookkeeping is as mathematics: a census is an element of $\mathbb{Z}[\varphi]$, prices of recognitions are compared by the integer sign test of Lemma 21.19 at no price, the stream of postings is the unique history that a sigma-delta rule produces, and the balances and rates of any ledger are exactly δ's integers and ratios.

Definition 21.24 (Censuses, the join and the posting history)**.**

1. A *census* is a pair (i, c) of natural numbers, not both 0: i independent steps and c closures. The *join* sends (i, c) to $(i + c, i)$. The *base census* is $(0, 1)$, and the kth recognition is the base census joined k times. Its number of *postings* is $i + c$.

2. The *golden value* of (i, c) is $c + i\varphi \in \mathbb{Z}[\varphi]$, and its *price* is the point $i\varphi + c$ of $\mathbb{R}_\delta$.

3. A *posting word* is a finite word in the letters d (a debit, for an independent step) and c (a credit, for a closure); its *balance* is the number of letters d minus the number of letters c. The join acts on words by replacing every d by dc and every c by d. Put $W_0 = \mathsf{d}$ and let W_{k+1} be the join of W_k.

4. Since W_k is an initial segment of W_{k+1}, the words define one infinite *recognition history* h, whose Nth letter is that of any W_k long enough. Write b_N for the balance of its first N letters.

The first words are d, dc, dcd, dcddc and $\mathsf{dcddcdcd}$. Write $F(n)$ for the Fibonacci numbers, $F(0) = 0$, $F(1) = 1$, $F(n + 2) = F(n + 1) + F(n)$, extended by $F(-1) = 1$. By induction, $\varphi^n = F(n)\varphi + F(n - 1)$ and $F(n + 1) - \varphi F(n) = \psi^n$ for $n \geq 0$; the second identity holds because $\psi(F(n+1) - \varphi F(n)) = \psi F(n+1) + F(n)$, using $\psi\varphi = -1$. Since $|\psi| = \varphi^{-1}$ and $F(n) \leq \varphi^n$, it gives

$$\left|\frac{F(n+1)}{F(n)} - \varphi\right| \leq \frac{1}{F(n)^2} \qquad (n \geq 1). \tag{21.7}$$

Theorem 21.25 (The recognition ledger is $\mathbb{Z}[\varphi]$)**.**

1. *The golden value is injective on censuses, and its image is the set of nonzero $a + b\varphi$ with $a, b \geq 0$.*
2. *The join multiplies the golden value by φ, and the kth recognition has golden value φ^k.*
3. *For censuses x and y, the price of x is less than the price of y exactly when the golden value of y minus that of x passes the sign test. Any two prices satisfy exactly one of $<, =, >$, and the case is decided; prices are equal only for equal censuses; the join multiplies the price by φ.*
4. *The kth recognition posts $P(k) = F(k+1)$ times, and $P(k+2)P(k) - P(k+1)^2 = (-1)^k$. No posting count times φ is the next posting count, yet the ratios $P(2n+4)/P(2n+3)$ form a regular sequence that names φ.*

No omniscience principle and no choice principle is used.

Proof. 1. $(i, c) \mapsto c + i\varphi$ reads off both coordinates, and the image is as stated. 2. $\varphi(c + i\varphi) = c\varphi + i(\varphi + 1) = i + (i + c)\varphi$, the golden value of $(i + c, i)$; the base census has value 1. 3. The price is the golden value read as a point, and the map from $\mathbb{Z}[\varphi]$ to $\mathbb{R}_\delta$ preserves sums and products; Lemma 21.19 gives the comparison and the trichotomy, and item 1 gives equality. 4. By induction the kth census is $(F(k), F(k-1))$, with $F(k) + F(k-1) = F(k+1)$ postings, and Cassini's identity $F(n+1)F(n-1) - F(n)^2 = (-1)^n$ [99] at $n = k + 2$ gives the second claim. A nonzero integer times φ has a nonzero φ-coordinate, so it is no integer. Finally $r_n = F(2n+5)/F(2n+4)$ satisfies $|r_n - \varphi| \leq 1/F(2n+4)^2 \leq 1/(2n+2)$ by (21.7), so $|r_m - r_n| \leq 1/(2m+2) + 1/(2n+2)$: the sequence is regular, and the point it names is within $2/(n+1)$ of φ for every n, hence equal to φ. □

Two examples show what the sign test does. Three independent steps cost less than five closures, $3\varphi < 5$: the difference $5 - 3\varphi$ has $s = 7$, $t = -3$ and $5t^2 = 45 < 49$. And eight closures cost less than five steps, $8 < 5\varphi$: here $s = -11$, $t = 5$ and $121 < 125$. A comparison of arbitrary points of $\mathbb{R}_\delta$ costs LPO; a comparison of recognition prices costs nothing, because the prices live in $\mathbb{Z}[\varphi]$.

The history h begins dcddcdcddcddc $\cdots$, the Fibonacci word [100]. Its running balance stays close to the line of slope $\varphi^{-3} = \sqrt{5} - 2 \approx 0.236$, and it is produced by a feedback rule of the kind used in sigma-delta converters [101].

Theorem 21.26 (The history is a sigma-delta encoder of φ^{-3})**.**

(a) $W_{k+2} = W_{k+1}W_k$. The word W_k has $F(k+1)$ debits and $F(k)$ credits, so it is the posting word of the $(k+1)$st recognition; its length is $F(k+2)$ and its balance $F(k+1) - F(k)$.

(b) For every N, the discrepancy $D_N = N\varphi^{-3} - b_N$, an element of $\mathbb{Z}[\varphi]$, satisfies

$$-\frac{2}{\varphi} < D_N < \frac{2}{\varphi^2},$$

so $|N\varphi^{-3} - b_N| < 2$. Each inequality is one sign test.

(c) The running rate b_N/N at $N = F(2n+6)$ equals $-3 + 2F(2n+7)/F(2n+6)$, and these rates form a regular sequence that names φ^{-3}.

(d) For a natural number r, there is an increasing sequence of depths K along which the ratios $P(K+r)/P(K)$ form a regular sequence that names φ^{r}, and there is another along which the ratios $P(K)/P(K+r)$ one that names φ^{-r}.

(e) The Nth posting of h is a debit exactly when $b_N < (N+2)\varphi^{-3}$, and h is the only infinite history with this property.

No omniscience principle and no choice principle is used.

Proof. (a) Write σ for the join on words. It respects concatenation and $\sigma(\mathsf{c}) = \mathsf{d}$, so $W_{k+2} = \sigma^{k+1}(\mathsf{dc}) = W_{k+1}\,\sigma^{k}(\mathsf{d}) = W_{k+1}W_k$. On letter counts σ is the join of censuses, and W_0 has census $(1,0)$, the first recognition. The counts follow from item 4 of Theorem 21.25.

(b) For a word w put $\Delta(w) = |w|\varphi^{-3} - \mathrm{bal}(w)$, which adds over concatenation, and $g_k = \Delta(W_k)$. By (a), $g_{k+2} = g_{k+1} + g_k$. Since $g_0 = \varphi^{-3} - 1 = -2\psi^2$, $g_1 = 2\varphi^{-3} = -2\psi^3$ and $\psi^2 = \psi + 1$, induction gives $g_k = -2\psi^{k+2}$. As $\psi < 0$, the g_k alternate in sign, negative for even k. Put

$$L_k = -\frac{2}{\varphi} + \max(g_k, g_{k+1}), \qquad U_k = \frac{2}{\varphi^2} + \min(g_k, g_{k+1}).$$

We claim that every initial segment p of W_k, the empty one and W_k included, has $L_k \le \Delta(p) \le U_k$. For $k = 0$ and $k = 1$, the segments have Δ equal to 0, g_0 and g_1, and the bounds are $[g_0, 0]$ and $[g_0, g_1]$, using $-2/\varphi = 2\psi$, $2/\varphi^2 = 2\psi^2$ and $1 - \psi^2 = -\psi$. For the step, a segment of $W_{k+2} = W_{k+1}W_k$ either lies in W_{k+1} or is $W_{k+1}p'$ with p' a segment of W_k, and then $\Delta = g_{k+1} + \Delta(p')$. Let k be even, so $g_k < 0 < g_{k+1}$, $g_{k+2} < 0 < g_{k+3}$ and $g_{k+3} < g_{k+1}$. Then $U_{k+2} = U_{k+1}$ and $L_{k+2} \le L_{k+1}$, which covers the first kind; for the second, $\Delta \le 2/\varphi^2 + g_k + g_{k+1} = U_{k+2}$ and $\Delta \ge -2/\varphi + 2g_{k+1} \ge -2/\varphi + g_{k+1} + g_{k+2} = L_{k+2}$. The case of odd k is the mirror image. Every comparison here is between elements of $\mathbb{Z}[\varphi]$, so it is a sign test. Now $|W_N| = F(N+2) \ge N$, so D_N is Δ of an initial segment of W_N; one of g_N, g_{N+1} is positive and the other negative, so $-2/\varphi < D_N < 2/\varphi^2$, and both bounds lie within 2 of 0.

(c) After $F(2n+6)$ postings the record is W_{2n+4}, with balance $F(2n+5) - F(2n+4)$, and $2F(2n{+}7) - 3F(2n{+}6) = F(2n{+}5) - F(2n{+}4)$. By (21.7) the rate is within $2/F(2n{+}6)^2 \le 1/(2n{+}2)$ of $-3 + 2\varphi = \varphi^{-3}$, and the argument of Theorem 21.25, item 4, applies.

(d) For $r \ge 1$, $F(K+r) = F(r)F(K+1) + F(r-1)F(K)$ and $\varphi^r = F(r)\varphi + F(r-1)$ give $F(K{+}r) - \varphi^r F(K) = F(r)\psi^K$, so $|F(K{+}r)/F(K) - \varphi^r| \le F(r)/F(K)^2$ and $|F(K)/F(K{+}r) - \varphi^{-r}| \le F(r)/F(K)^2$. Choose the depths so large that these bounds are at most $1/(2n+2)$ at the nth term, and argue as in (c). For $r = 0$ the ratios are 1.

(e) A debit changes D by $\varphi^{-3} - 1$ and a credit by $\varphi^{-3} + 1$; the interval of (b) has length $2/\varphi + 2/\varphi^2 = 2$. If posting N is a credit, $D_{N+1} < 2/\varphi^2$ gives $D_N < 6 - 4\varphi$; if it is a debit, $D_{N+1} > -2/\varphi$ gives $D_N > 6 - 4\varphi$. Since $6 - 4\varphi = -2\varphi^{-3}$, $D_N - (6 - 4\varphi) = (N+2)\varphi^{-3} - b_N$, which is the rule. A history obeying the rule is determined letter by letter, since the rule at N reads only the first N letters; so it is h. $\square$

The bounds of (b) have length exactly 2, the change of D between a debit and a credit, and this is what makes (e) a rule. The rule is a one-bit quantiser with feedback: it posts a debit whenever

the books have fallen below the target line, with a lead of two postings. Reading postings as physical events, debits as independent steps and credits as closures, is the identification of Definition 21.24; the counts, balances and rates do not depend on the order within a recognition, but the prefix bounds do.

Balances and rates of any ledger

The recognition history is one ledger. For an arbitrary history of postings on one account, the balances and rates are δ's integers and ratios (Definitions 4.3 and 4.9).

Theorem 21.27 (Balances are integers, rates are ratios, and every rate in $[-1, 1]$ is a running rate)**.**

1. *The balance of a posting word w is the signed record $[\#\mathsf{d}(w), \#\mathsf{c}(w)]$ of $\mathbb{Z}_\delta$. Every element of $\mathbb{Z}_\delta$ is a balance, concatenation adds balances, and two words have the same balance exactly when one is turned into the other by swapping adjacent letters and deleting or inserting adjacent pairs* dc*. A balance z and a number n of postings occur together exactly when $|z| \le n$ and $n - z$ is even. The balance forgets the record:* dc *and the empty word have balance* 0 *and different numbers of postings.*

2. *A* rate record *is a word w read over $t+1$ ticks; its value is $\langle \mathrm{bal}(w); t+1\rangle \in \mathbb{Q}_\delta$. Every element of $\mathbb{Q}_\delta$ is a rate record; (w, t) and (w', t') have equal values exactly when $\mathrm{bal}(w)(t' + 1) = \mathrm{bal}(w')(t+1)$; concatenation on one clock adds rates; exchanging the letters negates; replacing each debit of u by v and each credit by v with its letters exchanged, read over $(s + 1)(t + 1)$ ticks, multiplies the rates of (u, s) and (v, t).*

3. *Every point of $\mathbb{R}_\delta$ is named by a regular sequence of rate records.*

4. *For every point x with $-1 \le x \le 1$ there is an infinite history whose running rates b_N/N, read at $N = 6(n + 1)$, form a regular sequence naming x. Conversely, if the running rates of a history, read at any increasing sequence of stages, form a regular sequence, the point it names lies in $[-1, 1]$.*

No omniscience principle and no choice principle is used.

Proof. 1. Counting letters gives the signed record, and $\mathsf{d}^a\mathsf{c}^b$ has balance $[a, b]$. Moves preserve the balance. Conversely, swaps sort a word to $\mathsf{d}^p\mathsf{c}^q$, and deleting pairs leaves d^{p-q} or c^{q-p}, which depends only on the balance. A word with p debits and q credits has $z = p - q$ and $n = p + q$; conversely $p = (n + z)/2$ and $q = (n - z)/2$.

2. The word $\mathsf{d}^a\mathsf{c}^b$ over d ticks has value $\langle [a, b]; d\rangle$. Equality is cross equality of ratio records. In a nested word each debit of u contributes $\mathrm{bal}(v)$ and each credit $-\mathrm{bal}(v)$, so the balance is $\mathrm{bal}(u)\mathrm{bal}(v)$, over $(s + 1)(t + 1)$ ticks.

3. Every ratio record is a rate record, by item 2.

4. Fix a regular sequence q naming x; the proof needs one, and the assertion is a proposition, so nothing is chosen. Post a debit at tick N exactly when $b_N \le Nq_N$, and a credit otherwise. Fix K. Each stage satisfies $|q_K| \le 1 + 1/(K + 1)$, and $|Nq_N - Nq_K| \le N/(K + 1) + 1$ by regularity.

Put $E_N = b_N - Nq_K$. After a debit, $E_N \le N/(K+1) + 1$ and $E_{N+1} = E_N + 1 - q_K$; after a credit, $E_N > -N/(K+1) - 1$ and $E_{N+1} = E_N - 1 - q_K$. By induction from $E_0 = 0$,

$$|b_N - Nq_K| \le 3 + \frac{4N}{K+1} \qquad \text{for all } N \text{ and } K.$$

At $N = 6(n+1)$ this gives $|b_N/N - q_K| \le 1/(2n+2) + 4/(K+1)$ for every K, and since q_K is within $1/(K+1)$ of x, the running rate is within $1/(2n+2)$ of x. These rates therefore form a regular sequence naming x. Conversely, a balance never exceeds the number of postings in absolute value, so every running rate lies in $[-1, 1]$, and so does any point they name (Lemma 12.52, item 2). □

The interval $[-1, 1]$ is forced by one posting per tick. Which history nature runs, and that a measured quantity is a running rate, are identifications the theorem does not make. Chapter 24 builds the light cone on these rates.

21.6 What deciding a cost law costs

Theorem 21.14 takes the composition law as a premise. Checking the premise for a given cost is a decision with a price, and Proposition 21.21 found it already for constants: WLPO. For general costs the price depends on how the cost is given, on whether it is calibrated, and on the reading of maps. This section computes it. The same questions arise for Recognition Science's balance premise on the lattice, and the answers coincide.

Definition 21.28 (Zero tests, aggregation, and how a cost is given)**.**

1. The *function zero test* FZ: for every function H on $\mathbb{R}_\delta$, either $H(x) = 0$ for every x, or not.
2. The *pair zero test* PZ: the same for every function of two points.
3. The *sequence zero test* SZ: for every sequence (y_n) of points, either $y_n = 0$ for every n, or not.
4. *Aggregation* AGG: for every sequence (y_n) of points there is a point z with $z = 0$ exactly when $y_n = 0$ for every n.
5. A cost C is *continuous* when for every point x and every k there is a j with $|C(x) - C(y)| \le 1/(k+1)$ whenever $|x - y| \le 1/(j+1)$. It is *presented* when it is continuous and there are functions of the natural numbers n and j giving regular sequences that name $C(j/3^n)$ and $C(-j/3^n)$.
6. *Deciding the law* for a class of costs means: for every cost C in the class, C obeys the composition law or it does not.

The sequence zero test concerns one sequence of points at a time; it is not the principle $\mathrm{WLPO}_{\mathrm{seq}}$ of Definition 13.8, which decides a sequence of binary rows. Two constructions do most of the work. For a sequence (y_n) of points, its *interpolation* is

$$\iota_y(t) = y_0 + \sum_{k<K} r(t-k)\,(y_{k+1} - y_k), \qquad r(u) = \min\bigl(1, \max(0, u)\bigr),$$

for any natural number $K \geq t$; the terms with $k \geq t$ vanish, so the value does not depend on K. It is continuous, $\iota_y(n) = y_n$ by telescoping, and $\iota_y \equiv 0$ when every y_n is 0. For a function H on $\mathbb{R}_\delta$, the *coded cost* is

$$C_H(t) = \cosh t - 1 + \max(0, t-1)\, H(t-2) + \max(0, -t-1)\, H(t+2).$$

Both ramps vanish on $[-1, 1]$, so C_H agrees with $\cosh -1$ there and hides H outside.

Theorem 21.29 (The price ladder for costs given as functions)**.**

1. *If C obeys the composition law, then $C(0) = 0$ or $C(0) = -1$, and $C(0) = -1$ implies $C(t) = -1$ for every t.*
2. *For every function H, the coded cost C_H is calibrated, and it obeys the composition law exactly when $H(x) = 0$ for every x.*
3. *Deciding the law for all costs implies* FZ*.* FZ *implies* SZ*, and* SZ *is equivalent to WLPO together with* AGG*.*
4. PZ *implies deciding the law for all costs, and* WEM *implies* PZ*.*
5. *Deciding the law for all calibrated costs is equivalent to* FZ*.*

No choice principle is used, and parts 1 and 2 are free. With Theorem 28.36, which derives PZ *from* FZ *with no choice principle, parts 3 and 4 settle the price for all costs: deciding the law for all costs is equivalent to* FZ*, and so to* PZ*, as it is for calibrated costs by part 5; it implies WLPO and follows from* WEM*.*

Proof. 1. At $s = t = 0$ the law gives $2C(0) = 2C(0)^2 + 4C(0)$, so $C(0)(C(0) + 1) = 0$. Cotransitivity of $-1 < 0$ at $C(0)$ gives $-1 < C(0)$, where $C(0) + 1$ is invertible and $C(0) = 0$, or $C(0) < 0$, where $C(0)$ is invertible and $C(0) = -1$. This is a genuine disjunction. If $C(0) = -1$, the law at $(t, 0)$ reads $2C(t) = -2C(t) - 2 + 2C(t)$, so $C(t) = -1$.

2. C_H is calibrated because the calibration only concerns $|t| \leq 1/(j+1) \leq 1$, where $C_H = \cosh -1$. By Theorem 21.14, C_H obeys the law exactly when $C_H = \cosh -1$, that is, when $\max(0, t-1)H(t-2) + \max(0, -t-1)H(t+2) = 0$ for every t. If $H \equiv 0$ this holds. Conversely let x be a point; cotransitivity of $0 < 1$ gives $0 < x$ or $x < 1$. If $0 < x$, read the equation at $t = x + 2$: it says $(x+1)H(x) = 0$ with $x + 1 > 0$, so $H(x) = 0$. If $x < 1$, read it at $t = x - 2$: it says $(1 - x)H(x) = 0$ with $1 - x > 0$. Both cases conclude the same equation, so nothing is chosen.

3. Deciding the law for C_H decides $H \equiv 0$. Given a sequence y, FZ applied to ι_y decides whether every $y_n = \iota_y(n)$ is 0. If SZ holds, constant sequences give $r = 0 \vee r \neq 0$ for every point r, which is WLPO by Corollary 12.18, and the point $z = 0$ or $z = 1$, according to the decision, aggregates. Conversely WLPO decides $z = 0$ for an aggregating point z.

4. A cost obeys the law exactly when the function of two points $(s, t) \mapsto C(s+t) + C(s-t) - 2C(s)C(t) - 2C(s) - 2C(t)$ vanishes, which PZ decides. An assertion that a function vanishes is a conjunction of equations of points, and equations are stable under double negation; WEM gives $\neg P \vee \neg\neg P$, and $\neg\neg P$ gives P.

5. For a calibrated C, the law holds exactly when $C - (\cosh - 1) \equiv 0$, by Theorem 21.14; FZ decides this. Conversely C_H is calibrated, and part 2 turns a decision of its law into a decision of $H \equiv 0$.

For the closing sentence, parts 3 and 4 give that deciding the law for all costs implies FZ and that PZ implies it, and Theorem 28.36 gives PZ from FZ; the proof of that theorem uses parts 3 and 4 and part 1 of Proposition 21.34, and nothing that rests on the closing sentence. Part 3 gives WLPO from FZ, and part 4 gives the decision from WEM. □

The lower bound FZ is the easy half. For the upper bound, Chapter 28 reduces one pair zero test to countably many function zero tests, read along Schoenberg's space-filling curve, and FZ decides countably many at once (Proposition 21.34, part 1). Where FZ itself lies between WLPO and WEM is open; it is question (O2) at the end of this section.

Theorem 21.30 (Continuous and presented costs)**.**

1. *A continuous cost obeys the law exactly when it obeys it at all pairs $(a/3^n, b/3^n)$ with integers a, b and natural n.*
2. *Deciding the law for all continuous costs is equivalent to* SZ*, and so is deciding it for all continuous calibrated costs.*
3. *Deciding the law for all presented costs is equivalent to WLPO, and so is deciding it for all presented calibrated costs.*
4. *The cost* $\cosh - 1$ *is presented, calibrated and obeys the law, so for it the check costs nothing.*

No choice principle is used.

Proof. 1. Fix a triadic $s = a/3^n$. The function $t \mapsto C(s+t)+C(s-t)-2C(s)C(t)-2C(s)-2C(t)$ is continuous at every point and vanishes at every triadic $b/3^m$ with $m \geq n$, since $s = a3^{m-n}/3^m$. The triadic points are dense: every point is within $1/(j+1)$ of one, found from a stage of a regular sequence naming it, inside the proof of an equation. A function continuous at t and vanishing on a dense set vanishes at t. So the defect vanishes for triadic s and every t, and the same argument in s, for fixed t, finishes the proof.

2. An explicit surjection from $\mathbb{N}$ onto the triples (n, a, b) lists the triadic pairs in one sequence, and by part 1 the law is the zero test of the sequence of defects there; SZ decides it. Conversely, for a sequence y the coded cost C_{ι_y} is continuous and calibrated, and it obeys the law exactly when $\iota_y \equiv 0$, that is, when every $y_n = 0$.

3. Let C be presented. The triadic points of depth n are closed under sums and differences, so the defect at $(a/3^n, b/3^n)$ is a ring expression in presented values, and a regular sequence naming it is computed from the given ones. By Lemma 12.15, all these defects vanish exactly when every stage of every one of these sequences lies within $2/(k+1)$ of 0 at its stage k, a single binary sequence after the pairs (defect, stage) are listed. WLPO decides it, and part 1 carries the verdict to all pairs. Conversely, constant costs are presented, and deciding the law for them is WLPO (Proposition 21.21). For calibrated costs use instead C_c for the constant

function c: it is presented, since the exponential of a ratio and the ramps at triadic points are computed, it is calibrated, and it obeys the law exactly when $c = 0$.

4. The exponential of a ratio is computed from its constant sequence, so the values of $\cosh - 1$ at triadic points come with regular sequences; the rest is Proposition 21.12. □

A record of a value is a regular sequence that names it, what an apparatus writes stage by stage. Read that way, part 3 says that a cost recorded at the triadic grid of log-ratios is checked at the price WLPO, the price of checking one binary sequence. The gap between parts 2 and 3 is the difference between SZ and WLPO, which is aggregation.

Theorem 21.31 (Where aggregation comes from)**.**

1. *WLPO together with countable unique choice into* $\{0, 1\}$ *implies* SZ*.*
2. AGG *follows from each of: completeness of* $\mathbb{R}_\delta$ *for sequences with the modulus* $k \mapsto k$ *(every sequence* (F_m) *with* $|F_m - F_n| \le 1/(k+1)$ *for* $m, n \ge k$ *converges); completeness for all Cauchy sequences; least upper bounds of bounded sequences; and a choice of regular sequences naming the terms of each sequence of points, which follows from* AC_ω*.*

No choice principle is used beyond the ones named. So over any of these bases, SZ*, the law for continuous costs, and the balance premise of Theorem 21.32 each cost exactly WLPO.*

Proof. 1. WLPO decides $y_n = 0$ for each n (Corollary 12.18), so each n has exactly one bit b_n with $b_n = 1$ exactly when $y_n = 0$; countable unique choice gives the sequence (b_n), and WLPO applied to $(1 - b_n)$ decides whether every $y_n = 0$.

2. Let $a_i = \min(|y_i|, 1/(i+1))$ and $A_K = \max_{i \le K} a_i$. For $m \ge K$, $A_K \le A_m \le A_K + 1/(K+1)$, since the terms with $i > K$ are at most $1/(K+2)$; so (A_K) has the modulus $k \mapsto k$. Let L be its limit; as (A_K) is nondecreasing, $A_n \le L$ for every n. If every $y_n = 0$, every $A_K = 0$ and $L = 0$. If $L = 0$, then $a_n = 0$ for every n; if $|y_n| > 0$, then $a_n > 0$ as a minimum of positive points, so $|y_n| \le 0$ and $y_n = 0$. So L aggregates. A Cauchy sequence with that modulus is a Cauchy sequence. The least upper bound of $\min(|y_n|, 1)$ is 0 exactly when every $y_n = 0$. With regular sequences $s^{(n)}$ naming the terms, the binary sequence that lists, over all pairs (n, k), whether $|s_k^{(n)}| > 2/(k+1)$ is all zero exactly when every $y_n = 0$ (Lemma 12.15), and its jump point (Lemma 12.5) aggregates. AC_ω chooses the regular sequences. □

The balance premise

Recognition Science's balance premise says that the books close everywhere except at the source. Let a *current* assign to each site x of $\mathbb{Z}^3$ and each direction $i \in \{0, 1, 2\}$ a point $j(x, i)$ of $\mathbb{R}_\delta$, the net rate on the edge from x to $x + e_i$. Its divergence at x is $\sum_i \big(j(x, i) - j(x - e_i, i)\big)$, and the current is *balanced* when its divergence is 0 at every site other than the origin. It is *displayed* when regular sequences naming all its rates are given as one function of (x, i), and *integer* when its rates are integers.

Theorem 21.32 (The balance premise is one sequence zero test)**.**

1. *Deciding balance for every current is equivalent to* SZ*.*
2. *Deciding balance for every displayed current is equivalent to WLPO, and so is deciding it for every integer current.*
3. *Deciding balance for every current is equivalent to deciding it for every integer current together with* AGG*.*

No choice principle is used.

Proof. 1. An explicit surjection $m \mapsto x_m$ from $\mathbb{N}$ onto $\mathbb{Z}^3$, built from the diagonal walk through $\mathbb{N} \times \mathbb{N}$, turns balance into the zero test of the sequence whose mth term is the divergence at x_m, or 0 if x_m is the origin. Conversely, given (y_n), put the rate y_n on the edge leaving $(2n+1, 0, 0)$ in direction 0 and 0 on every other edge. The divergence is y_n at $(2n+1, 0, 0)$, $-y_n$ at $(2n+2, 0, 0)$ and 0 elsewhere, so this current is balanced exactly when every $y_n = 0$.

2. For a displayed current, regular sequences naming the divergences are computed, and as in Theorem 21.30, part 3, balance becomes one binary sequence, which WLPO decides. For an integer current the divergences are integers and WLPO decides directly. Conversely, the current of part 1 built from the constant sequence of the jump point of a binary sequence α, with its dyadic sequence, is displayed and is balanced exactly when α is all zero; with the bits $\alpha(n)$ themselves as rates it is an integer current.

3. Part 1, part 2 and Theorem 21.29, part 3. □

Read as physics, a displayed current is one given with the records of its rates. For such currents the continuum adds nothing to the price of integer postings. A difference could arise only for a current given as a bare function into the line, and then it is aggregation, a matter of completeness or choice, not of omniscience.

Under the default reading, and without it

Unique choice is part of the default reading of this book (Section 21.1). Under it the aggregation gap closes: SZ becomes WLPO. Table 21.1 collects the prices under both readings.

Corollary 21.33 (The prices under unique choice)**.** *Assume unique choice. Then* SZ *is equivalent to WLPO. Deciding the law for all continuous costs, and deciding the balance premise for all currents, each cost exactly WLPO.*

Proof. Countable unique choice into $\{0, 1\}$ is a case of unique choice; apply Theorems 21.31, 21.30 and 21.32. □

For costs given as functions unique choice changes nothing: by Theorem 21.29 the price is FZ under both readings.

More can be said about the bare law along rational lines, and two questions remain.

Table 21.1. The price of deciding a law for every member of a class. "Without unique choice" is the reading of Parts VI to VIII; every entry in that column is proved with no choice principle.

Decision, for every member	Without unique choice	With unique choice	Result
Law, constant costs	WLPO	WLPO	Prop. 21.21
Law, costs given as functions	FZ	FZ	Thm. 21.29, Thm. 28.36
Law, calibrated costs	FZ	FZ	Thm. 21.29
Law, continuous costs, calibrated or not	SZ, that is WLPO and AGG	WLPO	Thm. 21.30, Cor. 21.33
Law, presented costs, calibrated or not	WLPO	WLPO	Thm. 21.30
Law for $\cosh(ct) - 1$	free	free	Prop. 21.21
Balance, every current	SZ	WLPO	Thm. 21.32, Cor. 21.33
Balance, displayed or integer currents	WLPO	WLPO	Thm. 21.32

Proposition 21.34 (The law along rational lines)**.** *Say that C obeys the law* on rational lines *when the law holds at every pair (as, bs) with s a point and a, b integers.*

1. FZ *decides countably many function zero tests at once: for every sequence (H_n) of functions, whether $H_n(x) = 0$ for all n and x.*
2. *For a calibrated cost, the law, the law on rational lines and the duplication law* (21.4) *are equivalent.*
3. *A continuous cost that obeys the law on rational lines obeys the law.*
4. *Deciding the law on rational lines for all costs, and deciding the duplication law for all costs, are each equivalent to* FZ*.*
5. *In classical mathematics, the cost equal to $\cosh x - 1$ at rational x and to 0 elsewhere obeys the law on rational lines but not the law.*

Parts 1 to 4 use no choice principle.

Proof. 1. List the pairs $(n, g) \in \mathbb{N} \times \mathbb{Z}$ explicitly as (n_j, g_j). For a point z let v^z be the sequence whose terms $4j, \dots, 4j + 3$ all equal $H_{n_j}(z - 4j + g_j)$, and put $W(z) = \iota_{v^z}(z)$. On $[4j, 4j + 3]$ the interpolation of a sequence constant on that block is the common value, so $W(z) = H_{n_j}(z - 4j + g_j)$ there. Given n and x, take an integer g with $g - 1 \le x \le g + 2$, from a stage of a regular sequence naming x, take j with $(n_j, g_j) = (n, g - 1)$, and put $z = x + 4j - g + 1$; then $W(z) = H_n(x)$. So $W \equiv 0$ exactly when every $H_n \equiv 0$, and one test of W decides.

2. The line $(1, 1)$ with $C(0) = 0$ is the duplication law, and the duplication law with the calibration gives $C = \cosh - 1$ by Theorem 21.13, as in Theorem 21.14.

3. $a/3^n = a \cdot (1/3^n)$, so the law on rational lines contains the law at triadic pairs, and Theorem 21.30, part 1, applies.

4. Under FZ, part 1 decides the law on rational lines for every cost, a countable family of function zero tests, and the duplication law is one function zero test. Conversely C_H is calibrated, so by part 2 either decision for C_H decides $H \equiv 0$.

5. On the line of the points as with s rational, every point is rational and the cost is $\cosh -1$, which obeys the law. With s irrational, every as with $a \neq 0$ is irrational, and the cost is 0 on the whole line, since $\cosh 0 - 1 = 0$; the cost 0 obeys the law. At $s = \sqrt{2}$ and $t = 1 - \sqrt{2}$, the point $s + t = 1$ is rational and s, t, $s - t$ are not, so the law would give $\cosh 1 - 1 = 0$. □

The cost of part 5 is not continuous, by part 3, and it is defined by cases on rationality, which needs classical logic. Physically read, a comparison of a ratio with its own rational powers is one function zero test, and by Theorem 21.29 so is the full law, even for a cost that jumps between incommensurable ratios.

Conditions and scope.

Base and premises
The narrower reading of maps of Section 21.1; Corollary 21.33 adds unique choice.

Conclusion
Costs calibrated or not: exactly FZ when given as functions (for costs that are not calibrated, with Theorem 28.36), exactly SZ when continuous, exactly WLPO when presented. With unique choice, SZ is WLPO. Recognition Science's own cost is presented and calibrated, and its law is a free theorem.

Not claimed
The open statements below.

Two statements are open. The first is stated over the reading of Parts VI to VIII, without unique choice; the second is open even with unique choice.

(O1) Does WLPO imply AGG? By Theorems 21.29, 21.30 and 21.32, with no choice principle, each of the following is equivalent to a positive answer: SZ is equivalent to WLPO; deciding the law for continuous costs costs exactly WLPO; deciding balance for every current follows from deciding it for integer currents.

(O2) Where does FZ lie between WLPO and WEM?

21.7 A certain change costs a quarter cycle

A comparison is carried out by an apparatus, and the cost $J(x)$ is the action the apparatus spends, in units of a reference action. When can one comparison change a record with certainty, moving one configuration of a register to another with probability one? When the reference action is one full cycle, the answer is a threshold on the cost: $J(x) \geq \frac{1}{4}$, less what the holding of the register contributes (Figure 21.1). This section is proved in classical mathematics, over the classical real and complex numbers; it uses π for the classical number, and the model is stated in full.

Definition 21.35 (Registers, paid words and comparison controllers)**.** In classical mathematics:

1. A *register* of n binary channels has the 2^n configurations as basis; its operators are complex matrices on them, with the operator norm $\|\cdot\|$. A *word* w is a finite list of tokens, each carrying a skew-Hermitian generator G_t. Its *generator cost* is $g(w) = \sum_t \|G_t\|$ and its *drive action* is $\hbar\, g(w)$, for a constant $\hbar > 0$. Among the words are the *phase loops*, which act as the identity up to a phase and have any prescribed generator cost $\theta \geq 0$, and for channels $k \neq l$ the *entangling token*, whose generator is $\frac{\pi}{4}\mathrm{i}X$ with X an involution that sends each configuration to the configuration with channel l flipped, up to a sign.

2. A *holding* is a self-adjoint operator H. The *paid word* runs each token for a time $\varepsilon > 0$ under the holding plus its control: $W = U_{t_m} \cdots U_{t_1}$ with $U_t = \exp\bigl(-\frac{\mathrm{i}\varepsilon}{\hbar}\bigl(H + \frac{\hbar}{\varepsilon}(\mathrm{i}G_t + \|G_t\|)\bigr)\bigr)$. The *drift* of the word is $|w|\,\varepsilon\|H\|$, with $|w|$ the number of tokens.

3. The word makes a *certain change* when $|W_{vu}| = 1$ for some configurations $u \neq v$: the Born weight of moving u to v is 1.

4. A *comparison controller* with reference action $A_0 > 0$ selects a word $\mathrm{sel}(d, r)$ for records $d \geq 0$ and $r > 0$, such that pooled records drive the sum, $\hbar g(\mathrm{sel}(d+e, r)) = \hbar g(\mathrm{sel}(d, r)) + \hbar g(\mathrm{sel}(e, r))$, and a record read against itself drives the reference, $\hbar g(\mathrm{sel}(r, r)) = A_0$. Its *word at ratio* $x > 0$ is $w(x) = \mathrm{sel}(d(x), r(x))$, where $d(x)$ and $r(x)$ are the residual and reference records that Recognition Science's comparison apparatus stores at ratio x; they satisfy $d(x)/r(x) = J(x)$ (Chapter 22).

Each paid token is a phase times $\exp(Y_t)$ with $Y_t = G_t - \frac{\mathrm{i}\varepsilon}{\hbar}H$, a skew-Hermitian generator of norm at most $\|G_t\| + \varepsilon\|H\|/\hbar$. The scalar part $\frac{\hbar}{\varepsilon}\|G_t\|$ of the control is the baseline energy of the token, so the drive action is the time integral of the baseline.

Lemma 21.36 (The drive law and the step bound)**.** *In classical mathematics:*

1. *every comparison controller satisfies $\hbar g(\mathrm{sel}(d, r)) = A_0 d/r$, so its word at ratio x has drive action $A_0 J(x)$;*

2. *for every word, holding, $\hbar, \varepsilon > 0$ and configurations $u \neq v$,*

$$|W_{vu}| \leq \sin\Bigl(\min\Bigl(\frac{\pi}{2},\ g(w) + \frac{|w|\,\varepsilon\|H\|}{\hbar}\Bigr)\Bigr).$$

Proof. 1. Fix r. The function $f(d) = \hbar g(\mathrm{sel}(d, r))$ is nonnegative and additive on $[0, \infty)$, hence nondecreasing, and additivity gives $f(nd) = nf(d)$ for natural n, so $f(qr) = q\,f(r)$ for every rational $q \geq 0$. For $d \geq 0$ and rationals $0 \leq q \leq d/r \leq q'$, monotonicity gives $q\,f(r) \leq f(d) \leq q'\,f(r)$, and letting q and q' tend to d/r gives $f(d) = d\,f(r)/r$. Finally $f(r) = A_0$.

2. For a unit vector p and a skew-Hermitian Y with $\|Y\| = \theta \leq \pi/2$, write $e^Y = \sum_\lambda e^{\mathrm{i}\lambda} P_\lambda$ with spectral projections P_λ and $|\lambda| \leq \theta$; then the real part of $\langle p, e^Y p\rangle = \sum_\lambda e^{\mathrm{i}\lambda}\|P_\lambda p\|^2$ is at least $\cos\theta$. So the angle $d(p, q) = \arccos|\langle p, q\rangle|$ between unit vectors satisfies $d(p, U_t p) \leq \min(\pi/2, \|Y_t\|)$, phases being irrelevant. This angle obeys the triangle inequality: it is the Fubini–Study distance [102]. Hence $d(e_u, We_u) \leq \min(\pi/2, \sum_t \|Y_t\|)$. Since $e_v \perp e_u$ and $\|We_u\| = 1$, $|W_{vu}|^2 \leq 1 - |\langle e_u, We_u\rangle|^2 = \sin^2 d(e_u, We_u)$. □

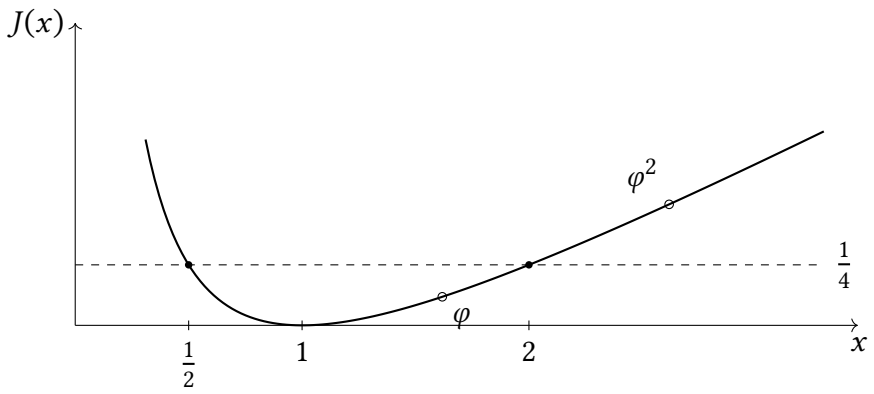

Figure 21.1. The cost $J(x) = \frac{1}{2}(x + x^{-1}) - 1$ and the quarter threshold. At zero holding, with reference action $A_0 = 2\pi\hbar$, a comparison can change a record with certainty exactly when $J(x) \geq \frac{1}{4}$, that is $x \leq \frac{1}{2}$ or $x \geq 2$ (filled dots). A golden step costs $J(\varphi) = \varphi - \frac{3}{2} \approx 0.118$ and falls short; two golden steps cost $\varphi^{-3} \approx 0.236$ and still fall short; $J(\varphi^2) = \frac{1}{2}$ (open dots).

Part 2 is a speed limit of the kind of Mandelstam and Tamm and of Margolus and Levitin [103, 104], in the form of a bound on generator norms along a word. Theorem 24.34 proves part 2 again for the registers of Section 24.9, with overlap angles in place of the Fubini–Study distance, and shows that the bound is attained.

Theorem 21.37 (A certain change needs $J \geq \frac{1}{4}$, less the drift)**.** *In classical mathematics: let a comparison controller have reference action $A_0 = 2\pi\hbar$, let H be a holding, $\varepsilon > 0$ and $x > 0$. If the paid word at ratio x makes a certain change, then*

$$J(x) \geq \frac{1}{4} - \frac{|w(x)|\,\varepsilon\|H\|}{A_0}.$$

Proof. A certain change gives $\sin(\min(\pi/2, \theta)) \geq 1$ in Lemma 21.36, so $\theta \geq \pi/2$, that is $\hbar g(w(x)) \geq \hbar\pi/2 - |w(x)|\varepsilon\|H\|$. By the drive law, $\hbar g(w(x)) = A_0 J(x)$, and $\hbar\pi/2 = A_0/4$. □

If the reference action is m cycles, $A_0 = 2\pi m\hbar$, the same proof gives the threshold $1/(4m)$.

Corollary 21.38 (The threshold, exactly)**.** *In classical mathematics, for comparison controllers with reference action $A_0 = 2\pi\hbar$, as in Theorem 21.37:*

1. *$J(x) \geq \frac{1}{4}$ exactly when $x \leq \frac{1}{2}$ or $x \geq 2$. Moreover $J(2) = \frac{1}{4}$, $J(\varphi) = \varphi - \frac{3}{2} < \frac{1}{4}$, $J(\varphi^2) = \frac{1}{2}$ and $2J(\varphi) = \varphi^{-3} < \frac{1}{4}$.*
2. *At zero holding on $n \geq 2$ channels, some controller's word at ratio x makes a certain change exactly when $x \leq \frac{1}{2}$ or $x \geq 2$. In particular 2 is the least ratio above 1 at which a certain change is possible, and it is attained.*
3. *If $\frac{1}{2} < x < 2$ and a controller's word at ratio x makes a certain change, its drift is positive.*
4. *At zero holding, the words at ratio φ of two controllers, run one after the other, never make a certain change.*

Proof. 1. $J(x) - \frac{1}{4} = (2x-1)(x-2)/(4x)$. Next $\varphi^{-1} = \varphi - 1$ gives $J(\varphi) = \varphi - \frac{3}{2}$, below $\frac{1}{4}$ since $\varphi < \frac{7}{4}$; and $\varphi^{-2} = 2 - \varphi$ gives $J(\varphi^2) = \frac{1}{2}$. Finally $2\varphi - 3 = \varphi^{-3}$, and $\varphi^{-3} = \sqrt{5} - 2 < \frac{1}{4}$ because $5 < \frac{81}{16}$.

2. The theorem at $H = 0$ gives one direction. For the other, let $J(x) \geq \frac{1}{4}$. The controller that selects a phase loop of generator cost $A_0 d/(\hbar r)$ for every pair of records obeys both laws. Change it at the records of ratio x only: select there two entangling tokens on channels $k \neq l$, followed by a phase loop of generator cost $2\pi J(x) - \pi/2 \geq 0$. The drive is unchanged, so both laws still hold. At zero holding the paid word is, up to a phase, $\exp(\frac{\pi}{2}\mathrm{i}X)$ times a phase, and $\exp(\frac{\pi}{2}\mathrm{i}X) = \mathrm{i}X$ because $X^2 = 1$; it moves every configuration to the one with channel l flipped. At $x = 2$ the phase loop has cost 0.

3. Here $J(x) < \frac{1}{4}$, so the theorem forces a positive drift.

4. The two words have generator cost $2A_0 J(\varphi)/\hbar = 2\pi\varphi^{-3} < \pi/2$, so by Lemma 21.36 every off-diagonal entry is below 1. □

Conditions and scope.

Base and premises

Classical complex matrices; the register, the paid word and the controller of Definition 21.35; the apparatus reading $d(x)/r(x) = J(x)$ of Chapter 22.

Conclusion

A certain change costs at least a quarter of the reference cycle, less the drift: $J(x) \geq \frac{1}{4} - |w|\varepsilon\|H\|/A_0$. At zero holding the threshold is exact: $x \notin (\frac{1}{2}, 2)$, attained at gain 2; a golden step, and even two, fall short.

Identification

Four identifications are not derived here: that the physical comparison words are selected by a controller from the stored records; that the reference action is one full cycle, $A_0 = 2\pi\hbar$, which needs a stop at the first return of the phase (with m cycles the threshold is $1/(4m)$), and which is exactly the statement that one comparison against the fundamental clock mode lasts eight ticks (Theorem 24.67); that the comparison and the register share one $\hbar$; and that "certain" means Born weight 1.

Not claimed

Certainty on Recognition Science's own register under its actual holding; Section 24.9 treats that question (Theorem 24.34 and Proposition 24.36).

The binary gain sits exactly at the threshold: comparing a quantity with its double is the cheapest comparison that can change a record with certainty when nothing else moves the register. The golden step, the forced ratio of the ledger, costs less than half of that, and two golden steps still fall short; inside the window $(\frac{1}{2}, 2)$, only the holding of the register can complete a certain change.

21.8 One binary distinction fixes the cost

Theorem 21.14 needs two premises: the composition law, and a calibration at the reference, the uniform expansion $C(t) = t^2/2 + o(t^2)$ with a modulus. The calibration is an analytic statement about infinitely many points near 0. Recognition Science also states one exact number: the cost of a single binary distinction, the comparison of a quantity with its double, is $J(2) = \frac{1}{4}$. Can that one number replace the calibration? This section proves that it can, as soon as the cost is monotone on $t \geq 0$, or has any curvature at all, or is bounded above on one interval, however short and wherever it sits. It also proves that the number alone does not suffice, and that the doubling slice of the law with the number does not either.

Throughout, $t = \log x$ is the logarithmic coordinate of Section 21.3, a cost is an arbitrary function G on $\mathbb{R}_\delta$, and the law is (21.2).

Definition 21.39 (The bit, a signed curvature and the branch-free cost)**.**

1. A cost G *charges the bit* when $G(\ell) = \frac{1}{4}$ for every point ℓ with $e^\ell = 2$.
2. For a point κ, G has *curvature* κ *at* 0 when for every k there is a j with
$$\left|G(t) - \frac{\kappa t^2}{2}\right| \leq \frac{t^2}{k+1} \qquad \text{whenever } |t| \leq \frac{1}{j+1}.$$
At $t = 0$ this gives $G(0) = 0$. Unlike Definition 21.10, the sign of κ is not prescribed.
3. For a point κ the *branch-free cost* is $B_\kappa(t) = \mathrm{C}(-\kappa t^2) - 1$, with $\mathrm{C}(s) = \sum_{j\geq 0}(-s)^j/(2j)!$ the series of Definition 21.6; so $B_\kappa(t) = \sum_{j\geq 1} \kappa^j t^{2j}/(2j)!$.

For $\kappa = c^2$ the series is that of $\cosh(ct) - 1$, and for $\kappa = -c^2$ it is $\cos(ct) - 1$. One formula covers both branches, and evaluating it decides nothing about the sign of κ.

Lemma 21.40 (The branch-free cost)**.** *For every point κ:*

1. *B_κ obeys the composition law, $B_\kappa(0) = 0$, and B_κ has curvature κ at 0;*
2. *a cost that obeys the law and has curvature κ at 0 equals B_κ at every point;*
3. *a function has at most one curvature at 0;*
4. *$B_{c^2}(t) = \cosh(ct) - 1$ and $B_{-c^2}(t) = \cos(ct) - 1$ for every point c.*

Every cost that obeys the law is even, and has $G(0) = 0$ or $G \equiv -1$. The proofs are free.

Proof. 1. The addition formulas of Lemma 21.7 hold for the pair of series $\mathrm{C}(bx^2)$, $x\mathrm{S}(bx^2)$ at every point b, with the same proof, since they are identities of power series in b and x. At (s, t) and $(s, -t)$ the sine terms cancel and $\mathrm{C}(b(s+t)^2) + \mathrm{C}(b(s-t)^2) = 2\mathrm{C}(bs^2)\mathrm{C}(bt^2)$; at $b = -\kappa$ this is d'Alembert's equation for $1 + B_\kappa$, which is the law for B_κ. For $|z| \leq 1$ the terms of $\mathrm{C}(z)$ of index $j \geq 2$ are at most $z^2/2^{j-1}$, so $|\mathrm{C}(z) - 1 + z/2| \leq z^2$, for either sign of z. With $z = -\kappa t^2$ and a natural number $M \geq |\kappa|$, $|B_\kappa(t) - \kappa t^2/2| \leq M^2 t^4$ for $|t| \leq 1/(M+1)$, which is at most $t^2/(k+1)$ once also $|t| \leq 1/(M(k+1)+1)$, since then $M^2 t^2 \leq 1/(k+1)$.

2. Both functions obey the duplication law (21.4), they agree to second order at 0 with a modulus, and $|B_\kappa(t)| \le (M+1)^2 t^2$ near 0; Theorem 21.13 applies.

3. If G has curvatures κ and κ', then at $t = 1/(m+1)$, for m beyond both moduli at k, $|\kappa - \kappa'|\, t^2/2 \le 2t^2/(k+1)$; so $|\kappa - \kappa'| \le 4/(k+1)$ for every k, and $\kappa = \kappa'$.

4. Compare the series term by term.

For the last sentence: the law at $(0,t)$ gives $G(t) + G(-t) = 2G(0)G(t) + 2G(0) + 2G(t)$. Theorem 21.29, part 1, gives $G(0) = 0$, and then $G(-t) = G(t)$, or $G \equiv -1$, which is even. □

Part 2 is Proposition 21.17 and Theorem 21.14 without the case split: the law and a curvature fix the cost as one formula in κ. Which of the two familiar shapes it has is a separate question, priced in Section 21.10.

One positive value fixes the sign of a solution everywhere. Write $g = 1 + G$, so that the law reads $g(s+t) + g(s-t) = 2g(s)g(t)$ and $G(0) = 0$ reads $g(0) = 1$.

Lemma 21.41 (One value fixes the sign)**.** *Let G obey the law with $G(0) = 0$, and let ℓ be a point. If $G(\ell) > 0$, then $G(t) \ge 0$ for every t; if $G(\ell) < 0$, then $G(t) \le 0$ for every t. No regularity is assumed. The proof is free.*

Proof. The law at (x,x) and at (y,y) gives $g(2x) = 2g(x)^2 - 1$, and at $(x+y, x-y)$ it gives $g(2x) + g(2y) = 2g(x+y)g(x-y)$; so $g(x+y)g(x-y) = g(x)^2 + g(y)^2 - 1$. With $A = g(x+\ell)$ and $B = g(x-\ell)$ we have $A + B = 2g(x)g(\ell)$ and $AB = g(x)^2 + g(\ell)^2 - 1$, so

$$\big(g(x+\ell) - g(\ell)g(x)\big)^2 = \Big(\frac{A-B}{2}\Big)^2 = \big(g(\ell)^2 - 1\big)\big(g(x)^2 - 1\big). \tag{21.8}$$

If $G(\ell) > 0$, then $g(\ell)^2 - 1 = G(\ell)(G(\ell)+2) > 0$, so $g(x)^2 \ge 1$ for every x, and $g(x) = 2g(x/2)^2 - 1 \ge 1$, that is $G(x) \ge 0$. If $G(\ell) < 0$, then $g(\ell/2)^2 - 1 = G(\ell)/2 < 0$, and (21.8) at $\ell/2$ gives $g(x)^2 \le 1$, so $g(x) \le 1$ and $G(x) \le 0$. □

Classically this is the dichotomy between the hyperbolic and the oscillating solutions of d'Alembert's equation, which needs no regularity [97]. On the line it needs no decision either: the hypothesis is a strict inequality at one point, and the conclusions are closed.

Theorem 21.42 (One binary distinction fixes the cost)**.** *Let G obey the composition law, have $G(0) = 0$ and charge the bit. Each of the following conditions gives $G(t) = \cosh t - 1$ for every point t:*

(a) G is nondecreasing on $t \ge 0$: $0 \le s \le t$ gives $G(s) \le G(t)$;

(b) G has some curvature κ at 0;

(c) G is bounded above on $[0,1]$: some point M has $G(t) \le M$ for $0 \le t \le 1$;

(d) G is bounded above on one interval $[a, a+d]$ with $d > 0$.

In ratio coordinates: a function F on the positive points with the multiplicative law, $F(1) = 0$ and $F(2) = \frac{1}{4}$, and with any one of the conditions read at $F(e^t)$, is J. No omniscience principle and no choice principle is used.

Proof. The bit. A logarithm ℓ of 2 exists (Proposition 21.5), and $\cosh \ell - 1 = \frac{1}{2}(2 + \frac{1}{2}) - 1 = \frac{1}{4}$. Also $\ell \geq \frac{1}{2}$, since $e^{1/2} \leq 1 + \frac{1}{2} + \frac{1}{4} < 2$ by Proposition 12.88, and the exponential reflects the order (Lemma 21.3, item 5).

The sign. Since $G(\ell) = \frac{1}{4} > 0$, Lemma 21.41 gives $G \geq 0$ everywhere.

The dyadic grid. The duplication law $G(2s) = 2G(s)^2 + 4G(s)$ has at most one nonnegative solution over each value: $2x^2 + 4x = 2y^2 + 4y$ with $x, y \geq 0$ gives $(x - y)(2(x + y) + 4) = 0$, and the second factor is at least 4. Starting from $G(\ell) = \cosh \ell - 1$, induction gives $G(\ell/2^n) = \cosh(\ell/2^n) - 1$ for every n, because both sides are nonnegative solutions over the same value. With $u = \ell/2^n$, the law at $((k + 1)u, u)$ gives the recursion

$$G((k + 2)u) = 2G((k + 1)u)G(u) + 2G((k + 1)u) + 2G(u) - G(ku),$$

which $\cosh - 1$ also obeys. So $G = \cosh - 1$ at every point $k\ell/2^n$ with natural k and n, and by evenness at their negatives.

Squeeze (a). Let $t \geq 0$, $t \leq N$, and $u = \ell/2^n$, so $u \geq 2^{-n-1}$. A finite search with cotransitivity of $<$ at $(k + 1)u < (k + 2)u$ finds j with $ju \leq t \leq (j + 2)u$; no comparison is decided exactly. Monotonicity gives $\cosh(ju) - 1 \leq G(t) \leq \cosh((j + 2)u) - 1$, and cosh is Lipschitz on $[-N - 1, N + 1]$ with a constant E (Lemma 21.3, item 4). So $|G(t) - (\cosh t - 1)| \leq 4Eu \leq 4E\ell/2^n$ for every n, and $G(t) = \cosh t - 1$. For a general t, equality of points is stable under double negation and $\neg\neg(t \geq 0 \vee t \leq 0)$ holds, so the case $t \leq 0$ follows by evenness.

Squeeze (c). Duplication with $G \geq 0$ gives $G(2s) \geq 4G(s)$, so $4^m G(s) \leq M$ whenever $0 \leq 2^m s \leq 1$. For $t \geq 0$ let $d = ju$ be a grid point with $s = t - d \in [0, 2u]$. With $g = 1 + G$, the identity (21.8) at the pair (d, s) reads

$$\big(g(t) - g(s)g(d)\big)^2 = \big(G(s)^2 + 2G(s)\big)\big(G(d)^2 + 2G(d)\big),$$

and $G(s) \leq 4M/4^n$; so $|G(t) - G(d)|$ is at most a constant, depending on M and a bound for t, times 2^{-n}. With the Lipschitz bound of cosh this gives $G(t) = \cosh t - 1$, and the sign of t is handled as in (a).

Curvature (b). Lemma 21.40 gives $G = B_\kappa$, so $B_\kappa(\ell) = \cosh \ell - 1 > 0$. The goal $\kappa = 1$ is stable, so we may split $\neg\neg(\kappa \geq 0 \vee \kappa \leq 0)$. If $\kappa \geq 0$, then $\kappa = c^2$ with $c \geq 0$ (Proposition 12.19), and $\cosh(c\ell) = \cosh \ell$. The function $\cosh - 1$ is strictly increasing on $[0, \infty)$, because $\cosh b - \cosh a = \frac{1}{2}(e^b - e^a)(1 - e^{-(a+b)})$ with both factors positive for $0 \leq a < b$; so it is one-to-one there, $c\ell = \ell$, and $c = 1$ since $\ell > 0$. If $\kappa \leq 0$, then $\kappa = -c^2$ and $B_\kappa(\ell) = \cos(c\ell) - 1 \leq 0$, which is impossible. So $\kappa = 1$ and $G = B_1 = \cosh - 1$.

A local bound (d). Put $c = a + d/2$. For $0 \leq s \leq d/2$ the law at (c, s) gives $2G(s) \leq 2G(s)(G(c) + 1) = G(c + s) + G(c - s) - 2G(c) \leq 2M$, using $G \geq 0$. So $G \leq M$ on $[0, d/2]$, and duplication bounds G on $[0, 2^k d/2]$ for every k. Taking k with $2^k d/2 \geq 1$ gives (c).

Ratio form. Proposition 21.46 below turns the multiplicative law for F into the law for $G(t) = F(e^t)$, and $F(2) = \frac{1}{4}$ is the bit, since every ℓ with $e^\ell = 2$ has $G(\ell) = F(2)$. □

Conditions and scope.

Base and premises
The line $\mathbb{R}_\delta$; a cost that is an arbitrary function with the composition law, $G(0) = 0$, the value $\frac{1}{4}$ at $\log 2$, and one of four mild conditions: monotone on $t \geq 0$, some curvature, a bound on $[0, 1]$, a bound on one interval.

Conclusion
$G = \cosh - 1$, that is $F = J$, with no omniscience principle and no choice principle. No continuity is assumed in (a), (c) or (d), and no value of the curvature in (b).

Identification
That the cost of one binary distinction is $J(2) = \frac{1}{4}$ is Recognition Science's calibration by one bit; the theorem derives the cost from it.

Not claimed
That the bit alone suffices: it does not (Proposition 21.43).

The four conditions cannot all be dropped, and the full law cannot be cut to its doubling slice. In classical mathematics $\mathbb{R}_\delta$ is a complete ordered field, so it has a reading onto the classical line (a bijective reading, which is unique); a classical function on the line is carried to $\mathbb{R}_\delta$ through it, and every premise and conclusion below is read through that bijection.

Proposition 21.43 (What one bit cannot do)**.** *In classical mathematics:*

1. *There is a function G on $\mathbb{R}_\delta$ that obeys the composition law, has $G(0) = 0$ and charges the bit, and differs from* $\cosh - 1$ *at some point.*

2. *There is a function G on $\mathbb{R}_\delta$ that obeys the doubling slice $G(2t) + G(0) = 2G(t)^2 + 4G(t)$ at every t, has $G(0) = 0$, is nondecreasing on $t \geq 0$ and charges the bit, and differs from* $\cosh - 1$ *at some point.*

3. *There is a function G on $\mathbb{R}_\delta$ that obeys the composition law, has $G(0) = 0$ and $|G| \leq 2$ everywhere, and has no curvature at* 0*. Hence the assertion "every cost that obeys the law, vanishes at* 0 *and is bounded on* $[-1, 1]$ *has a curvature" is false, and so is the assertion that for such costs naming the branch* $\cosh(ct) - 1$ *or* $\cos(ct) - 1$ *costs exactly LLPO.*

Proof. Work on the classical line and let $L = \log 2$. Let h be an additive map from the line to the rationals that is bounded on no neighbourhood of 0; it is built from a basis of the line over the rationals [202].

1. Put $a(x) = x + h(x) - (h(L)/L)x$. It is additive, $a(L) = L$, and it is unbounded near 0. The cost $G = \cosh \circ a - 1$ obeys the law, because $\cosh(u + v) + \cosh(u - v) = 2 \cosh u \cosh v$ and $a(s \pm t) = a(s) \pm a(t)$; it has $G(0) = 0$ and $G(L) = \frac{1}{4}$. At a point s with $|s| < 1$ and $|a(s)| > 2$, $G(s) > \cosh 2 - 1 > \cosh s - 1$.

2. Let $f(x) = (x + \lfloor x \rfloor)/2$, nondecreasing with $f(x + 1) = f(x) + 1$, $f(0) = 0$ and $f(\frac{1}{2}) = \frac{1}{4}$. For $t \neq 0$ put $x(t) = \log(|t|/L)/L$, so that $|t| = L\, 2^{x(t)}$ and $x(2t) = x(t) + 1$, and let $\psi(t) = L\, e^{Lf(x(t))}$, $\psi(0) = 0$. Then $\psi(2t) = 2\psi(t)$, ψ is nondecreasing on $t \geq 0$ and $\psi(L) = L$. The cost

$G = \cosh \circ \psi - 1$ obeys the slice, since $\cosh 2u = 2\cosh^2 u - 1$, is nondecreasing on $t \geq 0$ and has $G(L) = \frac{1}{4}$. At $t_0 = Le^{L/2}$, where $x(t_0) = \frac{1}{2}$, $\psi(t_0) = Le^{L/4} < t_0$, so $G(t_0) < \cosh t_0 - 1$.

3. Put $w = \cos \circ h - 1$. It obeys the law, $w(0) = 0$ and $|w| \leq 2$. Suppose it had a curvature κ; then $|w(s)| \leq (|\kappa|/2 + 1)s^2$ for small $|s|$. Take s_0 that small with $|h(s_0)| > 10$; some rational q with $0 < q < 1$ puts $qh(s_0) = h(qs_0)$ in $[\pi/2, 3\pi/2]$ up to sign, so $w(qs_0) \leq -1$, while $(|\kappa|/2 + 1)(qs_0)^2 < 1$. Both named branches have a curvature, by Lemma 21.40, so w is neither; and LLPO holds classically, so the second assertion would make w a branch. □

The bit fixes the cost only along the dyadic grid of $\log 2$ by itself; between the grid points the cost can be reshaped, octave by octave in part 2 and wildly in part 1. A mild regularity condition, of any of the four kinds of Theorem 21.42, closes the gaps. The calibration of Theorem 21.14 is one such condition, and the doubling slice with the calibration already gives J (Proposition 21.34, part 2).

The bit also selects the exponent within the families of Proposition 21.16, and on the line the selection is free.

Proposition 21.44 (The bit and the unit curvature select the exponent)**.** *Let $c > 0$ and $e^\ell = 2$. Then $\cosh(c\ell) - 1 = \frac{1}{4}$ exactly when $c = 1$, and $t \mapsto \cosh(ct) - 1$ is calibrated exactly when $c = 1$. Moreover, for every point t, $\cosh t - 1 = \frac{1}{4}$ exactly when $t = \ell$ or $t = -\ell$, and the disjunction is decided. The proofs are free.*

Proof. $\ell > 0$ and $\cosh - 1$ is one-to-one on $[0, \infty)$, as in the proof of Theorem 21.42(b), so $\cosh(c\ell) = \cosh \ell$ gives $c\ell = \ell$ and $c = 1$. The function $\cosh(ct) - 1$ has curvature c^2, and curvature is unique (Lemma 21.40), so it is calibrated exactly when $c^2 = 1$, that is $c = 1$. Finally $\cosh |t| = \cosh t = \cosh \ell$ gives $|t| = \ell$ (the sign of t enters only inside a negation, and equality is stable), so $|t| > 0$, t is apart from 0, and the sign of t is decided. □

21.9 Bounds force the curvature

The four conditions of Theorem 21.42 are regularity conditions, and they meet the bit. Without the bit, which bounds already force a curvature, and with it, by Lemma 21.40, the closed form B_κ? A bound of quadratic size near 0 does; so does any bound below $\frac{3}{2}$ near 0; and a sign with a bound does. The wild cosine of Proposition 21.43, part 3, bounded by 2, has no curvature.

Theorem 21.45 (Bounds near the reference give the curvature)**.** *Let G obey the composition law with $G(0) = 0$.*

1. *If $|G(t)| \leq Ct^2$ for $|t| \leq 1$, for a point C, then the dyadic estimates $b_m = 4^m G(2^{-m})$ satisfy $0 \leq b_m - b_{m+d} \leq C^2\, 4^{-m}$ for all m, d, they converge, and G has curvature $\kappa = 2 \lim_m b_m$ at 0.*
2. *If $|G(t)| \leq c$ for $|t| \leq 1/(j+1)$, for a natural number j and a point $c < \frac{3}{2}$, then G has a curvature at 0. In particular this holds when G is continuous at 0 with a modulus: for every k some j has $|G(t)| \leq 1/(k+1)$ for $|t| \leq 1/(j+1)$.*
3. *If $G \geq 0$ on $[-1, 1]$ and G is bounded on $[-1, 1]$, then there is a point $c \geq 0$ with $G(t) = \cosh(ct) - 1$ for $|t| \leq 1$, and G has curvature c^2 at 0.*

In cases 1 and 2, $G = B_\kappa$ at every point. No omniscience principle and no choice principle is used.

Proof. 1. With $u = 2^{-m-1}$ duplication gives $b_m - b_{m+1} = 2 \cdot 4^m G(u)^2 \geq 0$, and $|G(u)| \leq Cu^2$ bounds the step by $C^2\, 4^{-m}/8$; summing, $0 \leq b_m - b_{m+d} \leq C^2\, 4^{-m}$. The limit of a sequence of points exists without choice when representatives of the terms are computed from finitely many given ones, and here they are. Put $H = 1 + G$; if $C \leq 1$, then $H(v) \geq 0$ on $[-1, 1]$, and duplication $H(2v) = 2H(v)^2 - 1$ gives $H(v) = \sqrt{(1 + H(2v))/2}$, so $H(2^{-m})$ is the mth half-angle iterate of $H(1)$, and a regular sequence for b_m is computed from one for $H(1)$ by the operations of Proposition 12.19 and the square root. A general C is reduced to $C \leq 1$ by the rescaled cost $t \mapsto G(t/2^N)$, which obeys the law, with $N \geq C$; 4^N times its curvature is a curvature of G.

Let L be the limit. The rate passes to the limit, $|b_i - L| \leq C^2\, 4^{-i}$. At a dyadic point $q = n/2^i \leq 1$, the law along multiples of 2^{-i} and $n^2 G(2^{-i}) = q^2 b_i$ give $|G(q) - Lq^2| \leq C^2 q^4 + C^2 q^2\, 4^{-i}$. For $0 \leq t \leq 1$ choose a dyadic q with $q \leq t \leq q + 2^{1-i}$ by the search of Theorem 21.42; the law gives a Lipschitz bound for G on $[0, 1]$, so $|G(t) - Lt^2| \leq C^2 t^4 + K 2^{-i}$ for every i, and $|G(t) - Lt^2| \leq C^2 t^4$. Evenness extends this to $|t| \leq 1$. Given k, the right side is at most $t^2/(k+1)$ once $C^2 t^2 \leq 1/(k+1)$: the curvature is $2L$.

2. Rescaling as in part 1 makes the bound hold on $[-1, 1]$. First let $c = \frac{1}{2}$. With $g_m = |G(t/2^m)|$ for $|t| \leq 1$, duplication $G(2v) = G(v)(4 + 2G(v))$ and $|4 + 2G(v)| \geq 3$ give $g_{m+1} \leq g_m/2$, and by induction $g_m \leq 2^{-m-1}$ and $4^m g_m \leq 1 - 2^{-m-1}$. So $|G(u)| \leq 4^{-m}$ whenever $|u| \leq 2^{-m}$. A search over the scales 2^{-i}, using cotransitivity, finds for each k either an i with $2^{-i-2} \leq |u| \leq 2^{-i}$, where $|G(u)| \leq 4^{-i} \leq 16u^2$, or $|u| \leq 2^{-k}$, where $|G(u)| \leq 4^{-k}$; as k is arbitrary and the bound is closed, $|G(u)| \leq 16u^2$ on $[-1, 1]$, and part 1 applies. For $c < \frac{3}{2}$ one halving brings the bound to $\frac{1}{2}$. Put $y = G(t)$ and $z = G(2t) = 2y^2 + 4y$, both of size at most c. If $y > \frac{1}{2}$, then $z - \frac{5}{2} = 2(y - \frac{1}{2})(y + \frac{5}{2}) > 0$, so $|z| > \frac{5}{2} > c$; if $y < -\frac{1}{2}$, then $y > -\frac{3}{2}$ and $z + \frac{3}{2} = 2(y + \frac{1}{2})(y + \frac{3}{2}) < 0$, so $|z| > \frac{3}{2} > c$. Both are impossible, so $|y| \leq \frac{1}{2}$. Continuity at 0 with a modulus gives the bound $\frac{1}{2}$ near 0 at once. Finally Lemma 21.40 gives $G = B_\kappa$.

3. Duplication spreads $G \geq 0$ from $[-1, 1]$ to the line. Put $y = 1 + G(1) \geq 1$ and $r = \sqrt{y^2 - 1}$, and let $c = \log(y + r)$; then $e^{-c} = y - r$, so $\cosh c - 1 = G(1)$ and $c \geq 0$. The rate c is computed, not chosen. As in Theorem 21.42, halving keeps the unique nonnegative root of $2x^2 + 4x$, and the law is a recursion along multiples, so G and $\cosh(c\,\cdot) - 1$ agree at every $k/2^n$; the bounded squeeze of Theorem 21.42(c), on the grid of 1, gives $G(t) = \cosh(ct) - 1$ on $[0, 1]$, and evenness gives $[-1, 0]$. Its curvature is c^2. □

The bound $\frac{3}{2}$ in part 2 is where the argument stops: $1 + G = -\frac{1}{2}$, a third of a turn of the oscillating branch, is a fixed point of the doubling, $2(-\frac{1}{2})^2 - 1 = -\frac{1}{2}$. Whether a bound c with $\frac{3}{2} \leq c < 2$ near 0 gives a curvature on $\mathbb{R}_\delta$ with no omniscience principle is open; at $c = 2$ it fails, since the wild cosine is bounded by 2. Part 3 needs its sign premise: the wild cosine is never positive and has no curvature.

21.10 The prices of the branches

Lemma 21.40 names the solution with curvature κ without deciding anything: it is B_κ. The classical statement names it differently, as $\cosh(ct) - 1$ or as $\cos(ct) - 1$, and that naming is

a decision about the sign of κ. This section prices the decisions a reader of the cost asks for. The forcing theorems are free; the prices sit in the decisions, as in Chapter 22.

Proposition 21.46 (The ratio law is the logarithmic law)**.** *For every function F on $\mathbb{R}_{\delta}$: F obeys the multiplicative law $F(xy) + F(xz) = 2F(x)F(y) + 2F(x) + 2F(y)$ for all positive x, y with $yz = 1$ exactly when $t \mapsto F(e^t)$ obeys the composition law. The proof is free.*

Proof. Forward: $x = e^s$, $y = e^t$ give $xy = e^{s+t}$, and the inverse of a positive point is unique, so $xz = e^{s-t}$. Backward: put $s = \log x$ and $t = \log y$ (Proposition 21.5). □

So every result of this chapter stated in logarithmic coordinates holds in the ratio coordinates in which Recognition Science states its law, with no calibration and no price.

Theorem 21.47 (The prices of naming the branch)**.** *Each of the following assertions is equivalent to the principle named, with no choice principle in either direction.*

1. Naming the branch. *Every cost G that obeys the law, has $G(0) = 0$ and some curvature κ at 0 is $\cosh(ct) - 1$ for some point c, or $\cos(ct) - 1$ for some point c: LLPO.*
2. The flat decision. *Every such cost is identically 0 or not: WLPO.*
3. The three branches. *Every such cost is $\cosh(ct) - 1$ with $c > 0$, or identically 0, or $\cos(ct) - 1$ with $c > 0$: LPO.*
4. The sign decision with a curvature. *Every such cost is ≥ 0 everywhere or ≤ 0 everywhere: LLPO. Without the curvature premise, the sign decision for every cost that obeys the law with $G(0) = 0$ implies LLPO.*
5. Comparing two costs. *For all points s, t, $\cosh s \leq \cosh t$ or $\cosh t \leq \cosh s$: LLPO.*
6. The costly-join decision. *For every positive point x, $J(x) > 0$ or $J(x) = 0$: LPO.*

Proof. LLPO is the dichotomy $r \geq 0 \vee r \leq 0$ for every point, WLPO the decision of $r = 0$, and LPO the trichotomy (Corollary 12.18).

1. Given LLPO, decide $\kappa \geq 0$ or $\kappa \leq 0$. In the first case $\kappa = c^2$ and $G = B_{c^2} = \cosh(ct) - 1$; in the second $G = \cos(ct) - 1$ (Lemma 21.40). Conversely, for a point r apply the assertion to B_r, which has curvature r: a hyperbolic branch has curvature $c^2 \geq 0$, an oscillating branch $-c^2 \leq 0$, and the curvature is unique; so $r \geq 0$ or $r \leq 0$.

2. The flat cost has curvature 0, so $B_r \equiv 0$ exactly when $r = 0$; this gives WLPO from the assertion, and WLPO decides $\kappa = 0$.

3. Given LPO, decide $\kappa > 0$, $\kappa = 0$ or $\kappa < 0$; a positive point has a positive square root, so the three cases give the three branches. Conversely the branch of B_r decides $r > 0$, $r = 0$ or $r < 0$, because the three curvatures c^2 with $c > 0$, 0, and $-c^2$ with $c > 0$ are positive, zero and negative.

4. A cost ≥ 0 everywhere has curvature ≥ 0: if $\kappa < 0$, then $G(t) \leq \kappa t^2/4 < 0$ for small $t \neq 0$. Likewise ≤ 0 everywhere gives $\kappa \leq 0$. So the sign decision for B_r gives $r \geq 0$ or $r \leq 0$, which is LLPO, and this uses only costs B_r, which obey the law with $B_r(0) = 0$; that proves the last

sentence. Conversely LLPO decides the sign of κ, and $B_\kappa \geq 0$ when $\kappa \geq 0$ and $B_\kappa \leq 0$ when $\kappa \leq 0$.

5. LLPO orders the line, which gives the dichotomy. Conversely let a be a point. If $\cosh(a+1) \leq \cosh(a-1)$, then $a \leq 0$: for $a > 0$, $|a-1| < a+1$, and cosh is even and strictly increasing on $[0, \infty)$. If $\cosh(a-1) \leq \cosh(a+1)$, then $a \geq 0$ by the same argument. So every point has a weak sign: LLPO.

6. $J(x) = (x-1)^2/(2x)$ with $2x > 0$, so $J(x) > 0$ exactly when $x - 1$ is apart from 0, and $J(x) = 0$ exactly when $x = 1$. For a point r take $x = 1 + |r|$: the assertion gives $|r| \# 0$ or $r = 0$, that is $r > 0$, $r < 0$ or $r = 0$, the trichotomy, which is LPO. Conversely LPO decides $x - 1 > 0$, $x - 1 = 0$ or $x - 1 < 0$. □

Conditions and scope.

Base and premises
The line; costs given as functions with the law and, where stated, a curvature at 0 given as a point.

Conclusion
Naming the branch, deciding the sign of a cost that has a curvature, or ordering two costs: exactly LLPO. Deciding flatness: exactly WLPO. Deciding the three branches or whether a ratio costs anything: exactly LPO.

Not claimed
The converse of the last sentence of part 4, a sign decision for costs with no curvature premise, which is open. Recognition Science's own calibration gives the curvature as the number 1; for it every decision above is free.

21.11 Exact values of the cost

The cost J has a small set of exact properties that the later chapters and the ledger of Section 21.5 use. On the line they are all free.

Proposition 21.48 (The shape of the cost)**.** *For all points s, t, every natural number k, and all points $t_1, \dots, t_n$:*

1. Averaging never costs more: $\cosh \frac{s+t}{2} - 1 \leq \frac{1}{2}\big((\cosh s - 1) + (\cosh t - 1)\big)$.
2. Closed loops: *if $t_1 + \cdots + t_n = 0$, then $\sum_i (\cosh t_i - 1) \geq 0$, and the sum is 0 only when every $t_i = 0$.*
3. Quadratic bounds: $\frac{t^2}{2} \leq \cosh t - 1 \leq \frac{t^2}{2} \cosh t$.
4. Repeated comparisons: $\cosh(kt) = T_k(\cosh t)$, *where $T_0 = 1$, $T_1(y) = y$ and $T_{n+2}(y) = 2yT_{n+1}(y) - T_n(y)$ are Chebyshev's polynomials.*

The proofs are free.

Proof. 1. The law at $a = (s+t)/2$, $b = (s-t)/2$ gives $G(s) + G(t) = 2G(a)G(b) + 2G(a) + 2G(b)$ for $G = \cosh - 1$, so $\frac{1}{2}(G(s) + G(t)) - G(a) = G(a)G(b) + G(b) \geq 0$.

2. Each term is nonnegative and at most the sum. A term $\cosh t - 1 = 0$ forces $t = 0$: $\cosh - 1$ is even and one-to-one on $[0, \infty)$, and equality is stable, so the sign of t need not be decided. The hypothesis $t_1 + \cdots + t_n = 0$ is not used: both conclusions hold for all points $t_1, \ldots, t_n$, and the closed loop is the case the ledger meets.

3. Both bounds come from the series: $\cosh t - 1 = \sum_{j \geq 1} t^{2j}/(2j)!$, whose first term is $t^2/2$, and $t^{2j}/(2j)! \leq \frac{t^2}{2} \cdot t^{2j-2}/(2j-2)!$.

4. The law at $((n+1)t, t)$ is $\cosh((n+2)t) = 2\cosh t \cosh((n+1)t) - \cosh(nt)$, the Chebyshev recursion, and two-step induction finishes. □

Part 4 says that a comparison repeated k times costs a fixed polynomial of the cost of one comparison, $1 + J(x^k) = T_k(1 + J(x))$. Part 2 says that a closed loop of comparisons costs nothing only when every step is trivial.

Proposition 21.49 (Rational costs and the inverse of the cost)**.**

1. *For natural numbers $p, q \geq 1$ and a point ℓ with $e^\ell q = p$, $2pq(\cosh \ell - 1) = (p-q)^2$: the cost of the rational ratio p/q is the ratio $(p-q)^2/(2pq)$.*
2. *For every point $y \geq 0$ there is exactly one point $t \geq 0$ with $\cosh t - 1 = y$, and $x = e^t$ solves $x^2 + 1 = 2(1+y)x$.*

The proofs are free.

Proof. 1. $J(p/q) = \frac{1}{2}(p/q + q/p) - 1 = (p-q)^2/(2pq)$, with $e^{-\ell} = q/p$.

2. Put $r = \sqrt{(1+y)^2 - 1}$ and $t = \log(1 + y + r)$; then $e^{-t} = 1 + y - r$, so $\cosh t = 1 + y$, and $t \geq 0$ because $1 + y + r \geq 1$. Uniqueness is injectivity of $\cosh - 1$ on $[0, \infty)$, and $e^{2t} + 1 = 2\cosh t\, e^t$. □

The golden ratio enters through the ledger of Section 21.5. Its rungs have exact costs, and every additive ladder approaches it at a rate fixed by φ alone.

Theorem 21.50 (Golden ladders)**.** *Let $F(n)$ be the Fibonacci numbers and ℓ a point with $e^\ell = \varphi$.*

1. Even rungs. $2J(\varphi^{2n}) + 2 = F(2n-1) + F(2n+1)$ *for $n \geq 1$, a Lucas number.*
2. Odd rungs. $2J(\varphi^{2n+1}) + 2 = \sqrt{5}\, F(2n+1)$ *for $n \geq 0$.*
3. The attractor. *For all points a, b, the ladder $s_0 = a$, $s_1 = b$, $s_{n+2} = s_{n+1} + s_n$ satisfies $|s_{n+1} - \varphi s_n| = |b - \varphi a|\,(\varphi - 1)^n$.*
4. Record growth. *The binary words of length n with no two adjacent ones number $F(n+2)$, and $|F(n+1)/F(n) - \varphi| \leq 1/F(n)^2$ for $n \geq 1$.*
5. The record ladder. *The levels $s_n = F(n+2)$ are positive and have a costly initial join: $s_2 = s_0 + s_1$ with join ratio $s_1/s_0 = 2$, of cost $J(2) = \frac{1}{4} > 0$.*

Here $J(\varphi^m)$ means $\cosh(m\ell) - 1$. The proofs are free.

Proof. Every root x of $x^2 = x + 1$ has $x^{m+1} = F(m+1)x + F(m)$, by induction. Apply this to φ and $\psi = 1 - \varphi$, with $e^{-\ell} = \varphi^{-1} = \varphi - 1 = -\psi$.

1. $2J(\varphi^{2n}) + 2 = \varphi^{2n} + \psi^{2n} = F(2n)(\varphi + \psi) + 2F(2n-1) = F(2n) + 2F(2n-1) = F(2n-1) + F(2n+1)$.

2. For odd powers $(-\psi)^{2n+1} = -\psi^{2n+1}$, so $2J(\varphi^{2n+1}) + 2 = \varphi^{2n+1} - \psi^{2n+1} = F(2n+1)(\varphi - \psi) = \sqrt{5}\, F(2n+1)$, using $\varphi - \psi = 2\varphi - 1 = \sqrt{5}$.

3. The error $e_n = s_{n+1} - \varphi s_n$ has $e_{n+1} = s_{n+1} + s_n - \varphi s_{n+1} = (1 - \varphi)e_n$, because $\varphi(1 - \varphi) = -1$; and $|1 - \varphi| = \varphi - 1$.

4. Let c_n count the admissible words of length n and d_n those that stay admissible after a leading one. A leading zero changes nothing, and a leading one forces the next letter to be zero, so $c_{n+1} = c_n + d_n$ and $d_{n+1} = c_n$; with $c_0 = 1$, $c_1 = 2$ this is $c_n = F(n+2)$. For the ratio, part 3 at $(a, b) = (0, 1)$ gives $|F(n+1) - \varphi F(n)| = r^n$ with $r = \varphi - 1$, and $r^n F(n) \le 1$ by two-step induction, since $r^2 + r = 1$: $r^{n+2}F(n+2) = r^2(r^n F(n)) + r(r^{n+1}F(n+1)) \le 1$. Divide by $F(n)$.

5. $F(4) = 3 = 1 + 2 = F(2) + F(3)$, the parts 1 and 2 are distinct, and $J(2) = \frac{1}{4}$. □

Part 4 counts the records of a two-state register in which no two adjacent cells are both set, and their number grows by the golden ratio: the golden ratio is read off records by counting, with an explicit error. Part 5 is the premise of the costly join (Section 22.6) met by the record count itself, with apart parts, so it costs nothing. Part 3 says that every additive ladder, whatever its first two levels, is drawn to the golden ratio geometrically, with ratio $\varphi - 1 \approx 0.618$ per rung.

21.12 The cost on ratio records

Before the line, a cost can be stated on ratio records themselves (Chapter 4): a map F from records (u, d), with u a signed count and d a positive count, to records. A record is a display; the records $(3, 3)$ and $(1, 1)$ display the same value. Recognition Science states five premises for such a cost. The questions are which of them follow from the others, and which further premises force $F = J$ on values.

Definition 21.51 (The five premises on records)**.** Write $q \equiv q'$ when two records have the same value, $\bar{q}$ for the reduced record of q, 1 for the record $(1, 1)$, 0 for $(0, 1)$, and q^{-1} for the record that inverts q (with value 0 at value 0). A cost F on records has:

(F1) *value-invariance* when $F(q) \equiv F(\bar{q})$ for every record q;

(F2) *the law* when $F(xy) + F(x/y) \equiv 2F(x)F(y) + 2F(x) + 2F(y)$ for all records x, y of nonzero value;

(F3) *reciprocity* when $F(q) \equiv F(q^{-1})$ for every q;

(F4) *literal unit-zero* when $F(1) = 0$ as records;

(F5) *the calibration at two* when $F(2) \equiv J(2) = \frac{1}{4}$.

Further, F is *bounded near balance* when some ratio M bounds the value of $F(q)$ for every q with value in $[\frac{1}{2}, 2]$; *positive* when $F(q)$ has nonnegative value whenever q has positive value; and has the *signed unit* when $F(-1) \equiv J(-1) = -2$.

Theorem 21.52 (The ledger of the five premises)**.** *Proved over the classical rationals:*

1. *(F1), (F2) and (F5) give $F(1) \equiv 0$ and $F(q) \equiv F(q^{-1})$ for every record q of nonzero value, and with (F1) at value 0 they give (F3); (F4) is not needed. So reciprocity is redundant, and so is the value of unit-zero.*
2. *Each of (F1), (F2), (F4) and (F5) is independent of the other four premises: for each there is a cost with the other four and not it.*
3. *(F1)–(F5) with a bound near balance do not give $F(q) \equiv J(q)$ at every nonzero value.*
4. *(F1)–(F5) with a bound near balance, positivity and the signed unit give $F(q) \equiv J(q)$ at every record of nonzero value.*
5. *None of the three premises added in part 4 can be dropped: for each there is a cost with (F1)–(F5) and the other two, not equal to J.*

Proof. 1. By (F1) the cost depends only on values, since records of equal value have the same reduced record. The law at $(2, 1)$ reads $F(2) + F(2) \equiv 2F(2)F(1) + 2F(2) + 2F(1)$; with $F(2) \equiv \frac{1}{4}$ this is $\frac{5}{2}F(1) \equiv 0$. The law at $(1, q)$ then reads $F(q) + F(q^{-1}) \equiv 2F(q)$ for $q \not\equiv 0$; at value 0 the inverse record has value 0, and (F1) suffices.

2. In parts 2 and 3 the formulas are written for records of nonzero value. At the records of value 0 each cost below is constant, given by its formula with 0^{-1} read as 0; the law asks nothing there, and a constant meets (F1) and (F3).

(F1): for a record with numerator value N and denominator d put $c_1 = q \cdot 9^{v_3(d)}$ and $c_2 = q^{-1} \cdot 9^{v_3(|N|)}$, with v_3 the exponent of 3, and let F return the literal 0 at the literal unit and a record of $(c_1 + c_2)/2 - 1$ elsewhere. Multiplying records multiplies c_1 and c_2, and inversion swaps them, so $G = F + 1$ solves $G(xy) + G(x/y) = 2G(x)G(y)$; $F(2) \equiv \frac{1}{4}$; but $F(3/3) \equiv 8$ while $F(1/1) = 0$. *(F2):* J with its values at 3 and $\frac{1}{3}$ set to 0 fails the law at $(3, 3)$, where $J(9) = \frac{32}{9}$. *(F4):* J returning a different record of value 0 at the unit. *(F5):* the zero cost.

3. Let $\chi(v) = v(-1)^{v_3(v)}$, a multiplicative map on nonzero rationals with $\chi(1/v) = 1/\chi(v)$ and $\chi(2) = 2$. The cost $F(v) = \frac{1}{2}(\chi(v) + \chi(v)^{-1}) - 1$ meets (F1)–(F5) and $F \leq 1$ on $[\frac{1}{2}, 2]$, but $F(3) = -\frac{8}{3}$ while $J(3) = \frac{2}{3}$.

4. By part 1, $G = 1 + F$ is a function of values on the group of nonzero rationals with $G(1) = 1$, and the law is d'Alembert's equation $G(xy) + G(x/y) = 2G(x)G(y)$ there. On an abelian group every such solution is $G = \frac{1}{2}(\chi + \chi^{-1})$ for a multiplicative map χ into the nonzero complex numbers [203]. For $q > 0$ positivity gives $G(q) \geq 1$, so $\chi(q)$ is a root of $x^2 - 2G(q)x + 1$, which has two positive roots; so $\chi(q) > 0$. The calibration gives $\chi(2) \in \{2, \frac{1}{2}\}$, and $1/\chi$ gives the same G, so we may take $\chi(2) = 2$. For $q \geq 1$ and each natural number b choose a with $2^a \leq q^b < 2^{a+1}$; the ratio $r = q^b/2^a$ lies in $[1, 2)$, so $J(\chi(r)) = F(r) \leq M$, and $\chi(r) = \chi(q)^b/2^a$ lies in a fixed interval $[1/C, C]$ with C computed from M. Hence $(\chi(q)/q)^b$ lies in $[1/(2C), 2C]$

for every b, and Bernoulli's inequality forces $\chi(q) = q$. For $0 < q < 1$ use $\chi(1/q) = 1/\chi(q)$. Finally $\chi(-1)^2 = \chi(1) = 1$, and the signed unit $G(-1) = -1$ gives $\chi(-1) = -1$, so $\chi(q) = q$ for $q < 0$ too, and $F = J$ on nonzero values.

5. *The bound:* $\chi_3(v) = v \cdot 9^{-v_3(v)}$ is positive on positive values and has $\chi_3(-1) = -1$; its cost exceeds $9^b/2 - 1$ at $3^b/(3^b + 1) \in [\frac{1}{2}, 1]$, and $F(6) = J(\frac{2}{3}) = \frac{1}{12}$ while $J(6) = \frac{25}{12}$. *Positivity:* the cost of part 3. *The signed unit:* $F = J \circ |\cdot|$, with $F(-1) = 0$. □

Conditions and scope.

Base and premises

Ratio records and their values, read over the classical rationals; the five premises of Definition 21.51.

Conclusion

Reciprocity and the value of unit-zero follow from value-invariance, the law and the calibration at two. Value-invariance, the law, the literal unit-zero and the calibration at two are each independent: in particular "a cost reads only the value of a ratio" is a premise in its own right, because the law and the calibration allow a cost that depends on how a ratio is written. On values, a bound near balance, positivity and the signed unit together force J, and each is needed.

Not claimed

A price on $\mathbb{R}_\delta$. On the line, Theorems 21.14 and 21.42 force J from the law with the calibration (Theorem 21.14), or with the bit and any one of the four conditions of Theorem 21.42, for free.

Physically read, a cost that obeys the composition law and charges a binary distinction $\frac{1}{4}$ already charges a ratio the same as its inverse, and charges the unit record $(1, 1)$ nothing. The law and the calibration alone allow a cost that charges the record $(3, 3)$, of the same value, 8 (Theorem 21.52, part 2). What such a cost does not do on its own is ignore how a ratio is written: that is the separate premise that a cost reads values.

Questions to work through

1. The cost $F(x) = \frac{1}{2}(x - 1)^2$ is calibrated at 1. Show that it violates the multiplicative law, and find which hypothesis of Theorem 21.13 fails for $C(t) = \frac{1}{2}(e^t - 1)^2$ when it is compared with $g = \cosh - 1$. (Theorem 21.14.)

2. Let $\lambda = \frac{2}{3}$, so that $\kappa = 3$ in Proposition 21.16. Compute both sides of the composition law for $\lambda(\cosh - 1)$ at $s = t = 1$ and show directly that they differ.

3. Let $\alpha = \arctan\frac{1}{5}$ and $\beta = \arctan\frac{1}{239}$. Using part 1 of Theorem 21.8 and the addition formulas, show that $\cos(4\alpha - \beta) = \sin(4\alpha - \beta)$, and conclude Machin's identity $\pi_\delta = 4(4\alpha - \beta)$. (Theorem 21.8.)

4. A finitely supported law with weights summing to 1 has a cost C that obeys the composition law and satisfies $C(2) = J(4) = \frac{9}{8}$. Find the law. (Theorem 21.22.)

5. Write out the first thirteen letters of the recognition history. Check the bound $-2/\varphi < N\varphi^{-3} - b_N < 2/\varphi^2$ for $N \le 13$, and the rule of part (e) for each of the thirteen postings. (Theorem 21.26.)

6. For a point c, show without Theorem 21.14 that the coded cost of the constant function c obeys the composition law at $s = t = 2$ and at $s = t = 3$ only when $c = 0$. (Theorem 21.29, part 2.)

Chapter 22

The forcing chain of Recognition Science, priced

Recognition Science derives physical structure as a chain of forced steps. Records of repeated distinction give arithmetic. Comparing two records gives the cost J of Chapter 21. A costly join of levels forces the golden ratio. A kept, linked pair forces three dimensions and eight binary states, and from there the chain reaches the constants of nature. Its central steps are uniqueness results: given their premises, nothing else is possible. This chapter asks a sharper question of every step. On the line $\mathbb{R}_\delta$, where every number is a construction from ratios, what does the step cost in logical strength? Does it hold outright, or does it need an omniscience principle, and which one?

Here is a small case. For $x > 0$ the cost of the ratio x is

$$J(x) = \frac{1}{2}\Big(x + \frac{1}{x}\Big) - 1 = \frac{(x-1)^2}{2x}.$$

One step of the chain, row T2.8 of Table 22.1, asserts that a ratio other than 1 costs something. If x is apart from 1, so that $|x - 1|$ exceeds some positive ratio, then $(x-1)^2 > 0$ and $2x > 0$, and $J(x) > 0$ with no principle at all. But "x is other than 1" can also be read as $x \neq 1$, the bare refutation of $x = 1$, and that reading is weaker. Take a binary sequence α and the point j_α of its positive jump presentation (Chapter 12), and put $x = 1 + j_\alpha$. Then $x \neq 1$ says only that α is not identically 0, while $J(x) > 0$ says that j_α is apart from 0, which happens exactly when α has a 1 at some index. So the uniform statement "every $x \neq 1$ has $J(x) > 0$" turns every refutation of "α is all zero" into an index where α is 1. That is Markov's principle, and Theorem 22.16 proves the converse: the statement is equivalent to it. The fact itself is free; the whole price lies in reading "other than 1" as a negation.

The same pattern runs through the whole chain, and it gives the chapter its main result. Column 2 of Table 22.1 restates the steps of Recognition Science's forcing chain in this book's own words, in two forms: the statements of its rungs, and one numbered sequence of steps, from T−2, "nothing is not something", to T41, the count of modes, with a bound on the period of a walk through the eight states. Every price in this chapter is a theorem about that restatement. Every step of the numbered sequence is free on the line (Theorem 22.45). Table 22.1 at the end of the chapter prices both forms in 130 rows: the first rung (segments T1–T4: the arithmetic of records, the cost J, the golden hierarchy, three dimensions and eight states), the 43 steps of the numbered sequence that are not already rows, the second rung (thirty-five groups of consequences of the first, one of them in two forms) and the chain of fifteen constants. Of the 130 rows, 119 are free. Ten have an exact price, one lies below a named principle, and none is open. All eleven priced rows belong to the rungs; none is a step of the numbered sequence. Every price sits in one of three places: in a decision form of a fact whose apartness or double-negation form is free; in a real-valued type of object that a step asks for, or in a countermodel to a dropped premise; or in a reading of a premise that is weaker than apartness. In each case a free reading of the same step is proved beside the priced one.

Several conventions hold throughout. We write MP for the binary form $\mathrm{MP}_{\mathrm{bin}}$ of Markov's principle (Definition 7.8); WLPO, LPO and LLPO are as there. A statement is *free* when it is proved with no omniscience principle and no choice principle. Maps are rules given as data, and from "every input has exactly one output" we do not form a map (Section 21.1); *the LPO function* and *the WLPO function* are the data forms of Definition 21.1: one map d from binary sequences to $\{0, 1\}$ with $d(\alpha) = 1$ exactly when α has a 1, respectively exactly when α is all 0. For x apart from 0, written $x \# 0$, $1/x$ is its inverse (Proposition 12.19, item 3); $x < y$, $x \le y$ and $x \neq y$ are as in Chapter 12, so $x \le y$ means $\neg(y < x)$ and $x = y$ means $\neg(x \# y)$. A ratio compared with a point stands for its point. The cost J is that of Definition 21.11, the golden ratio $\varphi = (1 + \sqrt{5})/2$ that of Definition 21.18, and log and π are those of Section 21.2.

The jump point carries most of the converse directions. For a binary sequence α, j_α is the point of the presentation (12.3) with every sign $+1$. It is never negative; it is 0 exactly when α is all 0 (Lemma 12.5); and it is positive exactly when α has a 1, as shown with Table 12.2. Two further facts are used without comment: a product apart from 0 has both factors apart from 0 (the product is invertible, so each factor is), and two points that are within $1/(k + 1)$ of each other for every k are equal (Lemma 12.52, item 2, in both directions).

22.1 Steps, native statements and prices

Over the classical real numbers every proposition about a number is true or false, and a step either follows from its premises or does not; it has no price. To price a step we read its statement on $\mathbb{R}_\delta$. Real numbers become points of the line; a quotient a/b becomes a times the inverse of a point b apart from 0; $x \neq y$ keeps its meaning, the negation of $x = y$; and a decision "A or B" stays a decision. We call the result the *native statement* of the step. It is the only form of the step whose price has content.

Definition 22.1 (The price of a step)**.** Let S be the native statement of a step. S is *free* when it is proved with no omniscience principle and no choice principle. S has *exact price* P, for a named principle P, when $S \Leftrightarrow P$ is proved with no choice principle in either direction. S lies *between* P and Q when $S \Rightarrow P$ and $Q \Rightarrow S$ are proved with no choice principle; it lies *below* Q when only $Q \Rightarrow S$ is proved. In the last two cases we say S is *bracketed*. A step is *open* when none of these is proved. "With no choice principle" concerns the proofs of these implications, not the principles they connect: a named principle in a price may itself include a choice principle.

The rows fall into seven segments. T1 is the arithmetic of records, eight steps that are this book's own beginning. T2 derives the cost J from an instrument that reads energies against a reference, in twelve steps. T3 derives golden scaling from a costly join, in ten. T4 obtains eight binary states from three dimensions and three dimensions from a kept linked pair, in six. These four segments form the first rung. The second rung collects thirty-five groups of consequences of the first rung: records and information, the geometry of the cost, composition and balancing, the divergence that the cost defines, the golden hierarchy, the three-bit carrier and persistent topology. One group, the first homology of the circle, has a relation form and a data form, and the table gives each its own row. Another segment runs from φ to the constants of nature in fifteen steps. The seventh segment is the numbered sequence, T−2 to T41 and the period bound. Two of its steps, the uniqueness of J and of φ, are rows of the first rung and of

the constants already; the other 43 have their own rows, and Section 22.10 reads them one by one. The table lists the numbered sequence after the first rung.

The first segment shows the contrast that runs through the chapter. Records compare for free; points of the line do not.

Proposition 22.2 (Records compare for free; points do not)**.** *Equality of counts, of signed counts and of ratio records is decidable, with no omniscience principle and no choice principle. The assertion that $x = y$ or $x \neq y$ for all points x, y of $\mathbb{R}_\delta$ is equivalent to WLPO.*

Proof. Two counts are compared by removing one successor from each until one of them runs out (Chapter 3). Signed counts are balanced pairs, and (a, b) and (c, d) name the same signed count when $a + d = b + c$, a comparison of counts; ratio records (u, d) and (v, e) with positive denominators are equal when $ue = vd$, a comparison of signed counts (Chapter 4). For points, $x = y$ says $x - y = \eta(0)$, so the second assertion is the first item of Corollary 12.18. □

The core of T1 is proved in Chapters 1 to 4: the orbit of repeated distinction is initial (Theorem 2.3); counts, signed counts and ratios obey the laws of the natural numbers, the integers and the rationals (Theorems 3.3, 3.10, 4.5 and 4.12); and the reading of this arithmetic does not depend on the carrier that realizes it (Theorems 2.7 and 3.14). The remaining steps code hereditarily finite sets by Ackermann's numbering, under which the arithmetic of records interprets the three axioms of adjunctive set theory with extensionality (extensionality, the empty set, and adjunction $x \cup \{y\}$), and compare two carriers of the records, the natural numbers and the lists over a one-element set, formula by formula. All eight steps are free.

22.2 The meter reads ratios

The derivation of the cost begins with an instrument. It reads a nonnegative quantity d, an energy, against a reference r. It pools: reading $d + e$ gives the reading of d plus the reading of e. It never reads below zero, and it reads its own reference as 1. On $\mathbb{R}_\delta$ a reference must be positive for "reads as 1" to make sense, and we build that into the meter. The theorem behind the meter is Cauchy's functional equation [171], which on the line needs monotonicity rather than continuity.

Lemma 22.3 (Monotone additive maps of the line are linear)**.** *Let $f : \mathbb{R}_\delta \to \mathbb{R}_\delta$ satisfy $f(x + y) = f(x) + f(y)$ for all x, y, and $f(x) \leq f(y)$ whenever $x \leq y$. Then $f(x) = f(1)\,x$ for every x. The proof is free.*

Proof. Additivity gives $f(0) = f(0) + f(0)$, so $f(0) = 0$, then $f(-x) = -f(x)$, and by induction $f(nx) = nf(x)$ for natural numbers n. For a ratio a/b with $b > 0$ this gives $bf(a/b) = f(a) = af(1)$, so $f(a/b) = (a/b)f(1)$. Since $0 \leq 1$, monotonicity gives $f(1) \geq f(0) = 0$.

Fix a point x and a natural number k. By Lemma 12.52, item 4, there are ratios $a < b$ with $a < x < b$ and $b - a \leq 1/(k + 1)$. Monotonicity gives $af(1) \leq f(x) \leq bf(1)$, and $f(1) \geq 0$ gives $af(1) \leq xf(1) \leq bf(1)$. So $f(x)$ and $f(1)x$ both lie in an interval of length $(b - a)f(1) \leq f(1)/(k + 1)$. Take a natural number $M \geq 1$ above $f(1)$ and apply this with $M(k + 1)$ in place of k: the two points are within $1/(k + 1)$, for every k, hence equal. □

Definition 22.4 (A meter)**.** A *meter* assigns to every positive point r (the reference) and every point $d \geq 0$ a point $\mathrm{read}(d, r)$, so that for each $r > 0$: $\mathrm{read}(d, r) \geq 0$; $\mathrm{read}(d + e, r) = \mathrm{read}(d, r) + \mathrm{read}(e, r)$ for $d, e \geq 0$; and $\mathrm{read}(r, r) = 1$. The *ratio meter* is $\mathrm{read}(d, r) = d/r$.

Theorem 22.5 (A meter reads the ratio to its reference)**.** *Every meter satisfies* $\mathrm{read}(d, r) = d/r$ *for every* $r > 0$ *and every* $d \geq 0$*, and the ratio meter is a meter. The proof is free.*

Proof. The ratio meter meets the three laws by the field laws of Proposition 12.19. Conversely fix $r > 0$ and write $\mathrm{read}(d)$ for $\mathrm{read}(d, r)$. Pooling gives $\mathrm{read}(0) = 0$. Put $x^+ = \max(x, 0)$ and $x^- = \max(-x, 0)$, so that $x^+, x^- \geq 0$ and $x^+ - x^- = x$, and extend the reading to the whole line by

$$E(x) = \mathrm{read}(x^+) - \mathrm{read}(x^-).$$

E is additive. Indeed $(x + y)^+ + x^- + y^- = (x + y)^- + x^+ + y^+$, because $(x + y)^+ - (x + y)^- = x + y = (x^+ - x^-) + (y^+ - y^-)$; both sides are sums of nonnegative points, so reading them and pooling gives $E(x + y) = E(x) + E(y)$. E is monotone: if $x \leq y$ then $(y - x)^- = 0$, so $E(y) - E(x) = E(y - x) = \mathrm{read}((y - x)^+) \geq 0$. Lemma 22.3 gives $E(x) = E(1)x$. For $d \geq 0$ we have $d^+ = d$ and $d^- = 0$, so $\mathrm{read}(d) = E(d) = E(1)d$. Self-reference gives $E(1)r = 1$, so $E(1) = 1/r$. □

An instrument that pools energies and reads its own reference as 1 can only read the ratio to that reference. Row T2.1b of Table 22.1 states the meter differently: as one real-valued function of two real arguments, defined also at references that are not positive. That type of object has a price.

Theorem 22.6 (A total meter costs at least LPO)**.** *Call a map* $\mathrm{read} : \mathbb{R}_\delta \times \mathbb{R}_\delta \to \mathbb{R}_\delta$ *a* total meter *when, for every* $r > 0$*, its restriction to* $d \geq 0$ *satisfies the laws of Definition 22.4. Then:*

(a) a total meter exists if and only if some map $g : \mathbb{R}_\delta \to \mathbb{R}_\delta$ *satisfies* $r\,g(r) = 1$ *for every* $r > 0$*;*

(b) such a map g *gives LPO;*

(c) the LPO function gives such a map g*.*

So the existence of a total meter lies between LPO and the LPO function; Theorem 22.63 shows that it is exactly the LPO function. No choice principle is used.

Proof. (a) Given a total meter, put $g(r) = \mathrm{read}(1, r)$; for $r > 0$, Theorem 22.5 gives $g(r) = 1/r$. Given g, put $\mathrm{read}(d, r) = d\,g(r)$; for $r > 0$ this is the ratio meter.

(b) Let α be a binary sequence, $j = j_\alpha$ and $t = j\,g(j)$. Since $1/3 < 2/3$, cotransitivity gives $1/3 < t$ or $t < 2/3$. If $1/3 < t$, then $t \# 0$, so the factor j is apart from 0; it is not negative, so $j > 0$, and α has a 1. If $t < 2/3$, then $j > 0$ is impossible, since it would give $t = 1$; so α has no 1, and each $\alpha(n)$, being binary, is 0. That is LPO.

(c) Let D be the LPO function. For a regular sequence s let $p_s(n) = 1$ exactly when $s_n > 2/(n+1)$. The point named by s is positive exactly when p_s has a 1, and this belongs to the point, not to the sequence; so $D(p_s)$ depends only on the point r. Put $g(r) = 1/r$ if $D(p_s) = 1$, which then supplies $r > 0$, and $g(r) = 0$ otherwise. Two sequences naming r give the same bit and, in the first case, the same inverse; so g is a map, and $r\,g(r) = 1$ whenever $r > 0$. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; a total meter is one map on all pairs of points, with the meter laws at positive references.

Conclusion

A total meter gives LPO, and the LPO function gives one; the meter at positive references alone is free (Theorem 22.5).

Not claimed

The exact place of the total meter, which Theorem 22.63 settles: the LPO function. The derivation of J in this chapter reads only positive references, so it never needs the total type.

22.3 The apparatus and the native reporting theorem

The meter reads the energy that a comparison discards, against the energy of a reference. Which energies can an apparatus produce? A selection theorem answers: three premises about the balanced comparison and the empty operand force the energy law. The meter then forces the reported cost to be J, up to a scale. We state the apparatus on $\mathbb{R}_\delta$.

Definition 22.7 (The comparison apparatus)**.** The *complex numbers* $\mathbb{C}_\delta$ of the line are the pairs (x, y) of points, written $x + iy$, with the usual sum and product; $\mathrm{Re}(x + iy) = x$ and $|x + iy|^2 = x^2 + y^2$. A *signal* is a map f from $\{0, 1, \dots, 7\}$ to $\mathbb{C}_\delta$, and its *energy* is $\mathscr{E}(f) = \sum_{t<8} |f(t)|^2$. A *residual map* is a $\mathbb{C}_\delta$-linear map T of signals. Given two *operand pulses* u, v, the comparison of magnitudes $A, B \in \mathbb{R}_\delta$ at a phase z with $|z|^2 = 1$ is the signal $Au + zBv$, and its *discarded energy* is

$$\varepsilon(A, B, z) = \mathscr{E}\big(T(Au + zBv)\big).$$

Reference programs are built from records $\langle z\rangle$, one for each phase z with $|z|^2 = 1$, by sums and by multiplication with points. A program p *evaluates* to $p(A, B)$, with $\langle z\rangle(A, B) = \varepsilon(A, B, z)$, $(p + p')(A, B) = p(A, B) + p'(A, B)$ and $(c\,p)(A, B) = c\,p(A, B)$. Its *same weight* $\sigma(p)$ and *cross weight* $\chi(p)$ are additive and homogeneous in the same way, with $\sigma\langle z\rangle = 1/2$ and $\chi\langle z\rangle = -\mathrm{Re}(z)/2$.

Theorem 22.8 (The selection premises force the energy law)**.** *Let T, u, v and a reference program p satisfy*

$$\varepsilon(1, 1, 1) = 0, \qquad p(1, 0) = 0, \qquad p(1, 1) > 0.$$

Then $Tv = -Tu$, $\sigma(p) = 0$, the scale $k = \mathscr{E}(Tu)$ is positive, the gauge $\kappa = 4\chi(p)$ is positive, and for all points A, B

$$\varepsilon(A, B, 1) = k(A - B)^2, \qquad p(A, B) = \kappa\, k\, AB.$$

The proof is free.

Proof. A signal of energy 0 is 0: a sum of nonnegative points that is 0 has every term 0, and $x^2 + y^2 = 0$ gives $x^2 = y^2 = 0$, hence $x = y = 0$, since $x \# 0$ would make $x^2 > 0$. At $A = B = z = 1$ the comparison is $u + v$, so $T(u + v) = 0$, and linearity gives $Tv = -Tu$. Then $T(Au + zBv) = (A - zB)Tu$, and for $|z|^2 = 1$

$$\varepsilon(A, B, z) = |A - zB|^2 k = k\big(A^2 + B^2 - 2AB\,\mathrm{Re}(z)\big).$$

For a record this equals $2k\big(\frac{1}{2}(A^2 + B^2) + 2 \cdot (-\frac{1}{2}\mathrm{Re}(z))AB\big)$, and sums and multiples keep the form, so every program satisfies

$$p(A, B) = 2k\big(\sigma(p)(A^2 + B^2) + 2\chi(p)AB\big).$$

At $(1, 1)$ this is $2k(2\sigma(p) + 2\chi(p)) > 0$, so the factor $2k$ is apart from 0; since $k \geq 0$, $k > 0$. At $(1, 0)$ it is $2k\sigma(p) = 0$, and $2k$ is invertible, so $\sigma(p) = 0$. Then $p(1, 1) = 4k\chi(p)$, so $4\chi(p) = p(1, 1)/k > 0$, and $p(A, B) = 4\chi(p)kAB$. Finally $\varepsilon(A, B, 1) = k(A^2 + B^2 - 2AB) = k(A - B)^2$. □

No step argues by contradiction on the sign of k: k is a factor of a positive point, and that makes it apart from 0.

Remark 22.9 (A source witness)**.** Rows T2.3a and T2.3b of Table 22.1 restate a definite apparatus, the source witness. Its *pulse* with amplitudes a, b is the signal $(a, -a, 0, 0, -b, b, 0, 0)$; its residual map sends f to $t \mapsto (f(t) + f(t + 4))/2$, indices modulo 8; the operands are $u = \mathrm{pulse}(s, 0)$ and $v = \mathrm{pulse}(0, s)$ for an amplitude s with $|s|^2 > 0$ (the witness takes $s = 1/\sqrt{2}$); and the reference program is $(\kappa/2)(\langle i\rangle - \langle 1\rangle)$ with a gauge $\kappa > 0$. Then $Tu = (s, -s, 0, 0, s, -s, 0, 0)/2 = -Tv$, $k = |s|^2$, $\sigma = 0$, $\chi = \kappa/4$, $p(1, 0) = 0$ and $p(1, 1) = \kappa k$, so the three premises of Theorem 22.8 hold. The formation residual of row T2.3b, built with φ, acts on these operands as $1 + \varphi^{-2}$ times this residual, on $\mathbb{R}_\delta$ as over the classical complex numbers. Reading the classical apparatus of the two rows as the one above is an identification, made in classical mathematics; it is not part of the native statement.

Definition 22.10 (Reports at ratios)**.** Let $k, \kappa > 0$. The *apparatus law* at counts is $E(a, b) = k(a - b)^2$ and $R(a, b) = \kappa kab$ for natural numbers a, b. A map $F : \mathbb{R}_\delta \to \mathbb{R}_\delta$ *reports* a meter at ratios when $F(a/b) = \mathrm{read}(E(a, b), R(a, b))$ for all natural numbers $a, b > 0$. F is *continuous at positive points* when for every $x > 0$ and every k there is a j with $|F(y) - F(x)| \leq 1/(k + 1)$ for every $y > 0$ within $1/(j + 1)$ of x.

Theorem 22.11 (The native reporting theorem)**.** *Let a meter, the apparatus law with $k, \kappa > 0$, and a map F that reports the meter at ratios be given. Then $F(a/b) = (2/\kappa)\,J(a/b)$ for all natural numbers $a, b > 0$. If moreover F is continuous at positive points, then $F(x) = (2/\kappa)\,J(x)$ for every $x > 0$; for $\kappa = 2$, $F = J$ on the positive points. The proof is free.*

Proof. For $a, b > 0$ the reference $R(a, b) = \kappa kab$ is positive, so Theorem 22.5 gives

$$F\Big(\frac{a}{b}\Big) = \frac{k(a - b)^2}{\kappa kab} = \frac{2}{\kappa} \cdot \frac{(a - b)^2}{2ab} = \frac{2}{\kappa}\, J\Big(\frac{a}{b}\Big),$$

because $J(a/b) = (a/b + b/a)/2 - 1 = (a^2 + b^2 - 2ab)/(2ab)$.

Now let F be continuous at positive points and fix $x > 0$ and k. For $y > 0$,

$$J(y) - J(x) = \frac{(y - x)(xy - 1)}{2xy},$$

so for $y \geq x/2$ we get $|J(y) - J(x)| \leq C|y - x|$ with $C = (1 + 2/x^2)/2$: J is continuous at x with an explicit modulus. Take j for F at x with tolerance $1/(2k + 2)$, and by Lemma 12.52, item 4, a ratio q within $\min(1/(j + 1),\ x/2,\ \kappa/(4C(k + 1)))$ of x; it is positive because $q \geq x/2$. Then

$$\left|F(x) - \frac{2}{\kappa}J(x)\right| \leq |F(x) - F(q)| + \frac{2}{\kappa}|J(q) - J(x)| \leq \frac{1}{2k + 2} + \frac{1}{2k + 2}.$$

This holds for every k, so $F(x) = (2/\kappa)J(x)$. The moduli are used inside the proof of an equation, so no choice of moduli is made. □

Conditions and scope.

Base and premises

A meter (Definition 22.4); the apparatus law at counts; literal reports at every positive ratio a/b; continuity of F at positive points.

Conclusion

$F = (2/\kappa)J$ on the positive points, with no omniscience and no choice. With Theorem 22.8, every apparatus meeting the three selection premises has the apparatus law with $k = \mathscr{E}(Tu)$ and $\kappa = 4\chi(p)$, so the theorem applies to it.

Identification

a and b are the counted operands of one comparison, the meter reads discarded energy against the reference, and F is the reported dimensionless cost. That a physical instrument obeys the meter laws is a premise, not a result.

The balanced premise says that the report of the balanced comparison is $F(1) = 0$. With literal reports this gives the first premise of Theorem 22.8: $F(1) = \mathrm{read}(\varepsilon(1, 1, 1), p(1, 1)) = \varepsilon(1, 1, 1)/p(1, 1)$, and $p(1, 1) > 0$. The composition law with its calibration forces J by a second route (Theorem 21.14); both routes end at the same function.

Continuity is one way to pass from ratios to all positive points. Two further premises of the chain, reciprocity and monotonicity on $[1, \infty)$ (row T2.2b), do the same work without it.

Theorem 22.12 (Reciprocity and order replace continuity). *Let c be a point and $F : \mathbb{R}_\delta \to \mathbb{R}_\delta$ satisfy $F(a/b) = c\,J(a/b)$ for all natural numbers $a, b > 0$; $F(1/x) = F(x)$ for every $x > 0$; and $F(x) \leq F(y)$ whenever $1 \leq x \leq y$. Then $F(x) = c\,J(x)$ for every $x > 0$. The proof is free.*

Proof. First let $x \geq 1$, and fix k. Take ratios $l < x < u$ with $u - l$ as small as we please (Lemma 12.52, item 4). Whether $l < 1$ is a comparison of ratios; if it holds, replace l by 1, which keeps $l \leq x$ because $x \geq 1$. Now $1 \leq l \leq x \leq u$, both l and u are positive ratios, and the order premise gives $c\,J(l) = F(l) \leq F(x) \leq F(u) = c\,J(u)$. Hence

$$-|c|\,|J(l) - J(x)| \leq F(x) - c\,J(x) \leq |c|\,|J(u) - J(x)|,$$

and the explicit modulus of J at x from the proof of Theorem 22.11 makes both bounds smaller than $1/(k+1)$ once $u - l$ is small enough. So $F(x) = c\,J(x)$.

For general $x > 0$ the dichotomy $x \geq 1$ or $x \leq 1$ costs LLPO (Corollary 12.18), but we need it only under a double negation. An equation on the line is the negation of an apartness, so it follows from its own double negation. And $\neg\neg(x \geq 1 \vee x \leq 1)$ holds outright: if neither held, then $\neg\neg(x < 1)$ and $\neg\neg(1 < x)$, hence $\neg\neg(x < 1 \wedge 1 < x)$, which is absurd. In the case $x \geq 1$ the first part applies; in the case $x \leq 1$ we have $1/x \geq 1$, so $F(x) = F(1/x) = c\,J(1/x) = c\,J(x)$, since $J(1/x) = J(x)$. Hence $\neg\neg(F(x) = c\,J(x))$, and so $F(x) = c\,J(x)$. □

Can the passage from ratios to points be dropped altogether? Not for free. To alter a report at one irrational point, a map must recognize that point, and that needs a decision of equality on the line as data.

Lemma 22.13 (An equality test is the WLPO function)**.** *A map $d : \mathbb{R}_\delta \times \mathbb{R}_\delta \to \{0,1\}$ with $d(x,y) = 1$ exactly when $x = y$ exists if and only if the WLPO function exists. No choice principle is used.*

Proof. Given d, the map $\alpha \mapsto d(j_\alpha, 0)$ is the WLPO function, because $j_\alpha = 0$ exactly when α is all 0. Conversely let D be the WLPO function. For regular sequences s and t naming x and y, let u be the regular sequence of $x - y$ and $\beta(n) = 1$ exactly when $|u_n| > 2/(n+1)$, a comparison of ratios. By Bishop's zero condition (Lemma 12.15), β is all 0 exactly when $x = y$. So $D(\beta)$ depends only on the points x and y, and $d(x,y) = D(\beta)$ is a map with the required property. □

Theorem 22.14 (Ratio reports alone do not force J, given the WLPO function)**.** *Suppose the WLPO function exists. Then it is not the case that every map F on the positive points with $F(a/b) = J(a/b)$ for all natural numbers $a, b > 0$ equals J at every positive point. No choice principle is used.*

Proof. Let d be the equality test of Lemma 22.13, let $\sqrt{2}$ be the nonnegative square root of 2 (Proposition 12.19, item 5), and put $F(x) = J(x) + d(x, \sqrt{2})$, the bit read as the point 0 or 1. A ratio is never $\sqrt{2}$: $(a/b)^2 = 2$ with $b > 0$ would give $a^2 = 2b^2$ in the natural numbers, so a is even, $a = 2a'$, and $b^2 = 2a'^2$ is a smaller solution, which is impossible by descent. So $d(a/b, \sqrt{2}) = 0$ and $F(a/b) = J(a/b)$ at every positive ratio, while $F(\sqrt{2}) = J(\sqrt{2}) + 1 \neq J(\sqrt{2})$. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ and the WLPO function, a single map deciding "all zero" for every binary sequence.

Conclusion

Reports at ratios do not by themselves force J; the step needs a further premise. With continuity (Theorem 22.11) or with reciprocity and order (Theorem 22.12) the step is free.

Not claimed

A lower bound. Showing that some principle is needed to alter a report would take a model of the line in which every map is continuous; none is given here. WLPO as a proposition does not define F: a map needs the decision as data.

22.4 What deciding the consequences of J costs

Once J is forced, the chain reads off its consequences. Each holds on the line at no cost when it is stated with apartness. The decision forms are another matter, and the opening example belongs here.

Proposition 22.15 (The consequences of J are free)**.** *For every $x > 0$: $J(x) = (x-1)^2/(2x)$; $J(x) \geq 0$; $J(x) = 0$ exactly when $x = 1$; $J(1/x) = J(x)$; $J(x) > 0$ exactly when $x \# 1$; and $1 \leq x \leq y$ implies $J(x) \leq J(y)$. In particular $J(1) = 0$. The proofs are free.*

Proof. $\frac{1}{2}(x + 1/x) - 1 = (x^2 + 1 - 2x)/(2x)$. A square is nonnegative and $2x > 0$, so $J(x) \geq 0$. If $J(x) = 0$ then $(x-1)^2 = 0$, and $x - 1 \# 0$ would make the square positive; so $\neg(x - 1 \# 0)$, which is $x = 1$. The converse is immediate, and $J(1/x) = J(x)$ because the definition is symmetric in x and $1/x$. Since $2x$ is positive and invertible, $J(x) > 0$ exactly when $(x-1)^2 > 0$, and a square is positive exactly when its base is apart from 0. Finally

$$J(y) - J(x) = \frac{(y - x)(xy - 1)}{2xy},$$

and for $1 \leq x \leq y$ both factors $y - x$ and $xy - 1$ are nonnegative, so the difference is nonnegative. □

Theorem 22.16 (A ratio other than 1 has positive cost: exactly MP)**.** *On $\mathbb{R}_\delta$ each of the following assertions, made for every $x > 0$, is equivalent to the principle named, with no choice principle in either direction:*

(i) $x \neq 1$ *implies* $J(x) > 0$*: MP;*

(ii) $J(x) \neq 0$ *implies* $J(x) > 0$*: MP;*

(iii) $J(x) = 0$ *or* $J(x) \neq 0$*: WLPO;*

(iv) $J(x) = 0$ *or* $J(x) > 0$*: LPO.*

Proof. By Proposition 22.15, $J(x) = 0$ exactly when $x = 1$, so $J(x) \neq 0$ exactly when $x \neq 1$, and (i) and (ii) are the same assertion.

(ii) gives MP. Let α be a binary sequence that is not all 0, and put $x = 1 + j_\alpha > 0$. Then $j_\alpha \neq 0$, since $j_\alpha = 0$ would make α all 0; so $x \neq 1$ and $J(x) \neq 0$. By (ii), $J(x) > 0$, so $x \# 1$ by Proposition 22.15, that is, $j_\alpha \# 0$. As j_α is never negative, $j_\alpha > 0$, and α has a 1.

MP gives (ii). Let $J(x) \neq 0$. If $\neg(J(x) > 0)$, then $J(x) \leq 0$, and with $J(x) \geq 0$ this gives $J(x) = 0$; so $\neg\neg(J(x) > 0)$, and MP in the form $\neg\neg(y > 0) \to y > 0$ (Corollary 12.18) gives $J(x) > 0$.

For (iii) and (iv), let r be a point and $x = 1 + r^2$. Then

$$J(1 + r^2) = \frac{(1 + r^2)^2 + 1 - 2(1 + r^2)}{2(1 + r^2)} = \frac{r^4}{2(1 + r^2)}.$$

So $J(x) = 0$ exactly when $r = 0$, and $J(x) > 0$ exactly when $r \# 0$. Assertion (iii) therefore decides $r = 0$ or $r \neq 0$ for every r, which is WLPO by Corollary 12.18; conversely WLPO decides whether the point $J(x)$ is 0. Assertion (iv) decides $r = 0$ or $r > 0$ or $r < 0$ for every r, which is LPO; conversely LPO decides $J(x) > 0$, $J(x) = 0$ or $J(x) < 0$, and the last is excluded by $J(x) \geq 0$. □

Conditions and scope.

Base and premises
$\mathbb{R}_\delta$ and J on the positive points.

Conclusion
The step "$J(x) > 0$ for $x \neq 1$" (row T2.8), read on the line in its own form, is exactly Markov's principle; its apartness form "$J(x) > 0$ for $x \# 1$" is free. The decision "zero or not" is WLPO and "zero or positive" is LPO.

Not claimed
Any price for a single x: for one given point the facts of Proposition 22.15 hold outright. The price belongs to the uniform assertion over all positive points.

The last step of the segment, T2.9, is the cost-law route: on the line, a comparison cost that obeys the composition law and the unit calibration is J (Theorem 21.14), with no omniscience and no choice. The reporting route and the cost-law route meet at the same function. Of the twelve rows of T2, nine are free, two have an exact price, and one is bracketed (Table 22.1).

22.5 The golden hierarchy

The second segment of the first rung turns one costly join into the golden ratio. A carrier of states moves by a step map, and each state has a positive reading. The steps ask that the readings be presented additively, that the step preserve positive readings, and that the first new level be a join of earlier levels with a positive cost. These conditions leave one scaling: every step multiplies the reading by φ.

Definition 22.17 (Orbits, additive readings and costly joins)**.** An *orbit with positive readings* is a set S with a map $T : S \to S$ and a map $r : S \to \mathbb{R}_\delta$ with $r(s) > 0$ for every s. An *additive reading* of it consists of an abelian group G, a group homomorphism $A : G \to G$, a map $\ell : S \to G$ and an additive map $v : G \to \mathbb{R}_\delta$ with $v(\ell(s)) = r(s)$ and $\ell(Ts) = A(\ell(s))$ for every s. For a sequence of positive levels $s_0, s_1, s_2, \ldots$ and natural numbers $a \leq b$, the *join ratio* is s_{b-a}/s_0. The levels have a *costly initial join* when some $a \leq b < 2$ satisfy $s_2 = s_a + s_b$ and $J(s_{b-a}/s_0) > 0$. A *realized hierarchy* of the orbit is a state s_* whose levels $L_k = r(T^k s_*)$ satisfy $L_1/L_0 > 1$, $L_{k+2}/L_{k+1} = L_{k+1}/L_k$ for every k, and $L_2 = L_1 + L_0$.

The theorem uses J only through two of its properties: $J(1) = 0$, and $J(x) > 0$ exactly when $x \# 1$.

Lemma 22.18 (A costly initial join posts additively)**.** *If positive levels have a costly initial join, then $s_2 = s_1 + s_0$. The proof is free.*

Proof. The pairs $a \le b < 2$ are $(0,0)$, $(0,1)$ and $(1,1)$, and which one is given is decided on the natural numbers. If $a = b$, the join ratio is $s_0/s_0 = 1$ and $J(1) = 0$, which is not positive. So $(a,b) = (0,1)$ and $s_2 = s_0 + s_1$. □

Lemma 22.19 (Positive comparisons fix one scalar)**.** *Let $L, M : G \to \mathbb{R}_\delta$ be additive maps on an abelian group, let $e \in G$ have $L(e) > 0$, and suppose $L(x) > 0$ implies $M(x) > 0$ for every $x \in G$. Then $M(x)/M(e) = L(x)/L(e)$ for every x, so $M = \big(M(e)/L(e)\big)L$. The proof is free.*

Proof. $M(e) > 0$ by the hypothesis at e. Suppose $M(x)/M(e) < L(x)/L(e)$. By Lemma 12.52, item 1, there is a ratio p/q with $q > 0$ strictly between them. Then $L(qx - pe) = qL(x) - pL(e) > 0$, while $M(qx - pe) = qM(x) - pM(e) < 0$, against the hypothesis. So $\neg\big(M(x)/M(e) < L(x)/L(e)\big)$, which is $L(x)/L(e) \le M(x)/M(e)$. The same argument at $-x$ gives the reverse inequality, and the two give equality (Proposition 12.19, item 2). □

A classical proof of this lemma argues by contradiction to obtain a strict inequality. On the line that is unnecessary: refuting a strict inequality is all that $\le$ asks.

Theorem 22.20 (Golden scaling is free)**.** *Let an orbit with positive readings have an additive reading (G, A, ℓ, v) whose step preserves positive values: $v(x) > 0$ implies $v(Ax) > 0$ for every $x \in G$. Let $s_* \in S$. Then:*

(a) some $\rho > 0$ satisfies $r(Ts) = \rho\, r(s)$ for every $s \in S$;

(b) if the levels $r(T^k s_*)$ have a costly initial join, then $r(Ts) = \varphi\, r(s)$ for every $s \in S$, and these levels form a realized hierarchy;

(c) every realized hierarchy has $L_1/L_0 = \varphi$, $L_n = \varphi^n L_0$ and $L_0/L_n = \varphi^{-n}$ for every n.

No omniscience principle and no choice principle is used.

Proof. (a) Apply Lemma 22.19 to $L = v$ and $M = v \circ A$, which is additive, with $e = \ell(s_*)$; $v(e) = r(s_*) > 0$, and the step hypothesis is the positivity hypothesis of the lemma. With $\rho = v(Ae)/v(e) > 0$,

$$r(Ts) = v(\ell(Ts)) = v(A\ell(s)) = \rho\, v(\ell(s)) = \rho\, r(s).$$

(b) By (a), $r(T^k s_*) = \rho^k r(s_*)$. Lemma 22.18 gives $\rho^2 r(s_*) = \rho r(s_*) + r(s_*)$, and $r(s_*)$ is invertible, so $\rho^2 = \rho + 1$. The positive root is unique: $\rho^2 - \rho - 1 = (\rho - \varphi)(\rho + \varphi - 1)$, and $\rho + \varphi - 1 > 0$ is invertible, so $\rho = \varphi$. The levels $\varphi^k r(s_*)$ have ratio $\varphi > 1$ throughout, and $L_2 = L_1 + L_0$ by Lemma 22.18.

(c) Self-similarity makes every ratio L_{k+1}/L_k equal to $\lambda = L_1/L_0$, so $L_n = \lambda^n L_0$ by induction. Then $L_2 = L_1 + L_0$ gives $\lambda^2 = \lambda + 1$, and $\lambda > 1 > 0$ gives $\lambda = \varphi$ as in (b). The weights follow: $L_0/L_n = \varphi^{-n}$. □

Conditions and scope.

Base and premises
An orbit with positive readings on $\mathbb{R}_\delta$, an additive reading whose step preserves positive values, and a costly initial join of the levels of one state.

Conclusion
Every step multiplies readings by φ; levels are φ^n times the base and weights are φ^{-n}. Free.

Not claimed
That a costly join is supplied. The supply is the next step, and its price depends on how "costly" is read (Theorem 22.24).

The hypotheses are not empty. The model below has every one of them, with φ entering as an input of the model.

Proposition 22.21 (A model of golden scaling)**.** *Let S be the natural numbers with $T(n) = n+1$ and $r(n) = \varphi^n$; let $G = \mathbb{Z} \times \mathbb{Z}$, $A(a,b) = (a+b, a)$, $v(a,b) = a\varphi + b$ and $\ell(n) = A^n(0,1)$. This is an orbit with positive readings and an additive reading whose step preserves positive values, and the levels of 0 have a costly initial join. The proof is free.*

Proof. A is a homomorphism and v is additive. $v(A(a,b)) = (a+b)\varphi + a = \varphi(a\varphi + b)$ because $\varphi^2 = \varphi + 1$; so $v \circ A = \varphi v$ preserves positivity, and by induction $v(\ell(n)) = \varphi^n v(0,1) = \varphi^n$. The levels are $1, \varphi, \varphi^2$ with $\varphi^2 = \varphi + 1$, and the join ratio φ is apart from 1, so $J(\varphi) > 0$ by Proposition 22.15. □

Over the classical real numbers excluded middle holds for every statement about a number, so these steps have no price there; the native statements above are the ones whose price means something. The six steps T3.1–T3.6 are free.

22.6 Three readings of the first costly join

Golden scaling needs a costly initial join. Step T3.7 supplies it from the fact that the join is a recognition: its two parts differ, so the join costs something. There are three ways to read "its two parts differ", and each has its own price. The parts may be *apart*: the join ratio ρ satisfies $\rho \# 1$. They may be merely *distinct*: $\rho \neq 1$. Or their difference may be *witnessed by an integer pairing*, which is the reading of step T3.7 in Table 22.1.

Definition 22.22 (Pair kinematics and the deformation-erasure principle)**.** A *pair kinematics* is a set of configurations with an equivalence relation, read "deforms into", and two configurations, the *split* and the *pair*. A *pairing observable* is a map P from configurations to $\mathbb{Z}$ that is invariant under deformation and has $P(\text{split}) = 0$. The *deformation-erasure principle* (DEP) holds for a kinematics when some pairing observable has $P(\text{pair}) \neq 0$. The *rigid kinematics* of a point x of the line has the points of $\mathbb{R}_\delta$ as configurations, equality as deformation, split 1 and pair x; DEP holds for it exactly when some map $P : \mathbb{R}_\delta \to \mathbb{Z}$ has $P(1) = 0$ and $P(x) \neq 0$. Finally, *strong extensionality for integer-valued maps*, $\mathrm{SE}_{\mathbb{Z}}$, is the principle that every map $P : \mathbb{R}_\delta \to \mathbb{Z}$ is strongly extensional: $P(x) \neq P(y)$ implies $x \# y$.

The converse directions below rest on one device, a join whose parts differ by a prescribed point.

Lemma 22.23 (The tilted join). *For a point t put $s_0 = 1 + |t|$, $s_1 = 1 + |t| + t$ and $s_k = s_0 + s_1$ for $k \geq 2$. These levels are positive, $s_2 = s_0 + s_1$, and the join ratio $\rho = s_1/s_0$ satisfies $(\rho - 1)(1 + |t|) = t$. Hence $\rho \neq 1$ exactly when $t \neq 0$, and $\rho \# 1$ exactly when $t \# 0$. The proof is free.*

Proof. $s_1 \geq 1$ because $|t| \geq -t$, and $s_0 \geq 1$. Then $(\rho - 1)s_0 = s_1 - s_0 = t$. Since $1 + |t|$ is positive and invertible, $\rho - 1$ is 0 exactly when t is, and apart from 0 exactly when t is. □

Theorem 22.24 (Three readings of the first costly join). *Consider positive levels $s_0, s_1, \ldots$ and natural numbers $a \leq b < 2$ with $s_2 = s_a + s_b$, and let ρ be the join ratio s_{b-a}/s_0.*

(a) If $\rho \# 1$, the levels have a costly initial join. Conversely, levels have a costly initial join exactly when $s_2 = s_0 + s_1$ and $s_1/s_0 \# 1$. Free.

(b) The assertion "$\rho \neq 1$ gives a costly initial join", for all such levels and indices, is equivalent to MP.

(c) The assertion "DEP for the rigid kinematics of ρ gives a costly initial join", for all such levels and indices, is equivalent to $\mathrm{SE}_{\mathbb{Z}}$.

(d) MP implies $\mathrm{SE}_{\mathbb{Z}}$.

No choice principle is used.

Proof. (a) By Proposition 22.15, $J(\rho) > 0$ exactly when $\rho \# 1$, so $\rho \# 1$ with $s_2 = s_a + s_b$ is a costly initial join for the same a, b. Conversely, a costly initial join has $(a, b) = (0, 1)$ by Lemma 22.18, and then $J(s_1/s_0) > 0$ gives $s_1/s_0 \# 1$.

(b) Assume MP. If $\rho \neq 1$, then $\rho - 1 \neq 0$, and MP in the form $x \neq 0 \to x \# 0$ (Table 12.2) gives $\rho \# 1$; (a) gives the costly join. Conversely assume the assertion and let $r \neq 0$. The tilted join at $t = r$ has $\rho \neq 1$ by Lemma 22.23, so it has a costly initial join, so $\rho \# 1$ by (a), so $r \# 0$. That is MP in the same form.

(c) Assume $\mathrm{SE}_{\mathbb{Z}}$ and DEP for the rigid kinematics of ρ: some P has $P(1) = 0$ and $P(\rho) \neq 0$. Strong extensionality gives $\rho \# 1$, and (a) gives the costly join. Conversely assume the assertion, and let $P : \mathbb{R}_\delta \to \mathbb{Z}$ and points x, y satisfy $P(x) \neq P(y)$. Put $t = x - y$ and take the tilted join, with ratio ρ. The map

$$Q(c) = P\big(y + (c - 1)(1 + |t|)\big) - P(y)$$

has $Q(1) = 0$ and $Q(\rho) = P(y+t) - P(y) = P(x) - P(y) \neq 0$, so DEP holds for the rigid kinematics of ρ. The assertion gives a costly initial join, so $\rho \# 1$ by (a), so $t \# 0$ by Lemma 22.23: $x \# y$.

(d) If $P(x) \neq P(y)$ then $x \neq y$, because P is a map; so $x - y \neq 0$, and MP gives $x - y \# 0$. □

How far below MP does $\mathrm{SE}_{\mathbb{Z}}$ sit? With the WLPO function the two coincide, and the same function settles the rigid form of the step.

Proposition 22.25 (Equality as data closes the gap)**.** *Assume the WLPO function. Then for every point $x \neq 1$, DEP holds for the rigid kinematics of x; and* $\mathrm{SE}_{\mathbb{Z}}$ *implies MP, so the assertion of Theorem 22.24(c) is equivalent to MP. No choice principle is used.*

Proof. Let d be the equality test of Lemma 22.13, and put $P(c) = 0$ if $d(c, 1) = 1$ and $P(c) = 1$ otherwise. This is a map to $\mathbb{Z}$ with $P(1) = 0$, and $P(x) = 1$ for every $x \neq 1$: DEP for the rigid kinematics of x. Now let $r \neq 0$. Then $1 + r \neq 1$, so $P(1 + r) = 1 \neq 0 = P(1)$, and $\mathrm{SE}_{\mathbb{Z}}$ gives $(1 + r) \# 1$, that is, $r \# 0$. That is MP. □

Conditions and scope.

Base and premises
Positive levels on $\mathbb{R}_\delta$ with $s_2 = s_a + s_b$; the three readings of "the parts differ".

Conclusion
Apart parts: free. Distinct parts: exactly MP. Parts separated by an integer pairing (the route of step T3.7): exactly $\mathrm{SE}_{\mathbb{Z}}$, which MP implies, and which equals MP in the presence of the WLPO function.

Not claimed
That $\mathrm{SE}_{\mathbb{Z}}$ implies MP: this converse is open. It is expected to fail, since in models where every map from the line to $\mathbb{Z}$ is constant, strong extensionality holds trivially while MP need not; no such model is constructed here. The rigid form "$x \neq 1$ gives DEP" costs exactly the WLPO function (Theorem 22.64).

A classical proof of step T3.7 picks the pairing "1 at the pair, 0 elsewhere" by deciding, for each configuration, whether it equals the pair. On the line that decision is an equality test, and an equality test is the WLPO function (Lemma 22.13). In physical words: if the two parts of the first join are known to be apart, the join costs something for free; if they are only known not to coincide, extracting the positive cost is Markov's principle; if their difference is witnessed by an integer pairing, the price is the strong extensionality of integer readings of the line.

22.7 Eight states, and where three dimensions come from

The last segment of the first rung concerns a pair of loops that the world keeps: a configuration that cannot be deformed into the split one. DEP expresses that some integer pairing tells them apart. Three of its steps are logic, one is arithmetic, and two are topology.

Proposition 22.26 (What a kept pair gives)**.** *For every pair kinematics, DEP implies that the pair does not deform into the split. The* winding kinematics*, with configurations $\mathbb{Z}$, equality as deformation, split* 0 *and pair* 2*, satisfies DEP. The* erasable *kinematics, with configurations $\mathbb{Z}$, in which every configuration deforms into every other, split* 0 *and pair* 2*, does not. The proofs are free.*

Proof. If the pair deformed into the split, every pairing observable would give $P(\text{pair}) = P(\text{split}) = 0$. In the winding kinematics the identity map is a pairing observable, with value $2 \neq 0$ at the pair. In the erasable kinematics every configuration deforms into the split, so every pairing observable is 0 everywhere. □

Proposition 22.27 (Eight states exactly in dimension three)**.** *For a natural number D, $2^D = 8$ if and only if $D = 3$. The binary words of length n are 2^n in number and pairwise distinct, and every binary word of length 3 is one of* 000, 001, 010, 011, 100, 101, 110, 111. *The proofs are free.*

Proof. $2^0, 2^1, 2^2, 2^3 = 1, 2, 4, 8$, and $2^D \geq 16$ for $D \geq 4$. The words of length $n+1$ are the words of length n followed by 0 and by 1, so their number doubles at each length, and two words are equal exactly when they agree letter by letter, a finite check. □

This is arithmetic given $D = 3$; it is not the selection of the dimension. The selection is the content of steps T4.4 and T4.5, and it is the subject of Chapter 23. On the native spheres of $\mathbb{R}_\delta$, with continuous maps given with their moduli and chains presented by generators and relations, a natively embedded circle can be linked, that is, some loop in its complement bounds no native surface there, exactly when the dimension is 3. The proof uses no omniscience principle and no choice principle. Chapter 23 also treats the circle's first homology, the last group of the second rung: it is $\mathbb{Z}$ as a relation, with no principle, and its data form costs exactly the WLPO function (Theorem 22.65). Given that theorem, every native spatial realization in dimension D that satisfies DEP has $2^D = 8$; reading the kept pair of segment T4 as a linked circle in this topology is an identification, which the chain takes as a premise and which is not derived here. All six steps of T4 are free.

22.8 The second rung

The second rung collects what the first rung certifies, in thirty-five groups: records and information, the geometry of the cost, composition and balancing, the divergence that the cost defines, the golden hierarchy, the three-bit carrier and persistent topology. On the line, thirty-one groups hold with no omniscience, three have an exact price in one decision form, and the last, the first homology of the circle, is free as a relation and costs exactly the WLPO function as a function (Chapter 23 and Theorem 22.65). We prove the headline identities and the three prices first, and then the remaining identities and counts (Propositions 22.34, 22.35 and 22.36); Table 22.1 lists every group with the result that settles it.

Proposition 22.28 (Records and capacity)**.** *Let k, n, m, M be natural numbers. If an injective map sends M messages to the words of length n over k letters, then $M \leq k^n$. If an injective map sends the words of length m over $k \geq 1$ letters to M cells, then $k^m \leq M$. For $k \geq 2$ no injective map sends the words of length M over k letters to M cells: a store cannot hold its own history. The proofs are free.*

Proof. An injective map from a finite set of size N to one of size M gives $N \leq M$, by induction on M: remove the image of one element and its preimage. There are k^n words of length n, which gives the first two statements. For the third, the second gives $k^M \leq M$, but $k^M \geq 2^M > M$. □

Proposition 22.29 (The geometry of the cost)**.** *Let a, b, c, x, y, z be positive points.*

(a) $J(a/b) = (a-b)^2/(2ab)$, and $J(ca/(cb)) = J(a/b)$.

(b) If $c' \geq 0$ and $s \geq 0$ satisfy $s^2 = c'(c'+2)$, then $J(x) \leq c'$ exactly when $1+c'-s \leq x \leq 1+c'+s$.

(c) $J(xy) + J(x/y) = 2J(x)J(y) + 2J(x) + 2J(y)$. With $S(x) = (x - 1/x)/2$, $S(x)^2 = J(x)\big(J(x)+2\big)$ and $J(xy) = J(x)J(y) + J(x) + J(y) + S(x)S(y)$.

(d) If $m = tx + (1-t)y > 0$, then $tJ(x) + (1-t)J(y) - J(m) = t(1-t)(x-y)^2/(2xym)$.

(e) If $s > 0$ and $s^2 = ab$, then $J(a/z) + J(b/z) - J(a/s) - J(b/s) = (a+b)(z-s)^2/(2abz)$, so two parties meet most cheaply at the geometric mean.

(f) If $s \geq 0$ and $s^2 = ab$, then $s \leq (a+b)/2$, with equality exactly when $a = b$.

The proofs are free.

Proof. (a) $J(a/b) = (a/b + b/a)/2 - 1 = (a^2 + b^2 - 2ab)/(2ab)$, and $ca/(cb) = a/b$.

(b) Multiplying by $2x > 0$, $J(x) \leq c'$ becomes $(x-1)^2 \leq 2c'x$, that is, $\big(x - (1+c')\big)^2 \leq (1+c')^2 - 1 = s^2$. For nonnegative p and s, $p^2 \leq s^2$ holds exactly when $p \leq s$, since $p^2 - s^2 = (p-s)(p+s)$ and $p + s \geq 0$; applied to $p = |x - 1 - c'|$ this is the stated interval.

(c) $\big(J(xy)+1\big) + \big(J(x/y)+1\big) = \frac{1}{2}\big(xy + \frac{1}{xy} + \frac{x}{y} + \frac{y}{x}\big) = \frac{1}{2}(x + \frac{1}{x})(y + \frac{1}{y}) = 2\big(J(x)+1\big)\big(J(y)+1\big)$, which expands to the composition law. Next, $S(x)^2 = \big(\frac{1}{2}(x + \frac{1}{x})\big)^2 - 1 = (J(x)+1)^2 - 1$. Finally $(J(x)+1)(J(y)+1) + S(x)S(y) = \frac{1}{4}\big[(x + \frac{1}{x})(y + \frac{1}{y}) + (x - \frac{1}{x})(y - \frac{1}{y})\big] = \frac{1}{2}(xy + \frac{1}{xy}) = J(xy) + 1$.

(d) The left side is $\frac{1}{2}\big(t/x + (1-t)/y - 1/m\big)$, and $m\big(ty + (1-t)x\big) - xy = t(1-t)(x-y)^2$ after expanding.

(e) The left side equals $\frac{1}{2}(a+b)\big(1/z + z/(ab) - 2/s\big)$, because $s/(ab) = 1/s$; over the denominator abz the bracket is $(ab + z^2 - 2zs)/(abz) = (z-s)^2/(abz)$.

(f) $\big((a+b)/2\big)^2 - s^2 = (a-b)^2/4 \geq 0$, and the comparison of squares in (b) applies; equality holds exactly when $(a-b)^2 = 0$. □

The cost defines a divergence between distributions. It is half of Pearson's χ^2 [173], and it bounds total variation.

Proposition 22.30 (The divergence of the cost)**.** *Let $q_0, \dots, q_{n-1}$ be positive points and $p_0, \dots, p_{n-1}$ points, and put*

$$D(p\|q) = \frac{1}{2}\sum_{i<n} \frac{(p_i - q_i)^2}{q_i}, \qquad \mathrm{TV}(p,q) = \frac{1}{2}\sum_{i<n} |p_i - q_i|.$$

If every p_i is positive, then $\sum_i p_i J(p_i/q_i) = D(p\|q)$. $D(p\|q) = 0$ exactly when $p_i = q_i$ for every i. If $\sum_i q_i = 1$, then $2\,\mathrm{TV}(p,q)^2 \leq D(p\|q)$, with equality for $q = (\frac{1}{2}, \frac{1}{2})$ and $p = (\frac{1}{2} + e, \frac{1}{2} - e)$, for every point e. The proofs are free.

Proof. By Proposition 22.29(a), $p\,J(p/q) = (p-q)^2/(2q)$. A sum of nonnegative points is 0 exactly when each term is, and $(p_i-q_i)^2/(2q_i) = 0$ exactly when $p_i = q_i$. For the bound, the weighted Cauchy–Schwarz inequality $\big(\sum_i q_i w_i\big)^2 \le \big(\sum_i q_i\big)\big(\sum_i q_i w_i^2\big)$ for $q_i \ge 0$ follows from $\sum_{i,j} q_i q_j (w_i - w_j)^2 \ge 0$. With $w_i = |p_i - q_i|/q_i$ and $\sum_i q_i = 1$ it gives $\big(\sum_i |p_i - q_i|\big)^2 \le 2D(p\|q)$, that is, $4\,\mathrm{TV}^2 \le 2D$. In the example both sides equal $2e^2$. □

The first of the three prices concerns the reciprocal ambiguity. A cost determines a ratio only up to inversion: $J(x) = J(1/x)$.

Theorem 22.31 (The reciprocal ambiguity costs exactly LLPO)**.** *For positive points x, y,*

$$J(x) - J(y) = \frac{(x-y)(xy-1)}{2xy}.$$

Hence, with no principle: $J(x) = J(y)$ implies $\neg\neg(x = y \vee xy = 1)$; $x \# y$ and $xy \# 1$ imply $J(x) \# J(y)$; and $x = y$ or $xy = 1$ implies $J(x) = J(y)$. The assertion that $J(x) = J(y)$ implies $x = y$ or $xy = 1$, for all positive x, y, is equivalent to LLPO, with no choice principle in either direction.

Proof. The identity: $J(x) - J(y) = \frac{1}{2}(x-y) + \frac{1}{2}(1/x - 1/y) = \frac{1}{2}(x-y)(1 - 1/(xy))$. Write $w = (x-y)(xy-1)$, so $J(x) = J(y)$ exactly when $w = 0$. Let $w = 0$ and suppose that neither $x - y = 0$ nor $xy - 1 = 0$. If $x - y \# 0$, then $x - y$ is invertible and $xy - 1 = 0$, which is excluded; so $\neg(x - y \# 0)$, which is $x - y = 0$, also excluded. Hence $\neg\neg(x = y \vee xy = 1)$. A product of points apart from 0 is apart from 0, which gives the second statement, and the third holds because $J(1/x) = J(x)$.

Assume LLPO. By Table 12.2 it gives the domain law: a product equal to 0 has a factor equal to 0. Applied to $w = 0$ it gives $x = y$ or $xy = 1$.

Conversely assume the assertion; we prove the domain law, which gives LLPO by the same table. Let $uv = 0$, and put $x = \exp((u-v)/2)$ and $y = \exp(-(u+v)/2)$, using the exponential of Proposition 12.88. Both are positive, $x/y = \exp(u)$ and $xy = \exp(-v)$, so

$$w = (x-y)(xy-1) = y\big(\exp(u) - 1\big)\big(\exp(-v) - 1\big).$$

First, $\exp(h) \# 1$ implies $h \# 0$. Indeed, let $|\exp(h) - 1| > \delta > 0$ and $\mu = \min(\delta/2, 1)$; by cotransitivity $|h| > \mu/2$ or $|h| < \mu$, and in the second case Proposition 12.88, item 2, gives $|\exp(h) - 1| \le |h| + |h|^2 \le 2|h| < \delta$, which is excluded. Second, $\exp(h) = 1$ implies $h = 0$: $h > 0$ gives $\exp(h) \ge 1 + h > 1$, and $h < 0$ gives $\exp(h) = 1/\exp(-h) < 1$, so $h \# 0$ is impossible. Now if the product $(\exp(u) - 1)(\exp(-v) - 1)$ were apart from 0, both factors would be, so $u \# 0$ and $v \# 0$, and uv would be apart from 0, against $uv = 0$. So the product is 0, $w = 0$ and $J(x) = J(y)$. The assertion gives $x = y$, so $\exp(u) = 1$ and $u = 0$; or $xy = 1$, so $\exp(-v) = 1$ and $v = 0$. That is the domain law. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$, J on positive points, and the exponential of Proposition 12.88.

Conclusion

Deciding which branch of the reciprocal ambiguity holds is exactly LLPO. Its double-negated form, its apartness form and its converse are free.

Not claimed

Any price for the identity or for a single pair: for given x and y the identity holds outright.

The second price sits in the data-processing inequality. Pass a distribution through a channel and the divergence cannot grow; for divergences of this kind the inequality goes back to Csiszár [172]. The proof divides by the output probabilities, so it needs to know which outputs have probability 0.

Theorem 22.32 (Omitting empty bins costs exactly LPO)**.** *A* channel *from n inputs to m outputs is a family of points $K(j \mid i) \geq 0$ with $\sum_{j<m} K(j \mid i) = 1$ for each $i < n$. For $q_i > 0$ and points p_i put $P_j = \sum_i K(j \mid i)p_i$, $Q_j = \sum_i K(j \mid i)q_i$ and $T_j = \sum_i K(j \mid i)(p_i - q_i)^2/q_i$.*

(a) With no principle: $(P_j - Q_j)^2 \leq Q_j T_j$ for every j; $Q_j = 0$ implies $P_j = 0$; if every Q_j is positive, then $D(P\|Q) \leq D(p\|q)$; and for any set of outputs given by a list of yes and no on which every Q_j is positive, the sum of $(P_j - Q_j)^2/(2Q_j)$ over that set is at most $D(p\|q)$.

(b) The assertion that every output of every channel, for every positive input distribution q with $\sum_i q_i = 1$, satisfies $Q_j > 0$ or $Q_j = 0$ is equivalent to LPO, with no choice principle in either direction.

Proof. (a) $P_j - Q_j = \sum_i K(j \mid i)q_i \cdot (p_i - q_i)/q_i$, and the weighted Cauchy–Schwarz inequality with weights $K(j \mid i)q_i \geq 0$ gives $(P_j - Q_j)^2 \leq Q_j T_j$. If $Q_j = 0$ this gives $(P_j - Q_j)^2 \leq 0$, so $P_j = Q_j = 0$. If $Q_j > 0$, then $(P_j - Q_j)^2/Q_j \leq T_j$, and $\sum_j T_j = \sum_i \big(\sum_j K(j \mid i)\big)(p_i - q_i)^2/q_i = 2D(p\|q)$, because every column of the channel sums to 1. Summing over all outputs, or over the given set, gives the two inequalities, since every $T_j \geq 0$.

(b) LPO gives $Q_j > 0$, $Q_j = 0$ or $Q_j < 0$, and $Q_j \geq 0$ excludes the last. Conversely let r be a point and take one input, $q_0 = 1$, and two outputs with $K(0 \mid 0) = r^2/(1+r^2)$ and $K(1 \mid 0) = 1/(1+r^2)$. Then $Q_0 = r^2/(1 + r^2)$. If $Q_0 > 0$ then $r^2 > 0$, so $r \# 0$; if $Q_0 = 0$ then $r^2 = 0$, so $r = 0$. That decides $r > 0$, $r = 0$ or $r < 0$ for every r, which is LPO (Corollary 12.18). □

The inequality itself is free, bin by bin and over any known support; only the literal recipe "drop the bins of probability zero" is priced. The third price concerns the golden hierarchy under a budget. Levels k apart have ratio φ^k; a cost budget c admits the gaps with $J(\varphi^k) \leq c$.

Theorem 22.33 (The largest admissible gap as a value costs exactly WLPO)**.**

(a) Let $c \geq 0$ and $s \geq 0$ with $s^2 = c(c + 2)$. Every natural number k with $J(\varphi^k) \leq c$ satisfies $k \log \varphi \leq \log(1 + c + s)$. Free.

(b) The assertion that for every point $c \geq 0$ some natural number K satisfies $J(\varphi^K) \leq c$, while every natural number k with $J(\varphi^k) \leq c$ has $k \leq K$, is equivalent to WLPO, with no choice principle in either direction.

Proof. (a) By Proposition 22.29(b), $\varphi^k \le 1+c+s$. The logarithm is increasing and $\log \varphi^k = k \log \varphi$.

(b) First, $J(\varphi) = (\varphi + \varphi^{-1})/2 - 1 = \varphi - \frac{3}{2} > 0$, since $\varphi^{-1} = \varphi - 1$ and $\varphi > 1.6$ (Proposition 22.37). Assume the assertion and let x be a point. Apply it to $c = J(\varphi)/(1 + x^2) \ge 0$, obtaining K; whether $K = 0$ is decided on the natural numbers. If $K = 0$, then $x \ne 0$: for $x = 0$ the budget is $J(\varphi)$, the gap 1 is admissible, and $1 \le K$ would follow. If $K \ge 1$, then $J(\varphi) \le J(\varphi^K) \le c$ by Proposition 22.15, so $J(\varphi)x^2/(1 + x^2) \le 0$, hence $x^2 \le 0$ and $x = 0$. So $x = 0$ or $x \ne 0$: WLPO.

Conversely assume WLPO. For a point u, $u \le c$ holds exactly when $\max(u - c, 0) = 0$, so WLPO decides it. For $k \ge 1$ we have $J(\varphi^k) \ge \varphi^k/2 - 1$ and, by Bernoulli's inequality, $\varphi^k \ge 1 + k(\varphi - 1) \ge 1 + 3k/5$; so $J(\varphi^k) > c$ as soon as $k > (10c + 5)/3$. Take a natural number B above $(10c + 5)/3$ (Proposition 12.19, item 4). Decide admissibility for each $k \le B$; the gap 0 is admissible because $J(1) = 0$; the largest admissible $k \le B$ is the required K. □

The remaining seventeen groups are identities of the cost and of the golden weights, limits of partial sums, and finite counts on the three-bit carrier. All are free. We prove them in three propositions, with $G(t) = \cosh t - 1$ as in Definition 21.11, so that $J(e^t) = G(t)$.

Proposition 22.34 (The cost in logarithmic form)**.** *Let t, u be points and a, b, c, x, y positive points.*

(a) (R2-05) $J(x) = G(\log x)$, and for every t the partial sums $\sum_{k<N} t^{2k+2}/(2k + 2)!$ converge to $G(t)$.

(b) (R2-06) With $h = y - x$,

$$J(y) = J(x) + \frac{1 - x^{-2}}{2}\, h + \frac{h^2}{2x^3} - \frac{h^3}{2x^3 y};$$

at $x = 1$ this reads $J(y) = \frac{1}{2}(y - 1)^2 - (y - 1)^3/(2y)$. If $0 < \theta < 1$ and $x \# y$, then $\theta J(x) + (1-\theta)J(y) > J(\theta x + (1-\theta)y)$. In logarithmic form, $G(t + u) + G(t - u) - 2G(t) = 2\big(G(t) + 1\big)G(u) \ge u^2$, and this second difference is positive when $u \# 0$.

(c) (R2-09) $d(a, b) = |\log a - \log b|$ is a metric on the positive points: $d(a, b) \ge 0$, $d(a, b) = d(b, a)$, $d(a, b) = 0$ exactly when $a = b$, and $d(a, c) \le d(a, b) + d(b, c)$. Moreover $J(a/b) = G\big(d(a, b)\big)$, while J itself fails the triangle inequality: $J(2) + J(2) < J(4)$.

(d) (R2-10) $t^2/2 \le G(t)$. If $|u| \le q < 1$, then

$$\frac{u^2}{2(1 + q)} \le J(1 + u) \le \frac{u^2}{2(1 - q)}.$$

(e) (R2-13) Put $C_n(x) = J(x^n) + 1 = \frac{1}{2}(x^n + x^{-n})$. Then $C_0(x) = 1$ and $C_{n+2}(x) = 2C_1(x)C_{n+1}(x) - C_n(x)$, so $C_n(x) = T_n\big(C_1(x)\big)$ for the Chebyshev polynomials $T_0 = 1$, $T_1(w) = w$, $T_{n+2}(w) = 2wT_{n+1}(w) - T_n(w)$.

(f) (R2-14) Let $x_0, \dots, x_{n-1}$ be positive, and let $a_i \ge 0$ and c_i satisfy $G(a_i) = c_i$ and $J(x_i) \le c_i$ for every $i < n$. Then $J(x_0 x_1 \cdots x_{n-1}) \le G(a_0 + a_1 + \cdots + a_{n-1})$.

(g) (R2-16) Let $x_0, \dots, x_{n-1}$ and r be positive with $x_0 x_1 \cdots x_{n-1} = r^n$. Then $nJ(r) \le \sum_{i<n} J(x_i)$, with equality exactly when $x_i = r$ for every $i < n$.

The proofs are free.

Proof. (a) By Proposition 21.5, item 1, and Lemma 21.3, item 1, $x = e^{\log x}$ and $x^{-1} = e^{-\log x}$, so $J(x) = G(\log x)$. Let E_N be the partial sums of the exponential (Proposition 12.88). In $\frac{1}{2}\big(E_{2N+1}(t) + E_{2N+1}(-t)\big)$ the odd powers cancel, and what remains is $1 + \sum_{k<N} t^{2k+2}/(2k+2)!$. Both partial sums converge, so these sums converge to $\frac{1}{2}(e^t + e^{-t}) - 1 = G(t)$.

(b) By the identity $J(y) - J(x) = h(xy-1)/(2xy)$ of the proof of Theorem 22.11, the formula follows from $(1 - x^{-2}) + h/x^3 - h^2/(x^3 y) = 1 - 1/(xy)$. Multiplied by $x^3 y$ this reads $x^3 y - xy + hy - h^2 = x^3 y - x^2$, which holds because $hy - h^2 = hx = xy - x^2$. At $x = 1$ the first-order term vanishes. For convexity, Proposition 22.29(d) gives the gap $\theta(1-\theta)(x-y)^2/(2xy\bar{x})$ with $\bar{x} = \theta x + (1-\theta)y > 0$, a product of positive points when $x \# y$. In logarithmic form, $\cosh(t+u) + \cosh(t-u) = 2\cosh t \cosh u$ (proof of Proposition 21.12, item 1), so the second difference is $2\cosh t(\cosh u - 1) = 2\big(G(t)+1\big)G(u)$. Here $G(t) + 1 \geq 1$, since $G \geq 0$, and $G(u) \geq u^2/2$ by (d); so the second difference is at least u^2, which is positive when $u \# 0$.

(c) $d \geq 0$ and $d(a,b) = d(b,a)$ are properties of $|\cdot|$, and so is the triangle inequality, applied to the points $\log a$, $\log b$, $\log c$. $d(a,b) = 0$ exactly when $\log a = \log b$, which holds exactly when $a = b$, since exp and log invert each other (Proposition 21.5, items 1 and 2). By (a) and Proposition 21.5, item 3, $J(a/b) = G(z)$ with $z = \log a - \log b$. Now $G(-z) = G(z)$, and $G(|z|) = G(z)$: an equation follows from its double negation, $\neg\neg(z \geq 0 \vee z \leq 0)$ holds outright, by the argument in the proof of Theorem 22.12 with 0 in place of 1, and in either case $|z|$ is z or $-z$. Finally $J(2) + J(2) = \frac{1}{2} < \frac{9}{8} = J(4)$.

(d) The terms $t^{2k+2}/(2k+2)!$ are nonnegative, so the partial sums of (a) increase, and each is at most their limit $G(t)$ (Lemma 12.52, item 2); the one with $N = 1$ is $t^2/2$. Next, $J(1+u) = u^2/\big(2(1+u)\big)$ by Proposition 22.15, and $0 < 1 - q \leq 1 + u \leq 1 + q$ gives $1/(1+q) \leq 1/(1+u) \leq 1/(1-q)$.

(e) $C_0 = 1$, and $C_1 C_{n+1} = \frac{1}{4}(x + x^{-1})(x^{n+1} + x^{-n-1}) = \frac{1}{4}(x^{n+2} + x^{-n-2} + x^n + x^{-n}) = \frac{1}{2}(C_{n+2} + C_n)$. Induction on n, two steps at a time, gives $C_n = T_n(C_1)$.

(f) Put $t_i = \log x_i$. By (a) and Proposition 21.5, item 3, $J(x_0 \cdots x_{n-1}) = G(t_0 + \cdots + t_{n-1})$ and $J(x_i) = G(t_i)$. On $[0, \infty)$ the map G is nondecreasing and strictly increasing: for $0 \leq p \leq q$ we have $1 \leq e^p \leq e^q$ (Lemma 21.3, item 4), and $G(p) = J(e^p) \leq J(e^q) = G(q)$ by Proposition 22.15; for $0 \leq p < q$ we have $1 \leq e^p < e^q$ (item 5), and $J(e^q) - J(e^p) = (e^q - e^p)(e^p e^q - 1)/(2e^p e^q) > 0$. Hence $G(|t_i|) = G(t_i) \leq G(a_i)$ gives $|t_i| \leq a_i$: if $a_i < |t_i|$, then $G(a_i) < G(|t_i|)$. So $|t_0 + \cdots + t_{n-1}| \leq a_0 + \cdots + a_{n-1}$, and $G(t_0 + \cdots + t_{n-1})$, which is G of the absolute value of the sum, is at most $G(a_0 + \cdots + a_{n-1})$.

(g) Put $t_i = \log x_i$ and $m = \log r$, so that $\sum_{i<n} t_i = nm$ (Proposition 21.5, item 3). Let $g(v) = e^v - 1 - v$, which is nonnegative by Lemma 21.3, item 2. For all points t and m, expanding the definitions,

$$G(t) = G(m) + (t-m)\sinh m + \tfrac{1}{2}\big(e^m g(t-m) + e^{-m} g(m-t)\big).$$

Summing over $i < n$, the middle terms add to $(\sum_i t_i - nm)\sinh m = 0$, so $\sum_i J(x_i) = nJ(r) + \frac{1}{2}\sum_i R_i$ with $R_i = e^m g(t_i - m) + e^{-m} g(m - t_i) \geq 0$. This gives the inequality. Equality holds exactly when $\sum_i R_i = 0$, that is, when every $R_i = 0$, since a sum of nonnegative points is 0 exactly when each term is. As $e^{\pm m} > 0$, $R_i = 0$ exactly when $g(t_i - m) = g(m - t_i) = 0$, and then

$2G(t_i - m) = g(t_i - m) + g(m - t_i) = 0$, so $J(e^{t_i - m}) = 0$, $e^{t_i - m} = 1$ and $t_i = m$ (Proposition 22.15, Lemma 21.3, item 5); then $x_i = e^{t_i} = r$. Conversely $x_i = r$ gives $R_i = 0$. □

The golden hierarchy prices its gaps with J and weighs its levels by powers of φ^{-1}. An infinite sum below is the limit of its partial sums over $n < N$.

Proposition 22.35 (Golden gaps, golden weights and the golden distribution)**.** *Let $r = \varphi - 1$, so that $r\varphi = \varphi^2 - \varphi = 1$ and $r + r^2 = r\varphi = 1$.*

(a) (R2-24) For every natural number k, $J(\varphi^k) = G(k \log \varphi)$; and $J(\varphi) = \varphi - \frac{3}{2}$, $J(\varphi^2) = \frac{1}{2}$.

(b) (R2-25) The golden weights r^n refine, $r^n = r^{n+1} + r^{n+2}$, and $\sum_{n<N} r^n = \varphi^2(1 - r^N)$; so $\sum_{n \geq 0} r^n = \varphi^2$, and $\sum_{n \geq 0} r^{m+n} = \varphi^2 r^m$ for every m.

(c) (R2-26) The weights $p_n = r^{n+2}$ are positive, with $p_n \varphi^2 = r^n$. Their total is $\sum_n p_n = 1$, their tails are $\sum_n p_{m+n} = r^m$, their mean is $\sum_n n p_n = \varphi$, their second moment is $\sum_n n^2 p_n = \varphi^3 + \varphi^2$, and their variance is $\sum_n (n - \varphi)^2 p_n = \varphi^3$, which is also the limit of $\sum_{n<N} n^2 p_n - \left(\sum_{n<N} n p_n\right)^2$. Each weight has $-\log p_n = (n+2)\log\varphi$, and the entropy is $\sum_n p_n(-\log p_n) = (\varphi + 2)\log\varphi$.

The proofs are free.

Proof. (a) By Proposition 22.34(a) and Proposition 21.5, item 3, $J(\varphi^k) = G(\log \varphi^k) = G(k \log \varphi)$. Since $\varphi^{-1} = r = \varphi - 1$, $J(\varphi) = \frac{1}{2}(2\varphi - 1) - 1 = \varphi - \frac{3}{2}$; and $\varphi^2 + \varphi^{-2} = (\varphi + 1) + (1 - r) = 3$, so $J(\varphi^2) = \frac{1}{2}$.

(b) $r^n - r^{n+1} - r^{n+2} = r^n(1 - r - r^2) = 0$. For the finite sum, both sides are 0 at $N = 0$, and the step from N to $N + 1$ adds r^N on the left and $\varphi^2(r^N - r^{N+1}) = \varphi^2 r^N r^2 = r^N$ on the right. Multiplying by r^m gives $\sum_{n<N} r^{m+n} = \varphi^2 r^m (1 - r^N)$.

The limits here and in (c) follow from the closed forms once r^N, Nr^N and $N^2 r^N$ tend to 0, because sums and products of convergent sequences converge to the sums and products of the limits. The binomial expansion of $(1 + r)^N$ has nonnegative terms, so $(1 + r)^N \geq \binom{N}{3} r^3$, and $r^N(1 + r)^N = 1$. For $N \geq 4$, using $(N - 1)(N - 2) \geq N^2/4$ and $r^3 > \frac{1}{5}$ (as $r = \varphi - 1 > \frac{3}{5}$ by Proposition 22.37(c)),

$$0 \leq N^2 r^N \leq \frac{N^2}{\binom{N}{3} r^3} = \frac{6N}{(N-1)(N-2)\, r^3} \leq \frac{24}{N r^3} < \frac{120}{N}.$$

So for $N \geq 120(k + 1)$ the points $r^N \leq Nr^N \leq N^2 r^N$ are within $1/(k + 1)$ of 0.

(c) $p_n > 0$ as a power of the positive point r, and $p_n \varphi^2 = r^n (r\varphi)^2 = r^n$. From (b), $\sum_{n<N} p_n = r^2\varphi^2(1 - r^N) = 1 - r^N$ and $\sum_{n<N} p_{m+n} = r^m(1 - r^N)$. By induction on N,

$$\sum_{n<N} n p_n = \varphi - (N + \varphi) r^N, \qquad \sum_{n<N} n^2 p_n = \varphi^3 + \varphi^2 - (N^2 + 2\varphi N + 3\varphi + 2) r^N.$$

At $N = 0$ both are 0, since $\varphi^2 = \varphi + 1$ and $\varphi^3 = 2\varphi + 1$ give $\varphi^3 + \varphi^2 = 3\varphi + 2$. The steps need $(N + \varphi) - (N + 1 + \varphi) r = Nr^2$ and $(N^2 + 2\varphi N + 3\varphi + 2) - \big((N + 1)^2 + 2\varphi(N + 1) + 3\varphi + 2\big) r = N^2 r^2$,

and both follow from $\varphi r = 1$, $\varphi - r = 1$ and $1 - r = r^2$. Expanding $(n-\varphi)^2 = n^2 - 2\varphi n + \varphi^2$ and using $\varphi^2 = \varphi + 1$,

$$\sum_{n<N} (n-\varphi)^2 p_n = \varphi^3 - (N^2 + 2\varphi + 1) r^N.$$

The limits are φ, $\varphi^3 + \varphi^2$ and φ^3, and the second moment less the squared mean tends to $(\varphi^3 + \varphi^2) - \varphi^2 = \varphi^3$. Finally $\log r = -\log \varphi$, because $r\varphi = 1$ and $\log 1 = 0$ (Proposition 21.5, item 3); so $-\log p_n = (n+2)\log\varphi$, and

$$\sum_{n<N} p_n (n+2)\log\varphi = \log\varphi\Big(\sum_{n<N} n p_n + 2\sum_{n<N} p_n\Big) = \log\varphi\big(\varphi + 2 - (N+\varphi+2) r^N\big),$$

which tends to $(\varphi+2)\log\varphi$. □

The last groups concern the three-bit carrier, the cube $\{0,1\}^3$ of Proposition 22.27, and the eight-tick signals of Definition 22.7.

Proposition 22.36 (The three-bit carrier and its clock)**.** *Let $B = \{0,1\}^3$. Call two words* adjacent *when they differ in exactly one coordinate, let $h(x,y)$ be the number of coordinates in which x and y differ, and call a sequence $x_0, \dots, x_n$ of words in which consecutive words are adjacent a* walk *of length n from x_0 to x_n.*

(a) (R2-28) The cube has $\binom{3}{k} 2^{3-k}$ faces of dimension k, each obtained by freeing k coordinates and fixing the others: 8 *vertices,* 12 *edges,* 6 *squares and* 1 *cell.*

(b) (R2-29) For all $x, y \in B$ some walk of length $h(x,y)$ runs from x to y, and every walk from x to y has length at least $h(x,y)$. Every walk from a word to itself has even length.

(c) (R2-30) If a sequence of M slots shows every word of B, then $M \geq 8$. The Gray cycle 000, 100, 110, 010, 011, 111, 101, 001 *shows each word once and changes one coordinate at each step, the step from the last word back to the first included.*

(d) (R2-31) The states of n independent three-bit records, the maps from $\{0, \dots, n-1\}$ to B, correspond one to one with the numbers $0, \dots, 8^n - 1$; and an injective encoding of these states by binary words of length k has $3n \leq k$.

(e) (R2-32) For $A \subseteq \{0,1,2\}$ put $\chi_A(x) = (-1)^{\sum_{i \in A} x_i}$. Then $\sum_{x \in B} \chi_A(x)\chi_{A'}(x)$ is 8 if $A = A'$ and 0 otherwise. The Laplacian $(Lf)(x) = \sum_{i<3}\big(f(x) - f(x^{(i)})\big)$, where $x^{(i)}$ is x with coordinate i changed, satisfies $L\chi_A = 2|A|\chi_A$. Every map $f : B \to \mathbb{R}_\delta$ satisfies $f = \sum_A \hat{f}(A)\chi_A$ with $\hat{f}(A) = \frac{1}{8}\sum_x f(x)\chi_A(x)$, and if $f = \sum_A a_A \chi_A$, then $a_A = \hat{f}(A)$ for every A.

(f) (R2-33) Let $s \geq 0$ with $s^2 = 2$, and $\omega = \frac{s}{2}(1 + \mathrm{i})$ in $\mathbb{C}_\delta$. Then $\omega^2 = \mathrm{i}$, $\omega^8 = 1$, $|\omega|^2 = 1$, and the imaginary part of $\omega^7 - 1$ is apart from 0. For signals f, with indices read modulo 8, put $(Sf)(k) = f(k-1)$ and $(Cf)(k) = \omega^k f(k)$ for $0 \leq k \leq 7$. Then $CS = \omega\, SC$; S^8 and C^8 are the identity; S and C keep the energy $\mathscr{E}$; and for the constant signal $\mathbf{1}$ the imaginary part of $(CS\mathbf{1})(0) - (SC\mathbf{1})(0)$ is apart from 0, so CS and SC differ.

(g) (R2-34) Take a pair kinematics (Definition 22.22) in which the pair deforms into the split, and a map P from its configurations to $\mathbb{Z}$ with $P(\mathrm{split}) = 0$. Then either P is not invariant under deformation, or $P(\mathrm{pair}) = 0$. The same assertion for every pair kinematics and every map P into $\mathbb{R}_\delta$ is equivalent to WLPO, with no choice principle in either direction.

Parts (a) to (f), and the first assertion of (g), are free.

Proof. (a) A face of dimension k is given by its k free coordinates, chosen in $\binom{3}{k}$ ways, and the values of the other $3-k$, chosen in 2^{3-k} ways; different choices give different faces.

(b) Changing the coordinates in which x and y differ, one at a time, is a walk of length $h(x,y)$. For adjacent x' and x'' the numbers $h(x',y)$ and $h(x'',y)$ differ by exactly one, so along a walk of length n from x the distance to y drops by at most n, and reaching y, where it is 0, needs $n \geq h(x,y)$. Each step changes the number of coordinates equal to 1 by one, so its parity alternates, and a walk that returns to its start has even length.

(c) For each word the first slot that shows it is found by a bounded search, and different words have different first slots. This injective map from the eight words to $\{0,\dots,M-1\}$ gives $M \geq 8$, by the count in the proof of Proposition 22.28. The Gray cycle is checked step by step.

(d) Read a word x as the digit $x_0 + 2x_1 + 4x_2 \in \{0,\dots,7\}$. The map sending a state w to $\sum_{i<n} 8^i \cdot (\text{digit of } w(i))$ is a bijection onto $\{0,\dots,8^n-1\}$, with inverse the reading of base-8 digits. An injective encoding by binary words of length k gives $8^n \leq 2^k$ by Proposition 22.28; as $8^n = 2^{3n}$ and $k < 3n$ would give $2^k < 2^{3n}$, we get $3n \leq k$.

(e) $\chi_A \chi_{A'} = \chi_U$, where U is the set of coordinates in exactly one of A and A'. If U is empty the sum is 8. Otherwise take $i \in U$: changing coordinate i pairs the words of B and changes the sign of χ_U, so the sum is 0. Changing coordinate i changes the sign of χ_A exactly when $i \in A$, so each $i \in A$ contributes $2\chi_A(x)$ to $(L\chi_A)(x)$ and each other i contributes 0. For the expansion, with $x \oplus y$ the coordinatewise sum modulo 2,

$$\sum_A \chi_A(x)\chi_A(y) = \sum_A \chi_A(x \oplus y) = \prod_{i<3} \bigl(1 + (-1)^{x_i + y_i}\bigr),$$

which is 8 when $y = x$ and 0 otherwise; so $\sum_A \hat{f}(A)\chi_A(x) = \frac{1}{8}\sum_y f(y) \sum_A \chi_A(y)\chi_A(x) = f(x)$. If $f = \sum_A a_A \chi_A$, then $\hat{f}(A') = \frac{1}{8}\sum_A a_A \sum_x \chi_A(x)\chi_{A'}(x) = a_{A'}$ by orthogonality. Only the ring operations of $\mathbb{R}_\delta$ and $8 \cdot \frac{1}{8} = 1$ are used.

(f) $\omega^2 = \frac{s^2}{4}(1+\mathrm{i})^2 = \frac{2}{4} \cdot 2\mathrm{i} = \mathrm{i}$, so $\omega^8 = \mathrm{i}^4 = 1$, and $|\omega|^2 = 2 \cdot \frac{s^2}{4} = 1$. Hence $\omega^7 = \omega^{-1} = \bar{\omega} = \frac{s}{2}(1-\mathrm{i})$, and the imaginary part of $\omega^7 - 1$ is $-s/2$; it is apart from 0, because $s^2 = 2$ makes s apart from 0 and $s \geq 0$ makes it positive. For $1 \leq k \leq 7$, $(\omega SCf)(k) = \omega \cdot \omega^{k-1} f(k-1) = (CSf)(k)$, and at $k = 0$, $(\omega SCf)(0) = \omega \cdot \omega^7 f(7) = f(7) = (CSf)(0)$. S^8 shifts by 8, and C^8 multiplies by $\omega^{8k} = 1$. $|\omega^k f(k)|^2 = |\omega|^{2k}|f(k)|^2 = |f(k)|^2$, and S permutes the entries, so both keep $\mathscr{E}$. Finally $(CS\mathbf{1})(0) = 1$ and $(SC\mathbf{1})(0) = (C\mathbf{1})(7) = \omega^7$, and the imaginary part of $1 - \omega^7$ is $s/2$.

(g) $P(\text{pair})$ is an integer, so $P(\text{pair}) = 0$ or not is decided. In the second case P is not invariant, since invariance would give $P(\text{pair}) = P(\text{split}) = 0$. For maps into $\mathbb{R}_\delta$, WLPO decides $P(\text{pair}) = 0$ or $P(\text{pair}) \neq 0$ (Corollary 12.18), and the same argument applies. Conversely let v be a point. Take the kinematics with two configurations, the split and the pair, in which every configuration deforms into every other, and put $P(\text{split}) = 0$ and $P(\text{pair}) = v$. Then P is invariant exactly when $v = 0$, so the assertion gives $v \neq 0$ or $v = 0$, which is WLPO by Corollary 12.18. □

With Proposition 22.26, part (g) is the second-rung group R2-34: an invariant integer pairing that is nonzero at the pair forbids the deformation, and for integer values the decision is free.

The 48 symmetries of the cube in R2-28 are the signed permutations of the coordinates, by Proposition 24.44(d).

22.9 The constants

From φ the chain reaches the constants of nature in fifteen steps. On the line, fourteen of them are free, and the fifteenth is a decision. We give each with arithmetic a reader can repeat by hand: every decimal bound below becomes a comparison of integers once the denominators are cleared. Three kinds of statement must be kept apart here. A *derivation* is a theorem about points of the line. An *identification* reads such a point as a physical quantity. A *calibration* fixes units or inserts a measured value. The section ends by sorting the steps into these kinds.

Proposition 22.37 (The golden ratio)**.**

(a) $\varphi^2 = \varphi + 1$ *and* $1 < \varphi < 2$.

(b) For natural numbers a *and* $b > 0$, $b\varphi - a \# 0$*:* φ *is apart from every ratio.*

(c) $1.61 < \varphi < 1.62$.

(d) With Fibonacci numbers $F_0 = 0$, $F_1 = 1$, $F_{n+2} = F_{n+1} + F_n$, $\varphi^{n+2} = \varphi^{n+1} + \varphi^n$ *and* $\varphi^{n+1} = F_{n+1}\varphi + F_n$ *for every* n*. In particular* $\varphi^5 = 5\varphi + 3$*, and* $10.7 < \varphi^5 < 11.3$.

The proofs are free.

Proof. (a) With $\sqrt{5} \geq 0$ and $(\sqrt{5})^2 = 5$, $\varphi^2 = (6+2\sqrt{5})/4 = \varphi+1$. Since $(\sqrt{5}-1)(\sqrt{5}+1) = 4 > 0$ and $\sqrt{5}+1 > 0$, $\sqrt{5} > 1$ and $\varphi > 1$; since $(3-\sqrt{5})(3+\sqrt{5}) = 4$, $\sqrt{5} < 3$ and $\varphi < 2$.

(b) From $\varphi^2 = \varphi + 1$, $(b\varphi - a)\big(b(1-\varphi) - a\big) = a^2 - ab - b^2$. The integer $a^2 - ab - b^2$ is not 0 when $b > 0$: a solution of $a^2 = ab + b^2$ has $b < a < 2b$, and then $(b, a-b)$ is a solution with a smaller positive second entry, since $b(a-b) + (a-b)^2 = a^2 - ab = b^2$; descent excludes this. A nonzero integer is apart from 0, so the product is, and so is its factor $b\varphi - a$.

(c) For natural numbers p and $q > 0$,

$$(q\varphi - p)\big(q(\varphi - 1) + p\big) = q^2 + pq - p^2,$$

and the second factor is positive. So $p/q < \varphi$ when $p^2 < q^2 + pq$, and $\varphi < p/q$ when $q^2 + pq < p^2$. Now $161^2 = 25921 < 26100 = 100^2 + 100 \cdot 161$ and $162^2 = 26244 > 26200 = 100^2 + 100 \cdot 162$.

(d) Multiply $\varphi^2 = \varphi + 1$ by φ^n, and induct with the Fibonacci recurrence. Then $\varphi^5 = F_5\varphi + F_4 = 5\varphi + 3$, and (c) gives $11.05 < \varphi^5 < 11.1$. □

We use the comparison in (c) repeatedly. For instance, $1618033^2 = 2\,618\,030\,789\,089 < 2\,618\,033\,000\,000$ and $1618034^2 = 2\,618\,034\,025\,156 > 2\,618\,034\,000\,000$ give $1.618033 < \varphi < 1.618034$.

Proposition 22.38 (The locked constants and the action quantum)**.** *Put $r = \varphi - 1$. Then $r\varphi = 1$ and $1 - r = r^2$. The locked constants $\alpha_{\mathrm{lock}} = (1 - 1/\varphi)/2$ and $C_{\mathrm{lock}} = (\varphi - 1)^5$ satisfy $\alpha_{\mathrm{lock}} = (\varphi - 1)^2/2$, and every point w with $\varphi^5 w = 1$ equals C_{lock}. With the native time unit $\tau_0 = 1$, the action quantum $\hbar = C_{\mathrm{lock}}\tau_0$ satisfies*

$$\hbar = (\varphi - 1)^5 = \varphi^{-5} = 5\varphi - 8, \qquad 0.088 < \hbar < 0.093.$$

The proofs are free.

Proof. $r\varphi = \varphi^2 - \varphi = 1$ and $r^2 + r = \varphi^2 - \varphi = 1$. So $1 - 1/\varphi = 1 - r = r^2$. The inverse of φ^5 is unique, and $\varphi^5 r^5 = 1$; also $(5\varphi + 3)(5\varphi - 8) = 25(\varphi^2 - \varphi) - 24 = 1$, so $r^5 = 5\varphi - 8$. The bounds say $1.6176 < \varphi < 1.6186$, and the comparison of Proposition 22.37(c) gives them: $16176^2 = 261\,662\,976 < 261\,760\,000 = 10000^2 + 10000 \cdot 16176$ and $16186^2 = 261\,986\,596 > 261\,860\,000$. □

Proposition 22.39 (The cube's curvature and the recognition length)**.** *The cube has 8 vertices, 12 edges and 6 faces, so its Euler characteristic is $\chi = 2$. Its faces meet at the angle $\pi/2$; at each vertex three faces meet, leaving the angular deficit $2\pi - 3 \cdot \pi/2 = \pi/2$. Then:*

(a) the eight deficits total $4\pi = 2\pi\chi$;

(b) the curvature coefficient $8 \cdot (\pi/2)/(2\pi)$ equals $\chi = 2$, so the curvature cost $\lambda \mapsto (\text{coefficient}) \cdot \lambda^2$ is $2\lambda^2$;

(c) exactly one point $\lambda > 0$ satisfies $2\lambda^2 = 1$.

The proofs are free.

Proof. The counts are a listing of $\{0,1\}^3$ and its faces. (a) $8 \cdot \pi/2 = 4\pi$ and $2\pi \cdot 2 = 4\pi$. (b) $4\pi/(2\pi) = 2$. (c) The point $\lambda_0 = \sqrt{1/2}$ (Proposition 12.19, item 5) is a positive root, and $\lambda_0\sqrt{2} = 1$ because both sides are nonnegative with square 1. If $\lambda, \mu > 0$ are roots, then $(\lambda - \mu)(\lambda + \mu) = 0$ and $\lambda + \mu > 0$ is invertible, so $\lambda = \mu$. □

Part (a) is Descartes' theorem on the total angular defect, which for the cube is a count. In (b) the coefficient is derived; that the curvature cost of step S6 has the quadratic form $\lambda \mapsto \text{coefficient} \cdot \lambda^2$ is a modelling input of that step, an identification. The constant π is that of Section 21.2, the half-period of the sine (Theorem 21.8); it is $\pi = 4(\arctan\frac{1}{2} + \arctan\frac{1}{3})$, an identity due to Euler, with Gregory's series $\arctan(1/m) = \sum_{j\ge 0}(-1)^j/\big((2j+1)m^{2j+1}\big)$.

The next constants need decimal brackets for exp and log. For $x \ge 0$ put $S_N(x) = \sum_{m<N} x^m/m!$. Every $S_N(x)$ is at most $\exp(x)$, since the partial sums increase to it (Lemma 12.52, item 2). For $0 \le x \le 1$ and $N \ge 1$, $\exp(x) \le S_N(x) + 2x^N/N!$, because $x^{m+1}/(m+1)! \le \frac{1}{2}x^m/m!$ for $m \ge 1$, so the tail from N on is at most $(x^N/N!)(1 + \frac{1}{2} + \frac{1}{4} + \cdots)$. Since log is the inverse of the increasing map exp on positive points (Definition 21.4), $\exp(x) < a$ gives $x < \log a$, and $a < \exp(x)$ gives $\log a < x$.

Proposition 22.40 (Newton's constant, the Einstein coupling and the Boltzmann scale)**.**

(a) $2.7725887 < 4\log 2 < 2.7725888$.

(b) In the native units of the chain, with recognition length $\lambda_{\mathrm{rec}} = 1$, $c = 1$ *and* $\hbar\varphi^5 = 1$, *the Clausius form* $G = \lambda_{\mathrm{rec}}^2 c^3/(4\log 2\cdot\hbar)$ *of Newton's constant equals* $\varphi^5/(4\log 2)$. *The Einstein coupling* $\kappa = 8\pi G/c^4$ *equals* $2\pi\varphi^5/\log 2$, *and* $\kappa\hbar = 2\pi/\log 2$.

(c) The Boltzmann scale $k_R = \log\varphi$ *satisfies* $0.47 < k_R < 0.49$*; more precisely* $0.4812 < k_R < 0.4813$.

The proofs are free.

Proof. (a) Let $x_- = 0.6931471805$ and $x_+ = 0.6931471806$. Exact rational arithmetic gives

$$S_{12}(x_-) + \frac{2x_-^{12}}{12!} = 1.99999999990\ldots < 2, \qquad S_{12}(x_+) = 2.00000000005\ldots > 2.$$

So $x_- < \log 2 < x_+$, and $2.772588722 < 4\log 2 < 2.7725887224$.

(b) $G = 1/(4\log 2\cdot\hbar) = \varphi^5/(4\log 2)$ because $1/\hbar = \varphi^5$. Then $\kappa = 8\pi G = 2\pi\varphi^5/\log 2$ and $\kappa\hbar = 2\pi/\log 2$. With (a) and $11.05 < \varphi^5 < 11.1$, $3.98 < G < 4.01$.

(c) With $1.618033 < \varphi < 1.618034$,

$$S_6(0.4812) + \frac{2\cdot 0.4812^6}{6!} = 1.6180308\ldots < \varphi, \qquad S_6(0.4813) = 1.6181581\ldots > \varphi,$$

so $0.4812 < \log\varphi < 0.4813$. □

The chain does not derive the fine-structure constant. Step S14 says that the coupling is a boundary datum, which no closure condition blind to the coupling can pin, and Proposition 22.43(a) below proves it on the line. What the chain forces is the kinematic part of α^{-1}, $4\pi\varphi^5 - 5\log\varphi$.

Theorem 22.41 (The forced content of α^{-1})**.** *The point* $\alpha_{\mathrm{kin}}^{-1} = 4\pi\varphi^5 - 5\log\varphi$ *satisfies* $136.947 < \alpha_{\mathrm{kin}}^{-1} < 136.959$*; in particular it lies below* 137.030. *The proof is free.*

Proof. Gregory's series is alternating with terms decreasing in size, so its value lies between any two consecutive partial sums. With A_J and B_J the sums of the first J terms for $m = 2$ and $m = 3$, this gives $4(A_{10} + B_8) < \pi < 4(A_{11} + B_7)$, that is,

$$3.1415925 < 3.14159257797\ldots < \pi < 3.14159268738\ldots < 3.1415927.$$

By Proposition 22.37(d), $11.090165 < \varphi^5 < 11.09017$, so $139.36311 < 4\pi\varphi^5 < 139.36319$; and $2.406 < 5\log\varphi < 2.4065$ by Proposition 22.40(c). Hence $136.95661 < \alpha_{\mathrm{kin}}^{-1} < 136.95719$. □

Step S13 keeps a witness value $\sigma\exp(-f/\sigma)$, built on the seed $\sigma = 4\pi\cdot 11 = 44\pi$ with a gap term f through an exponential; the photon normalization that fixes it is one of the calibrations listed at the end of this section. We treat it as a construction. Reading it as the inverse fine-structure constant is an identification that no theorem here uses; by step S14 the coupling itself is a boundary datum. Its band and the uniqueness of its exponential form are both free.

Theorem 22.42 (The band and the exponential form of the witness α_W^{-1})**.** *Let $\sigma = 44\pi$.*

(a) For every $s \geq 0$ with $s^2 = 2$, put $w_8 = \big(348 + 210s - (204 + 130s)\varphi\big)/7$, $f = w_8 \log\varphi$ and $\alpha_W^{-1} = \sigma\exp(-f/\sigma)$. Then $137.030 < \alpha_W^{-1} < 137.039$.

(b) Let $g : \mathbb{R}_\delta \to \mathbb{R}_\delta$ have positive values and $g(0) = \sigma$, and suppose that $\log\circ g$ has uniform derivative $-1/\sigma$ on every bounded interval: for all natural numbers T and k there is a j such that

$$\left|\log g(t) - \log g(u) + \frac{t-u}{\sigma}\right| \leq \frac{|t-u|}{k+1}$$

whenever $|t|, |u| \leq T$ and $|t-u| \leq 1/(j+1)$. Then $g(x) = \sigma\exp(-x/\sigma)$ for every x.

The proofs are free.

Proof. (a) Since $1414213^2 = 1\,999\,998\,409\,369 < 2 \cdot 10^{12} < 2\,000\,001\,237\,796 = 1414214^2$, $1.414213 < s < 1.414214$. On these ranges w_8 decreases in s (its coefficient $(210 - 130\varphi)/7$ is negative, as $\varphi > 21/13$) and in φ, so $2.4905686 < w_8 < 2.4906241$, and with Proposition 22.40(c), $1.19846 < f < 1.19874$. The bracket for π gives $138.23007 < \sigma < 138.23008$. For $0 \leq y \leq 1$ the series of $\exp(-y)$ alternates with decreasing terms, so $1 - y \leq \exp(-y) \leq 1 - y + y^2/2$. With $y = f/\sigma$,

$$\sigma - f \leq \alpha_W^{-1} \leq \sigma - f + \frac{f^2}{2\sigma},$$

and the brackets give $137.03133 < \alpha_W^{-1} < 137.03682$.

(b) Put $h = \log\circ g$ and fix x, a natural number $T \geq |x|$ and k; take j from the hypothesis. With $N = (T+1)(j+1)$ the points $t_i = ix/N$, $i \leq N$, lie in $[-T, T]$ and are spaced by $|x|/N \leq 1/(j+1)$. Telescoping,

$$\left|h(x) - h(0) + \frac{x}{\sigma}\right| \leq \sum_{i<N}\left|h(t_{i+1}) - h(t_i) + \frac{t_{i+1} - t_i}{\sigma}\right| \leq \frac{|x|}{k+1}.$$

This holds for every k, so $h(x) = \log\sigma - x/\sigma$. Applying exp, which inverts log and turns sums into products, $g(x) = \sigma\exp(-x/\sigma)$. □

The witness, as a function of the gap, meets the hypothesis of (b), so the statement is not empty, and on the line the uniqueness of its exponential form is a theorem. Reading α_W^{-1} as the inverse fine-structure constant is an identification, and no part of the theorem; the forced part α_{kin}^{-1} lies below the band of (a).

Proposition 22.43 (What the constants cannot fix)**.**

(a) Let $A > 0$. No point t satisfies $\kappa A = t$ for every $\kappa > 0$. If a property P of points does not depend on its argument, that is, $P(\kappa) \Leftrightarrow P(\kappa')$ for all κ, κ', and holds for some κ, then no point t satisfies $\kappa A = t$ for every $\kappa > 0$ with $P(\kappa)$.

(b) *The exponents of length, time and mass in $c^a\hbar^b G^d$ are $a+2b+3d$, $-a-b-2d$ and $b-d$. The determinant of this linear map is -2, so the monomial is dimensionless only for $a=b=d=0$.*

(c) *For positive points $\hbar_{\mathrm{SI}}$ and c_{SI}, the map $G \mapsto \pi\hbar_{\mathrm{SI}}G/c_{\mathrm{SI}}^5$ sends positive points to positive points and is injective.*

The proofs are free.

Proof. (a) $\kappa = 1$ and $\kappa = 2$ would give $A = t = 2A$, so $A = 0$. A property that holds for some κ and does not depend on its argument holds at 1 and at 2. (b) c, $\hbar$ and G have dimensions LT^{-1}, ML^2T^{-1} and $L^3M^{-1}T^{-2}$. The matrix with rows $(1,2,3)$, $(-1,-1,-2)$ and $(0,1,-1)$ has determinant $1\cdot 3 - 2\cdot 1 + 3\cdot(-1) = -2$, and a linear map of nonzero determinant has only the zero solution. (c) $\pi\hbar_{\mathrm{SI}}/c_{\mathrm{SI}}^5$ is positive, hence invertible. □

Read physically, (a) says that no closure condition blind to the coupling can pin the value of α: it is a boundary datum. Parts (b) and (c) say that values in SI units need an anchor, and that the map from an input G to the squared SI tick is a calibration, not a prediction.

The one priced constant is a test. The units check of step S11 tests four approximate equalities $|a-b| \le 10^{-6}$ as yes-or-no questions.

Theorem 22.44 (The units test costs exactly WLPO and fails at its own values)**.**

(a) *The assertion that $|a-b| \le t$ or $\neg(|a-b| \le t)$ for all points a, b, t is equivalent to WLPO. A map f from triples of points to $\{0,1\}$ with $f(a,b,t) = 1$ exactly when $|a-b| \le t$ exists if and only if the WLPO function exists. No choice principle is used.*

(b) *Let units τ_0, ℓ_0, c satisfy $c\tau_0 = \ell_0$ with τ_0 and ℓ_0 apart from 0, and put $\tau_{\mathrm{rec}} = 2\pi\tau_0/(8\log\varphi)$ and $\lambda_{\mathrm{kin}} = 2\pi\ell_0/(8\log\varphi)$. Then $\tau_{\mathrm{rec}}/\tau_0 = \lambda_{\mathrm{kin}}/\ell_0 = \pi/(4\log\varphi)$ and $c\,\tau_{\mathrm{rec}} = \lambda_{\mathrm{kin}}$. Exactly one $K \ge 0$ has $K^2 = \varphi$, and $1 < K < 3/2$. Moreover $\pi/(4\log\varphi) > 3/2$. Free.*

(c) *The units check of step S11 takes base units $\tau_0 = \ell_0 = c = 1$, scaled units $\tau_0 = \ell_0 = 2$, $c = 1$, and tolerance 10^{-6}. It tests the base clock ratio against the base length ratio, the base clock ratio against 1, the scaled clock ratio against the scaled length ratio, and the base clock ratio against the scaled clock ratio, and it passes when all four tests pass. For every map f as in (a), the check fails: the second test returns 0.*

Proof. (a) $|r-0| \le 0$ holds exactly when $r = 0$, so the decision at $(r,0,0)$ is $r = 0$ or $r \ne 0$, which is WLPO (Corollary 12.18); and $f(j_\alpha, 0, 0)$ is the WLPO function. Conversely, $|a-b| \le t$ holds exactly when $\max(|a-b|, t) = t$, an equality, which WLPO decides and the equality test of Lemma 22.13 decides as data.

(b) The ratios are $2\pi/(8\log\varphi)$ in both cases, and $c\tau_{\mathrm{rec}} = 2\pi\ell_0/(8\log\varphi)$. The root K exists and is unique by Proposition 12.19, item 5; $(1+K)(K-1) = \varphi - 1 > 0$ gives $K > 1$, and $(3-2K)(3+2K) = 9 - 4\varphi > 0$, as $\varphi < 2$, gives $K < 3/2$. Next, $(31+48\varphi)(79-48\varphi) = 2449 - 2304(\varphi^2 - \varphi) = 145 > 0$, so $48\varphi < 79$, and $79/48 = 1 + \frac{1}{2} + \frac{1}{8} + \frac{1}{48} = S_4(\frac{1}{2}) \le \exp(\frac{1}{2})$; so $\log\varphi < \frac{1}{2}$. With $\pi > 3$ and $\log\varphi > 0$, $\pi/(4\log\varphi) > 3/2$.

(c) By (b), the clock and length ratios are equal in each pack, and halving both τ_{rec} and τ_0 leaves the ratio unchanged; so the first, third and fourth tests compare equal points and return 1. The second compares $\pi/(4\log\varphi)$ with 1, and their difference exceeds $1/2 > 10^{-6}$, so it returns 0. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; the check's packs and tolerance as step S11 states them.

Conclusion

The test as a total yes-or-no decision is exactly WLPO, and as one map it is exactly the WLPO function. At the values of step S11 the check fails for every faithful test, with no principle: one of its comparisons is refuted outright. The clock ratio $\pi/(4\log\varphi)$, about 1.632, is compared with 1 rather than with K, and it differs from both.

Not claimed

Anything about the physical constants themselves: the packs are unit conventions, and the theorem is about the test.

Derived, identified and calibrated

Of the fifteen steps of the constants, fourteen are free and one, the test, costs exactly WLPO. The steps divide as follows.

Derived

Theorems about points of the line: the properties and bounds of φ and its powers; α_{lock}, C_{lock} and $\hbar = \varphi^{-5}$ with its bounds; the cube's total deficit 4π and the coefficient $\chi = 2$; the unique positive root of $2\lambda^2 = 1$; $G = \varphi^5/(4\log 2)$, $\kappa = 2\pi\varphi^5/\log 2$ and $k_R = \log\varphi$ with their bounds; the identities of the units test; $\alpha_{\mathrm{kin}}^{-1}$ with its bounds; the band and the uniqueness of the exponential form; and the two boundary statements.

Identified

Readings, named and not priced: the quadratic form of the curvature cost; G as the Clausius coefficient with one bit per face; k_R in units of temperature; the gap formula α_W^{-1} read as the inverse fine-structure constant, an identification that no theorem here uses (by step S14 the coupling is a boundary datum); and the line's log and π read as the classical logarithm and circle constant.

Calibrated

Six calibrations, named and not priced: the native units (tick, voxel and c equal to 1, with λ_{rec} the voxel); the unit of bit cost; the photon normalization; the measured values of c, $\hbar$ and G in SI units; the anchor of the SI bridge (seconds per tick, metres per voxel, joules per unit of cost); and the measured value of α^{-1} with its uncertainty.

Selecting the complete table of constants physically is not one of the fifteen steps, and this chapter does not price it.

22.10 The numbered chain, step by step

The chain also comes as one numbered sequence. It begins with T−2, "nothing is not something", and T−1, the floor below logic; it passes through the Boolean floor of logic and cost (T0–T4), the uniqueness of J and of φ (T5, T6), the count of eight states and three dimensions (T7, T8), and a run of structural steps (T9–T15); and it ends with the constants, the masses on the golden ladder, a series of formulas compared with measured values, and three counts (T16–T41). A separate statement bounds the period of a walk through the eight states. What T7 states, as restated in Table 22.1, is the count $2^3 = 8$, the number of states of three bits; it contains no process and no period. A period enters only through the separate bound: a periodic walk that reaches all eight states has period at least 8. We write Cn for step Tn of this sequence, and P8 for the period bound, to keep these steps apart from the segments T1–T4 of the first rung, which number other statements. Each step is a short list of statements.

We read the sequence on the line as in Section 22.1, statement by statement. A real number becomes a point of $\mathbb{R}_\delta$; φ, π, log, exp and square roots are those of the line; a power φ^t with a point t as exponent is $e^{t \log \varphi}$, which at an integer t is the ordinary power; a measured number written into a statement, such as 0.2229, is the same ratio, $2229/10000$; and a quotient x/y is x times the inverse of a positive point y. Statements about counts, finite lists and finite sets are read as they stand. The native statement keeps every statement of the restated step and adds none; step C11 is restated for every assignment of virtues to its fourteen names.

Many steps are a definition followed by arithmetic, and the native statement then proves exactly that arithmetic. Where a step compares a formula with a measured value, the theorem is the comparison of the ratios and points involved. Whether the formula is the physical quantity it is named after is an identification, and whether the measured value is right is an observation; neither enters the price.

Theorem 22.45 (The numbered chain is free)**.** *Read on $\mathbb{R}_\delta$ as above, every step C−2, C−1, C0, ..., C41 of the numbered chain, and the period bound P8, holds with no omniscience principle and no choice principle.*

Proof. C−2, C−1 and C0–C4 are Proposition 22.47. C5, the uniqueness of J, is Theorem 21.14 with Theorem 22.12; C6, φ as the unique positive root of $\lambda^2 = \lambda + 1$, is Proposition 22.37(a) with the uniqueness argument in the proof of Theorem 22.20(b). The counting steps C7, C12, C14, C27, C28, C35, C39, C40, C41, the arithmetic of C8 and the counts of C31 are Proposition 22.48; the rest of C8 and the bound P8 are Proposition 22.49, and the topological form of C8 and the linking statement of C9 are step T4.4, proved free in Chapter 23. The symmetry count of C12 is Proposition 24.44(d) (row R2-28). C9, C15, C25, C29, C30, C31 and C37 are Proposition 22.50, and C36 is Proposition 22.15. C10, C11 and C13 are Proposition 22.51. C16–C18, C20–C24, C26, C32–C34 and C38 are Theorem 22.52, and C19 is Theorem 22.53. Each of these results is proved below or earlier with no omniscience principle and no choice principle. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; each step of the numbered chain as restated in Table 22.1, read statement by statement; the measured numbers written into its statements, taken as the same ratios.

Conclusion

Every step of the numbered chain, T−2 to T41, and the period bound are free. None of the eleven priced rows of Table 22.1 is a step of this sequence.

Not claimed

That the formulas are the physical quantities they are named after, or that the measured values are correct. For C11, that any particular fourteen maps are virtues: the restated step covers every assignment of virtues to the fourteen names, and its proof uses nothing beyond the law that defines a virtue. For C8, more than the integer encoding of linking in the step; its topological form is step T4.4.

What makes the native proofs free is the same in every step. They compute with counts, signed counts and ratios, which compare for free (Proposition 22.2); they use the field laws and the order of the line in its apartness form; they bound φ, π, $\log 2$ and $\log \varphi$ by the integer comparisons of Section 22.9; and they never decide whether two points are equal, or which sign a point has, unless it is known to be apart from 0. A classical proof of such a step may split on excluded middle or count a finite set through a choice principle: for C−1 it may argue by cases on whether P holds; a Gray cycle in every dimension, or a time at which a periodic walk reaches each corner, may be obtained by a choice; and a finite set may be counted through an enumeration chosen for it. The native proofs need none of this: $P \neq \neg P$ needs no case split, the Gray cycle is written down, each corner's first visit is found by a bounded search, and the counts are made on explicit lists.

Definition 22.46 (The Boolean floor)**.** The *floor* has two states, the *empty* state e and the *marked* state m. The *join* of two states is m when either is m, and e otherwise. A state is *consistent* when it is e, and two states are *independent* when at least one of them is e. A *cost* on the floor assigns to each state Γ a point $C(\Gamma) \geq 0$ of $\mathbb{R}_\delta$, with $C(\Gamma) = 0$ exactly when Γ is consistent, and $C(\mathrm{join}(\Gamma_1, \Gamma_2)) = C(\Gamma_1) + C(\Gamma_2)$ for independent Γ_1, Γ_2. The *floor cost* is $C(e) = 0$, $C(m) = 1$.

Proposition 22.47 (The floor of the chain is free)**.**

(a) (C−2) A set with no element is not equal to a set with one element.

(b) (C−1) No proposition equals its negation, and two different propositions exist. A set with an element has two different elements exactly when some property holds of one of its elements and fails of another; the floor has both.

(c) (C0) The floor cost is a cost. It is positive exactly on the inconsistent state, and every cost that agrees with it on a set S of states agrees with it on the join of any two independent states of S.

(d) (C1) An inconsistent state has positive cost, a state of cost 0 is consistent, and $C(m) > 0$.

(e) (C2) Every state is e or m, and $e \neq m$; a state of cost 0 is e, and a state of positive cost is m.

(f) (C3) $C(e) = 0$; $\mathrm{join}(e, \Gamma) = \Gamma$ and $C(\mathrm{join}(e, \Gamma)) = C(\Gamma)$ for every state; costs add over independent joins.

(g) *(C4) The floor is a two-point floor normalized by* $C(e) = 0$ *and* $C(m) = 1$*: two different states, every state one of them, consistent exactly when empty. It carries a recognition structure, its states with the relation of equality, and a recognition, the ordered pair* (e, e)*.*

The proofs are free.

Proof. (a) An equation between the two sets would carry the element of the second to an element of the first.

(b) Suppose $P = \neg P$. If P held, then $\neg P$ would hold too, which is absurd; so $\neg P$. But $\neg P$ is P, so P holds, a contradiction. The argument makes no case split on P. The propositions "true" and "false" differ, because the first holds and the second does not. If $x \neq y$, the property "equals x" holds of x and fails of y; conversely an element with a property and an element without it are different. On the floor, $e \neq m$.

(c)–(g) Every statement concerns the two states, and each is checked state by state. This is a case split on a two-element set, not on a proposition. The values are $C(e) = 0$ and $C(m) = 1$, and $0 < 1$; so $C \geq 0$, $C = 0$ exactly at e, and $C > 0$ exactly at m. The independent pairs are (e, e), (e, m) and (m, e), with joins e, m, m and costs $0 = 0 + 0$, $1 = 0 + 1$ and $1 = 1 + 0$, and $\mathrm{join}(e, \Gamma) = \Gamma$ for both states. If a cost C' agrees with C on S, and $\Gamma_1, \Gamma_2 \in S$ are independent, additivity of both gives $C(\mathrm{join}(\Gamma_1, \Gamma_2)) = C(\Gamma_1) + C(\Gamma_2) = C'(\Gamma_1) + C'(\Gamma_2) = C'(\mathrm{join}(\Gamma_1, \Gamma_2))$. The relation of equality and the pair (e, e) are given outright. □

The counting steps are identities between natural numbers, integers and ratios. They hold for the reason records compare for free: both sides are computed.

Proposition 22.48 (Every count and ratio identity of the chain is free)**.** *Each of the following holds, with no omniscience principle and no choice principle.*

(a) *(C7, C8)* $2^3 = 8$*. For a natural number* D*, each of* $D - 2 = 1$ *(in the integers) and* $2^D = 8$ *gives* $D = 3$*.*

(b) *(C12) The numbers recorded in step C12 for its three gauge layers form the triple* $(3, 2, 1)$*;* $3 + 2 + 1 = 6 = 2 \cdot 3$*, the number of faces of the cube* $\{0, 1\}^3$*; and the recorded numbers are not* 4*,* 3 *and* 2*.*

(c) *(C14, C27, C28) The cube* $\{0, 1\}^3$ *has* 3 *pairs of opposite faces, one for each axis, and* $3 \neq 2$*,* $3 \neq 4$*.*

(d) *(C31)* $56 = 7 \cdot 8$*, and* $50 \leq 56 \leq 70$*.*

(e) *(C35)* $\frac{23}{4} - \frac{31}{4} = -2$*,* $-2 - \frac{10}{4} = -\frac{9}{2}$ *and* $-\frac{9}{2} - \frac{22}{4} = -10$*.*

(f) *(C39) List the pairs* (n, l) *of natural numbers with* $1 \leq n \leq 7$*,* $l < \min(4, n)$ *and* $n + l \leq 8$ *in order of increasing* $n + l$*, and of increasing* n *when* $n + l$ *ties, and give* (n, l) *the capacity* $2(2l + 1)$*. There are* 19 *pairs; their running totals are* 2*,* 4*,* 10*,* 12*,* 18*,* 20*,* 30*,* 36*,* 38*,* 48*,* 54*,* 56*,* 70*,* 80*,* 86*,* 88*,* 102*,* 112*,* 118*; and the number* 1 *falls in the first pair,* $(1, 0)$*, which has* $l = 0$*.*

(g) *(C40) A set listed as four different letters U, C, A, G has exactly four elements;* $4^3 = 64$*; and* $3 \cdot 8 - 4 = 20$.

(h) *(C41)* $2^{3+1} = 16$, $3 + 2 = 5$ *and* $16 - 5 = 11$.

Proof. Each item compares counts, signed counts or ratios given by explicit expressions, and by Proposition 22.2 such comparisons are decided by computing both sides. We record the computations. (a) $2^3 = 8$; $D - 2 = 1$ gives $D = 3$ in the integers; and $2^0, 2^1, 2^2 = 1, 2, 4$ while $2^D \geq 16$ for $D \geq 4$. (b) The record is $(3, 2, 1)$ term by term, $3 + 2 + 1 = 6$, and the cube has two faces for each of its three axes, one with the coordinate 0 and one with 1; $3 \neq 4$, $2 \neq 3$, $1 \neq 2$. (c) The faces with a given coordinate fixed are the two opposite faces of that axis, so there are 3 pairs. (d) $7 \cdot 8 = 56$. (e) In quarters: $23 - 31 = -8$, $-8 - 10 = -18$ and $-18 - 22 = -40$. (f) The pairs in order are $(1, 0)$, $(2, 0)$, $(2, 1)$, $(3, 0)$, $(3, 1)$, $(4, 0)$, $(3, 2)$, $(4, 1)$, $(5, 0)$, $(4, 2)$, $(5, 1)$, $(6, 0)$, $(4, 3)$, $(5, 2)$, $(6, 1)$, $(7, 0)$, $(5, 3)$, $(6, 2)$, $(7, 1)$, with capacities $2, 2, 6, 2, 6, 2, 10, 6, 2, 10, 6, 2, 14, 10, 6, 2, 14, 10, 6$; summing gives the totals, and the first total, 2, is at least 1. (g) Every element is one of the four letters and no two letters are equal; $4^3 = 64$ and $24 - 4 = 20$. (h) $2^4 = 16$. □

The items prove the arithmetic of the steps as restated in Table 22.1. The steps define the number of generations, and the sizes of the two mixing matrices, as the number of face pairs of the cube; the three gauge numbers are values assigned to the layers, not consequences of a group; the quark residues are quarter-rung values, and in the restatement the integer rungs are the core convention and the quarter ladder is a hypothesis; the pairs (n, l) are subshells and 118 the last element; and the 16 modes split as step C41 assigns them. Reading these numbers as generations, gauge groups, quarks, elements, codons or modes is an identification; the proposition proves the arithmetic.

Proposition 22.49 (Dimension three and the period bound)**.**

(a) *(C8) Call a natural number D* compatible *when $D - 2 = 1$, $2^D = 8$, 2^D divides* 360*, the 2^D points of $\{0, 1\}^D$ can be listed in a cycle in which each point differs from the next, and the last from the first, in exactly one coordinate, and three structural conditions of step C8, stated in a form every dimension meets. Exactly one natural number is compatible, namely* 3.

(b) *(P8) Let w be a sequence of points of $\{0, 1\}^3$ and $p > 0$ a natural number with $w(n+p) = w(n)$ for every n. If every point of $\{0, 1\}^3$ is a value of w, then $p \geq 8$.*

The proofs are free.

Proof. (a) For $D = 3$: $3 - 2 = 1$, $2^3 = 8$, $360 = 45 \cdot 8$, and the cycle

$$000,\ 100,\ 110,\ 010,\ 011,\ 111,\ 101,\ 001$$

lists the eight points once each, with each point, and the last against the first, differing from the next in one coordinate. A compatible D has $D - 2 = 1$, so $D = 3$ by Proposition 22.48(a).

(b) By induction on q, $w(r+qp) = w(r)$, so every value of w is one of $w(0), \ldots, w(p-1)$. Equality of points of $\{0, 1\}^3$ is decided coordinate by coordinate, so for each point x the least $r < p$ with

$w(r) = x$ is found by checking $r = 0, 1, \dots, p-1$ in turn. Different points have different first visits, so this is an injective map from the eight points to $\{0, \dots, p-1\}$, and $p \geq 8$ by the count in the proof of Proposition 22.28. □

The golden ladder carries the masses of the chain. For an integer n we write φ^n for the ordinary power when $n \geq 0$ and for $(\varphi - 1)^{-n}$ when $n < 0$; since $\varphi(\varphi - 1) = 1$, $\varphi^{a+b} = \varphi^a \varphi^b$ for all integers, and $\varphi^n = e^{n \log \varphi}$. The ladder is $m(r) = \varphi^{-5} \varphi^r$ for integers r.

Proposition 22.50 (The golden ladder is free)**.**

(a) (C15) $\varphi > 1$ *and* $\varphi^2 = \varphi + 1$*. For every* $y > 0$*, integer* r *and point* g*,* $y\varphi^{r-8+g} > 0$*; the ladder is this law at* $y = \varphi^{-5}$ *and* $g = 8$*.*

(b) (C29) Every $m(r)$ *is positive, and* $r < s$ *gives* $m(r) < m(s)$*; so* $r_1 < r_2 < r_3$ *gives* $m(r_1) < m(r_2) < m(r_3)$*.*

(c) (C25) $m_e = m(2)$ *is positive, and every* $m_p = m(r_p)$ *satisfies* $m_p / m_e = \varphi^{r_p - 2}$*.*

(d) (C30) The valence mass $3m(4)$ *and the binding mass* $m(14)$*, at the binding rung* 14 *of the step, are positive,* $m(14) > 40 \cdot 3m(4)$*, and their sum is positive.*

(e) (C31) $1 < 56/\varphi^8 < 6/5$*.*

(f) (C37) $\eta = \varphi^{-44}$ *is positive, and* $\eta \varphi^{44} = 1$*.*

(g) (C9) For positive points $c_1, \dots, c_N$ *and a set* S *of indices,* $\sum_{i \in S} J(c_i) = 0$ *exactly when* $c_i = 1$ *for every* $i \in S$*.*

The proofs are free.

Proof. (a) Proposition 22.37(a). Exponentials are positive (Section 21.2), so $\varphi^{r-8+g} = e^{(r-8+g)\log\varphi} > 0$, and so is its product with y. At $y = \varphi^{-5}$, $g = 8$ the law gives $\varphi^{-5}\varphi^r = m(r)$.

(b) Powers of the positive point φ are positive. For $k \geq 1$, $\varphi^k > 1$ by induction, since $\varphi^{k+1} - \varphi^k = \varphi^k(\varphi - 1) > 0$. Then $m(s) - m(r) = m(r)(\varphi^{s-r} - 1) > 0$ for $r < s$.

(c) $m(r_p)/m(2) = \varphi^{r_p - 5}\varphi^{5-2} = \varphi^{r_p - 2}$.

(d) $m(14) = \varphi^{10} m(4)$, and $\varphi^{10} = 55\varphi + 34$ by Proposition 22.37(d). Since $86^2 = 7396 < 7755 = 55^2 + 55 \cdot 86$, the comparison in the proof of Proposition 22.37(c) gives $86/55 < \varphi$, so $\varphi^{10} > 86 + 34 = 120$ and $m(14) > 120\, m(4)$.

(e) $\varphi^8 = 21\varphi + 13$. From $\varphi < 2$, $\varphi^8 < 55 < 56$. From $101^2 = 10201 < 10332 = 63^2 + 63 \cdot 101$, $\varphi > 101/63$, so $\varphi^8 > 101/3 + 13 = 140/3$, that is, $6\varphi^8 > 280 = 5 \cdot 56$.

(f) $\varphi^{-44}\varphi^{44} = \varphi^0 = 1$.

(g) Each $J(c_i) \geq 0$ (Proposition 22.15). If $a, b \geq 0$ and $a + b = 0$, then $0 \leq a \leq a + b = 0$, so $a = 0$ and $b = 0$; by induction on S, a sum of nonnegative points is 0 exactly when each term is. And $J(c) = 0$ exactly when $c = 1$. □

Three steps remain that are neither counts nor numbers.

Proposition 22.51 (Conservation, virtues and the half-period phase)**.**

(a) (C10) An eight-tick signal *is a map from* $\{0,\dots,7\}$ *to the complex numbers* $\mathbb{C}_\delta$ *of the line. Step C10 defines the total charge Z of a signal to be* 0*, so every map of signals conserves it. If a map R of a set and an integer-valued z satisfy* $z(R(s)) = z(s)$ *for every s in a subset P that R maps into itself, then* $z(R^n(s)) = z(s)$ *for every* $s \in P$ *and every n.*

(b) (C11) A moral state *carries a finite ledger of directed bonds with positive multipliers, an agent, a tick and a positive energy. Its* skew *is the sum of the logarithms of the multipliers of the agent's outgoing bonds minus that of its incoming bonds, and a finite list of states is* admissible *when its skews sum to* 0*. A* virtue *is a map of lists of states that sends admissible lists to admissible lists and, on lists whose ticks lie within* 8 *of each other, gives ticks at most* 8 *after every old tick. For every assignment of virtues to the fourteen named virtues of step C11, each of them and every composition of them sends admissible lists to admissible lists. The identity map is a virtue, and the empty list is admissible.*

(c) (C13) $\cos\pi = -1$, $\sin\pi = 0$, $\cos 0 = 1$ *and* $\sin 0 = 0$*. So the eight-tick phase* $\cos(k\pi/4) + \mathrm{i}\sin(k\pi/4)$ *is* -1 *at* $k = 4$ *and* 1 *at* $k = 0$*.*

The proofs are free.

Proof. (a) Both sides are 0. For the second statement, R^n maps P into P, and $z(R^{n+1}(s)) = z(R(R^n(s))) = z(R^n(s))$; induct on n.

(b) Each virtue sends admissible lists to admissible lists by definition. A composition applies the virtues of a list of names in turn; induct on the list. The identity keeps the list and its ticks, and the empty sum is 0.

(c) Theorem 21.8 gives $\cos(\pi/2) = 0$ and $\sin(\pi/2) = 1$, and the addition formulas for the cosine and the sine (Section 21.2) give $\cos\pi = \cos^2(\pi/2) - \sin^2(\pi/2) = -1$ and $\sin\pi = 2\sin(\pi/2)\cos(\pi/2) = 0$. At 0 the two series give $\cos 0 = 1$ and $\sin 0 = 0$. □

Item (a) is as thin as it reads: step C10, as restated, defines the total charge as 0, and the theorem proves no more. Item (b) is the law that defines a virtue, carried through compositions; the step needs nothing else.

The constants and predictions of the sequence come next. Several of these steps contain measured values; we name them where they enter, and $\alpha_m = 0.0072973525643$ denotes the measured fine-structure constant used in the steps, as a ratio. The count $W = 17$ is the number of wallpaper groups [174], a classical count that enters as a given number.

Theorem 22.52 (The constants and comparisons of the numbered chain)**.** *With no omniscience principle and no choice principle:*

(a) (C16) In native units $\tau_0 = \ell_0 = 1$ *put* $c = \ell_0/\tau_0$, $\hbar = \varphi^{-5}\tau_0$, $G = \varphi^5/(4\log 2)$ *and* $\ell_P = \sqrt{\hbar G/c^3}$*. Then* $c = 1$*;* $\hbar$ *is the integer power* φ^{-5}*, and* $G \cdot 4\log 2$ *the integer power* φ^5*;* $G\hbar = 1/(4\log 2)$*; and* $\ell_P = \sqrt{1/(4\log 2)}$*.*

(b) *(C17) The seed, the cube's total angular deficit* 4π *times* $11 = 12-1$ *(the twelve edges less the one active edge of a tick), is* 44π*; the seam numerator and denominator are* $6 \cdot 17 + 1 = 103$ *and* $6 \cdot 17 = 102$*; and* $137.030 < \alpha_W^{-1} < 137.039$*, with* α_W^{-1} *as in Theorem 22.42(a) at* $s = \sqrt{2}$*.*

(c) *(C18) With* $B = -2 \cdot 11 = -22$*,* $R_0 = 2^2 \cdot 17 - (8-2) = 62$ *and coherence exponent* $2^3 - 3 = 5$*, the electron's structural mass on its rung* $r_e = 2$*,* $2^B \varphi^{-5} \varphi^{R_0} \varphi^{r_e - 8}$*, equals* $2^{-22}\varphi^{51}$ *and is positive.*

(d) *(C20, C24)* $s_W = (3-\varphi)/6$ *satisfies* $0 < s_W < 1/2$ *and* $|s_W - 0.2229| < 0.01$*, and* $0.76 < (3+\varphi)/6 < 0.78$*. With the measured masses of step C24,* $m_H = 125.25$*,* $m_W = 80.3692$ *and* $m_Z = 91.1876$*:* $|m_H/m_W - \varphi| < 0.1$ *and* $m_W/m_Z < 1$*.*

(e) *(C21)* $2/17 = 2/W$*, and* $|2/17 - 0.1179| < 0.0009$*.*

(f) *(C22)* $|\varphi^{-3} - \frac{3}{2}\alpha_m - 0.22500| < 0.00067$*,* $|\frac{1}{24} - 0.04182| < 0.00085$ *and* $|\frac{1}{2}\alpha_m - 0.00369| < 0.00011$*.*

(g) *(C23, C26, C34)* $\Omega_\Lambda = \frac{11}{16} - \alpha_m/\pi$ *satisfies* $0.6851 < \Omega_\Lambda < 0.6852$*; so* $0 < \Omega_\Lambda < 1$*,* $0 < 1 - \Omega_\Lambda < 1$ *and* $|\Omega_\Lambda - 0.6847| < 0.0073$*. Also* $\frac{13}{12} = \frac{12+1}{12}$*, and* $|67.4 \cdot \frac{13}{12} - 73.04|/73.04 < 0.0005$*.*

(h) *(C32)* $b_0 = 11/(2\pi)$ *with* $11 = 3 \cdot 2^2 - 1$*; and with* $\hbar = \varphi^{-5} = e^{-5\log\varphi}$ *and* $\ell_0 = 1$*, every point* r *satisfies* $\hbar/(\ell_0 \varphi^r) = (\hbar/\ell_0)\,\varphi^{-r}$*.*

(i) *(C33)* $\kappa = 2\pi\varphi^5/\log 2$ *is positive, and* $96.9 < \kappa < 102.5$*.*

(j) *(C38)* $\frac{3}{5} = \frac{3}{3+2}$*, and* $a_C = \frac{3}{5}\,\alpha_m \cdot 197.327/1.2$ *satisfies* $0.7 < a_C < 0.75$ *and* $|a_C - 0.714| < 0.036$*.*

Proof. We use the brackets $1.618033 < \varphi < 1.618034$, $3.1415925 < \pi < 3.1415927$, $2.772588722 < 4\log 2 < 2.7725887224$ and $0.4812 < \log\varphi < 0.4813$ of Section 22.9; every other number below is a ratio.

(a) $c = 1/1$. $G \cdot 4\log 2 = \varphi^5$ because $4\log 2 > 0$ is invertible, and $G\hbar = \varphi^5\varphi^{-5}/(4\log 2)$. Then $\hbar G/c^3 = 1/(4\log 2)$, and ℓ_P is its nonnegative square root.

(b) By Proposition 22.39(a) the deficits total 4π, and $4\pi \cdot 11 = 44\pi$; $6 \cdot 17 = 102$. The band is Theorem 22.42(a).

(c) $2^{-22}\varphi^{-5}\varphi^{62}\varphi^{-6} = 2^{-22}\varphi^{51}$, a product of positive points.

(d) $0.2303276 < s_W < 0.2303279$, so $0 < s_W < 1/2$ and $0.0074 < s_W - 0.2229 < 0.0075$; and $0.7696721 < (3+\varphi)/6 < 0.7696724$. The ratio $m_H/m_W = 125.25/80.3692$ lies between 1.5584328 and 1.5584329, so $0.0596 < \varphi - m_H/m_W < 0.0597$; and $80.3692 < 91.1876$.

(e) $0.1179 - 2/17 = 0.0043/17 < 0.0003$.

(f) $\varphi^3 = 2\varphi + 1$ and $(2\varphi+1)(2\varphi-3) = 4(\varphi^2 - \varphi) - 3 = 1$, so $\varphi^{-3} = 2\varphi - 3$, between 0.236066 and 0.236068. With $\frac{3}{2}\alpha_m = 0.01094602884645$, the first difference lies between 0.000119 and 0.000123. Next $\frac{1}{24} - 0.04182 = -0.000153\ldots$ and $\frac{1}{2}\alpha_m - 0.00369 = -0.0000413\ldots$, both ratios.

(g) The bracket for π gives $0.0023228194 < \alpha_m/\pi < 0.0023228196$, so $0.6851771804 < \Omega_\Lambda < 0.6851771806$, and the three bounds follow; $0 < \Omega_\Lambda - 0.6847 < 0.00048$. Finally $67.4 \cdot 13/12 = 73.01666\ldots$, and $73.04 - 73.01666\ldots = 7/300 < 0.0005 \cdot 73.04 = 0.03652$.

(h) $3 \cdot 4 - 1 = 11$. Since $e^a e^{-a} = 1$, $\hbar/(\ell_0 e^{r \log \varphi}) = (\hbar/\ell_0) e^{-r \log \varphi}$.

(i) $\varphi^5 = 5\varphi + 3$, so $\kappa = 2\pi(5\varphi + 3)/\log 2$, a product and quotient of positive points; the brackets give $100.5292 < \kappa < 100.5293$.

(j) $a_C = 0.7199823447\ldots$, a ratio, and $a_C - 0.714 < 0.006$. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ with its φ, π, log and exp; native units; the measured values written into the steps (α_m, 0.2229, 0.1179 ± 0.0009, the three mixing entries with their errors, the boson masses in GeV, the Hubble rates 67.4 and 73.04, 0.6847 ± 0.0073, $\hbar c = 197.327$ MeV fm, $r_0 = 1.2$ fm), taken as ratios.

Conclusion

Each comparison as stated, with no omniscience and no choice.

Identification

Reading $(3 - \varphi)/6$ as the weak mixing angle, $2/17$ as the strong coupling, the three expressions of (f) as mixing-matrix entries, Ω_Λ as the dark-energy fraction, b_0 and the scale law as the running of the strong coupling, κ as Einstein's coupling, and a_C as the Coulomb coefficient of nuclear binding.

Not claimed

The identifications themselves, and the measured values.

Step C19 builds the muon and tau masses from the electron's structural mass by residues on the golden ladder. The ingredients are a gap term $\mathrm{gap}(Z) = \log(1 + Z/\varphi)/\log\varphi$ at the charged-lepton index $Z = 1332$; a shift $2W + (W + E)/(4E_p) + \alpha^2 + E\alpha^3$ with $W = 17$, $E = 12$ edges and $E_p = 11$ passive edges; a step $E_p + 1/(4\pi) - \alpha^2$ from electron to muon; and a step $6 - \frac{1}{2}(2W + 3)\alpha$ from muon to tau, with 6 the cube's faces. Here $\alpha = 1/\alpha_W^{-1}$ is the construction value of C17, the witness value of Theorem 22.42(a), not a derived coupling.

Theorem 22.53 (The lepton window). *Let $\alpha = 1/\alpha_W^{-1}$, with α_W^{-1} as in Theorem 22.42(a) at $s = \sqrt{2}$, and put*

$$\rho_\mu = \mathrm{gap}(1332) - \Big(34 + \frac{29}{44} + \alpha^2 + 12\alpha^3\Big) + \Big(11 + \frac{1}{4\pi} - \alpha^2\Big), \qquad \rho_\tau = \rho_\mu + 6 - \frac{37}{2}\alpha,$$

$m_\mu = 2^{-22}\varphi^{51}\varphi^{\rho_\mu}$ and $m_\tau = 2^{-22}\varphi^{51}\varphi^{\rho_\tau}$, with $\varphi^t = e^{t\log\varphi}$. Then, with $z = \frac{15}{44} + \frac{1}{4\pi} - 2\alpha^2 - 12\alpha^3$,

$$2^{22} m_\mu = (\varphi^{27} + 1332\varphi^{26})\, e^{z\log\varphi}, \qquad 2^{22} m_\tau = (\varphi^{33} + 1332\varphi^{32})\, e^{(z - 37\alpha/2)\log\varphi},$$

and

$$105 < m_\mu < 107, \qquad 1768 < m_\tau < 1792.$$

The proof is free.

Proof. Since $e^{\log y} = y$, $\varphi^{\mathrm{gap}(1332)} = 1 + 1332/\varphi$. The constant terms of ρ_μ are $-34 - \frac{29}{44} + 11 = -24 + \frac{15}{44}$, so $\rho_\mu = \mathrm{gap}(1332) - 24 + z$ and

$$2^{22} m_\mu = \varphi^{51}\Big(1 + \frac{1332}{\varphi}\Big)\varphi^{-24} e^{z\log\varphi} = (\varphi^{27} + 1332\varphi^{26})\, e^{z\log\varphi}.$$

Likewise $\rho_\tau = \mathrm{gap}(1332) - 18 + z - \frac{37}{2}\alpha$, which gives the second identity. By Proposition 22.37(d), with $F_{25}, \dots, F_{33} = 75025$, 121393, 196418, ..., 2178309, 3524578,

$$\varphi^{27} + 1332\varphi^{26} = 161891894\,\varphi + 100054693,$$
$$\varphi^{33} + 1332\varphi^{32} = 2905032166\,\varphi + 1795408617,$$

and $1.618033 < \varphi < 1.618034$ puts the first between 362001119 and 362001282 and the second between 6495846527 and 6495849433.

From $137.030 < 1/\alpha < 137.039$, $0.007297 < \alpha < 0.007298$, so $0 < 2\alpha^2 + 12\alpha^3 < 0.000112$ and $0.1349945 < \frac{37}{2}\alpha < 0.135013$. With $0.0795774 < 1/(4\pi) < 0.0795775$ and $0.3409090 < \frac{15}{44} < 0.3409091$,

$$0.4203744 < z < 0.4204866, \qquad 0.2853614 < z - \tfrac{37}{2}\alpha < 0.2854921.$$

Multiplying by $0.4812 < \log\varphi < 0.4813$, $y = z\log\varphi$ lies in $(0.20228, 0.20239)$ and $y' = (z - \frac{37}{2}\alpha)\log\varphi$ in $(0.13731, 0.13741)$. For $0 \le x \le 1$, $1 + x + x^2/2 + x^3/6 \le e^x \le 1 + x + x^2/2 + x^3/3$ (Section 22.9), which gives $1.2241 < e^y < 1.2257$ and $1.1471 < e^{y'} < 1.1478$. With $2^{22} = 4194304$,

$$105.64 < \frac{362001119 \cdot 1.2241}{4194304} < m_\mu < \frac{362001282 \cdot 1.2257}{4194304} < 105.79,$$

$$1776.5 < \frac{6495846527 \cdot 1.1471}{4194304} < m_\tau < \frac{6495849433 \cdot 1.1478}{4194304} < 1777.7.$$

□

Reading m_μ and m_τ as the muon and tau masses in MeV, and α as the fine-structure constant, are identifications; the theorem uses neither, and by step S14 the coupling itself is a boundary datum. The theorem shows that the two formulas of step C19, evaluated on the line, land in the windows the step states for them, with no principle.

22.11 Where the prices sit

Ten steps have an exact price, each beside a free reading of the same step.

1. A ratio other than 1 has positive cost (T2.8): MP, by Theorem 22.16. Free beside it: $J(x) > 0$ for $x \# 1$.

2. The route of step T3.7 to the first costly join, an integer pairing that separates its parts: strong extensionality for integer-valued maps, $\mathrm{SE}_{\mathbb{Z}}$, by Theorem 22.24(c). MP implies it, and with the WLPO function it is MP (Proposition 22.25); whether it implies MP outright is open. Free beside it: the join of apart parts.

3. The costly join of merely distinct parts (T3.7b): MP, by Theorem 22.24(b).

4. The reciprocal ambiguity of equal costs (R2-08): LLPO, by Theorem 22.31. Free beside it: the double-negated, apartness and converse forms.

5. Omitting the output bins of probability zero from the data-processing inequality (R2-20): LPO, by Theorem 22.32. Free beside it: the inequality bin by bin and over any known support.

6. The largest admissible level gap as a value (R2-27): WLPO, by Theorem 22.33. Free beside it: the bound $k \log \varphi \leq \log(1 + c + s)$.

7. The constants' approximate-equality test $|a - b| \leq 10^{-6}$ as a yes-or-no decision (S11): WLPO, and as one map the WLPO function, by Theorem 22.44. Free beside it: the identities of the test; and at the values of step S11 the check returns false.

8. The total real-valued meter type (T2.1b): the LPO function, by Theorem 22.63. Free beside it: the meter at positive references.

9. The rigid form of DEP for every point other than 1 (T3.7c): the WLPO function, by Theorem 22.64. Free beside it: the join of apart parts.

10. The first homology of the circle in data form (R2-35d): the WLPO function, by Theorem 22.65. Free beside it: the relation form R2-35.

One step is bracketed, with its exact place open: dropping continuity and the order premises (T2.6) lies below the WLPO function (Theorem 22.14); no lower bound is proved.

Every price sits in one of three places. Five are decision forms of facts whose apartness or double-negation form is free (T2.8, R2-08, R2-20, R2-27, S11). Two concern real-valued object types or a countermodel to a dropped premise (T2.1b, T2.6). Four are readings of a premise weaker than apartness (T3.7, T3.7b, T3.7c and the data form of R2-35). None of them is the mathematical content of a step: every forced structure of the chain holds on the line with no omniscience and no choice. All eleven belong to the rungs: the first rung's segments T2 and T3, the second rung, and the constants. None is a step of the numbered chain, which is free from T−2 to T41 and through the period bound (Theorem 22.45). Table 22.1 gives all 130 rows: 119 free, 10 with an exact price, 1 bracketed, none open.

Table 22.1. The forcing chain of Recognition Science, restated and priced on $\mathbb{R}_\delta$, in 130 rows. Column 2 restates each step in this book's own words; the prices are theorems about these statements. The rows run in the order of the chain: the first rung (T1–T4), the numbered chain (C−2 to C41 and the period bound P8, where Cn is step Tn of that sequence; Section 22.10), the second rung (R2-01 to R2-35, the last in relation and data form) and the constants (S1–S15). "Free" means proved with no omniscience principle and no choice principle; a named principle is an exact price, an equivalence proved in both directions with no choice; "between" and "below" are brackets (Definition 22.1). The last column names the result of this book that settles the step, or the elementary argument that does. Counts: 119 free, 10 exact prices, 1 bracketed, 0 open.

Step	Statement (restated)	Price on $\mathbb{R}_\delta$	Settled by
T1: the arithmetic of records (8 steps, 8 free)			
T1.1	Records of repeated distinction form an initial structure: the orbit maps uniquely into every structure with a point and a self-map.	free	Thm 2.3
T1.2	Counts, signed counts and ratios obey the laws of $\mathbb{N}$, $\mathbb{Z}$ and $\mathbb{Q}$.	free	Thms 3.3, 4.5, 4.12
T1.3	The arithmetic of records supports a fragment of Heyting arithmetic and, by Ackermann codes, a model of adjunctive set theory with extensionality, in which $\{\emptyset\} \neq \emptyset$.	free	Ackermann coding
T1.4	Hereditarily finite codes, and the number two, are derived from records, not posited.	free	Ackermann coding
T1.5	The arithmetic does not depend on the carrier that holds the records.	free	Thm 2.7
T1.6	Two independent carriers, the natural numbers and the lists over a one-element set, give the same arithmetic.	free	Thms 2.7, 3.14
T1.7	The hereditarily finite model is definable in the arithmetic of records: every code is the value of a closed numeral.	free	Ackermann coding
T1.8	A formula is valid on the natural numbers exactly when it is valid on the lists over a one-element set.	free	transport by isomorphism
T2: the cost (12 steps, 9 free)			
T2.1	A meter that pools, is nonnegative and reads its reference as 1 reads d/r.	free	Thm 22.5
T2.1b	The meter is one real-valued map of two real arguments.	the LPO function	Thms 22.6, 22.63
T2.2	A balanced zero, an empty operand and a positive reference force opposite operand images, energy $k(A-B)^2$ with $k>0$ and reference κkAB.	free	Thm 22.8
T2.2b	Reports at ratios, reciprocity and order on $[1,\infty)$ force $(\kappa/2)F = J$ without continuity.	free	Thm 22.12

Step	Statement (restated)	Price on $\mathbb{R}_\delta$	Settled by
T2.3a	A source witness, the eight-slot pulse with its half-sum residual, meets the selection premises.	free; identification classical	Rem. 22.9
T2.3b	The formation residual acts on the operands as $1+\varphi^{-2}$ times the source residual.	free; identification classical	Rem. 22.9
T2.4	Literal reports at ratios a/b are $(2/\kappa)J(a/b)$.	free	Thm 22.11
T2.5	Continuity at positive points extends this to every $x>0$; at $\kappa=2$, $F=J$.	free	Thm 22.11
T2.6	Continuity cannot be dropped: a report can be altered at an irrational point.	below the WLPO function	Thm 22.14
T2.7	$J(x)=(x-1)^2/(2x)$; $J\geq 0$; $J(x)=0$ iff $x=1$; $J(1/x)=J(x)$; $J(x)>0$ iff $x\#1$; J increases on $[1,\infty)$.	free	Prop. 22.15
T2.8	$x\neq 1$ gives $J(x)>0$.	MP; the decisions of $J=0$ cost WLPO and LPO	Thm 22.16
T2.9	The composition law with its calibration forces J.	free	Thm 21.14
T3: the golden hierarchy (10 steps, 7 free)			
T3.1	A costly initial join posts additively: $s_2=s_1+s_0$.	free	Lem. 22.18
T3.2	Positive comparisons fix one scalar between two additive readings.	free	Lem. 22.19
T3.3	One rule holds along the orbit: $r(Ts)=\rho r(s)$ with $\rho>0$.	free	Thm 22.20(a)
T3.4	The step factor satisfies $\lambda^2=\lambda+1$, so $\lambda=\varphi$.	free	Thm 22.20(b)
T3.5	The realized hierarchy exists.	free	Thm 22.20(b), Prop. 22.21
T3.6	Levels are φ^n times the base, and weights are φ^{-n}.	free	Thm 22.20(c)
T3.7	The join is a recognition, so it costs something; the route: an integer pairing separates its parts.	$\mathrm{SE}_{\mathbb{Z}}$, strong extensionality (implied by MP; MP given the WLPO function)	Thm 22.24(c), Prop. 22.25
T3.7a	The same step with apart parts, $\rho\#1$.	free	Thm 22.24(a)
T3.7b	The same step with distinct parts, $\rho\neq 1$.	MP	Thm 22.24(b)
T3.7c	Every point $x\neq 1$ carries DEP on its rigid kinematics.	the WLPO function	Prop. 22.25, Thm 22.64
T4: eight states and three dimensions (6 steps, 6 free)			
T4.1	DEP separates the pair from the split.	free	Prop. 22.26
T4.2	The winding kinematics keeps the pair.	free	Prop. 22.26
T4.3	An erasable world keeps no pair.	free	Prop. 22.26

22.12 The verdict with no cited premise

Recognition Science gathers its first rung into one theorem, its verdict: from a list of premises about the world, the cost of a comparison is J, the levels of a recognition hierarchy are powers of φ, space has three dimensions and the recognition period is eight. The proof of that theorem used one result of transcendental number theory without proving it, the six exponentials theorem, in a form adapted to the cost. This section proves that result, so the verdict holds from its premises alone. The verdict is a theorem about the classical real numbers; it is proved in classical mathematics, and its price on $\mathbb{R}_\delta$ is not determined here. The last part of the section says how far its transcendence step reaches on the line.

Definition 22.54 (The premises and conclusions of the verdict)**.** In classical mathematics, let F be a real function on the positive reals, κ a real number, D a natural number, and $s_0, s_1, \dots$ the levels of a recognition hierarchy, read by $s_n = r(T^n b)$ from a base state b, a self-map T and a reading r of the states: positive reals with $s_1/s_0 > 1$, equal adjacent ratios $s_{n+2}/s_{n+1} = s_{n+1}/s_n$, and the additive posting $s_2 = s_1 + s_0$. For $c > 0$ write $J_c(x) = J(x^c)$. The *premises* are:

(V1) $\kappa > 0$;

(V2) $F(xy) + F(x/y) = \kappa F(x)F(y) + 2F(x) + 2F(y)$ for all $x, y > 0$;

(V3) $F(x) \neq F(y)$ for some $x, y > 0$;

(V4) $t \mapsto F(e^t) + 1$ is nondecreasing on $[0, \infty)$;

(V5) *(the cost is native to the carrier)* for every $c > 0$ with $\frac{\kappa}{2}F = J_c$ on the positive reals, J_c maps positive rationals to rationals;

(V6) *(its character is an automorphism)* for every such c, every positive rational is r^c for some positive rational r;

(V7) the hierarchy above exists;

(V8) *(a completed recognition is kept)* some spatial realization in dimension D satisfies the deformation-erasure principle of Definition 22.22; a spatial realization is a pair kinematics together with the identification that a deformation-invariant integer pairing nonzero on the pair exists exactly when some embedded circle in the sphere S^D has a complement with nonzero first homology.

The *conclusions* are: $\frac{\kappa}{2}F(x) = J(x)$ for every $x > 0$; $s_n = \varphi^n s_0$; φ is the only positive root of $r^2 = r + 1$; $D = 3$; $2^D = 8$; and $s_0/s_n = \varphi^{-n}$.

Premises (V2)–(V4) are the cost laws of Section 21.3 with an amplitude κ, (V5) and (V6) are the two qualitative calibration premises of the carrier, (V7) is the hierarchy of Section 22.6, and (V8) is the linking premise of Chapter 23. The cited result entered between (V5), (V6) and the conclusion $c = 1$.

Theorem 22.55 (The six exponentials theorem)**.** *In classical mathematics:*

1. *If d is real and 2^d, 3^d and 5^d are rational, then d is rational.*
2. Trace form. *If c is real and $n^c + n^{-c}$ is rational for $n = 2, 3, 4, 5$, then c is rational.*

Both parts are cases of the six exponentials theorem of Lang and Ramachandra [204, 205]: if x_1, x_2 and y_1, y_2, y_3 are each linearly independent over the rationals, one of the six numbers $e^{x_i y_j}$ is transcendental; here $x = (1, d)$, or $(1, c)$, and $y = (\log 2, \log 3, \log 5)$, and in part 2 each n^c is algebraic, a root of $X^2 - tX + 1$ with t rational. That two bases would suffice is the open four exponentials problem [206], so, with present knowledge, a proof must use all three. Because every number here is real, Rolle's theorem replaces both the Schwarz lemma and the algebraic zero estimate of the textbook proof. The argument uses four tools.

Lemma 22.56 (The four tools)**.**

1. Siegel's lemma. *Let a be an $M \times N$ matrix of integers of size at most A, and B a natural number with $(2NAB+1)^M < (B+1)^N$. Then some nonzero integer vector v with entries of size at most B has $av = 0$. If $N \geq 2M$ and $N \geq 1$, the size $B = 2NA + 1$ always works. The proof is free.*

2. Extrapolation. *In classical mathematics, if f is a smooth function on the line that vanishes at N distinct points of $[0, R]$, and $|f^{(N)}| \leq M$ on $[0, R]$, then $|f(x)| \leq MR^N/N!$ for $0 \leq x \leq R$.*

3. Zero estimate. *In classical mathematics, an exponential sum $\sum_{i \in S} a_i e^{\lambda_i t}$ with distinct real frequencies λ_i that vanishes at $|S|$ distinct real points has every $a_i = 0$.*

4. Growth. *For every $c > 0$ and every sequence f with $0 \leq f(n) \leq n^a G^{n^5}$ for all $n \geq 1$, for some fixed a and $G \geq 1$, some $n \geq 1$ has $f(n)\,(9n^5 c)^{n^6} < (n^6)!$.*

Proof. 1. Consider the $(B+1)^N$ vectors with entries in $\{0, \dots, B\}$. Each entry of av lies in an interval of at most $2NAB + 1$ integers, so av takes at most $(2NAB+1)^M$ values, and two vectors $v \neq v'$ have $av = av'$; their difference works. The count is a finite comparison of explicit lists. For $N \geq 2M$ and $B = 2NA + 1$: $2NAB + 1 \leq B^2 + 1 < (B+1)^2$, so $(2NAB+1)^M < (B+1)^{2M} \leq (B+1)^N$.

2. Let $z_1 < \cdots < z_N$ be the zeros and x a point of $[0, R]$ not among them; choose λ with $g = f - \lambda \prod_j (t - z_j)$ zero at x. Then g has $N+1$ zeros in $[0, R]$, and N applications of Rolle's theorem give ξ with $g^{(N)}(\xi) = 0$, that is $f^{(N)}(\xi) = \lambda N!$. So $|f(x)| = |\lambda| \prod |x - z_j| \leq MR^N/N!$.

3. Induction on $|S|$. Multiply by $e^{-\lambda_0 t}$ and differentiate: the derivative is an exponential sum with $|S| - 1$ terms and distinct frequencies $\lambda_i - \lambda_0$, coefficients $a_i(\lambda_i - \lambda_0)$, and by Rolle it vanishes at $|S| - 1$ distinct points; so $a_i = 0$ for $i \neq 0$, and then $a_0 = 0$.

4. $\log f(n) + n^6 \log(9n^5 c) \leq a \log n + n^5 \log G + n^6 \log(9c) + 5n^6 \log n$, while $\log(n^6)! \geq n^6(6 \log n - 1)$. The difference grows like $n^6 \log n$. □

Proof of Theorem 22.55. Part 1. Suppose d is irrational and $p^d = r_p$ is rational for $p = 2, 3, 5$, with height H (the largest numerator or denominator). Choose n by Lemma 22.56, item 4, with $c = (1 + |d|) \log 30$ and the explicit bounds below; put $K = 2n^3$, $S = n^2$ and $S' = 2n^2$.

Siegel step. Look for integers a_k, $k = (k_1, k_2)$ with $k_1, k_2 < K$, not all 0, such that

$$\Phi(x) = \sum_k a_k \, e^{(k_1 + k_2 d)x}$$

vanishes at the n^6 points $x = \log m$, $m = 2^{s_0} 3^{s_1} 5^{s_2}$, $s_j < S$. At such a point $\Phi(\log m) = \sum_k a_k m^{k_1} (m^d)^{k_2}$ with $m^d = r_2^{s_0} r_3^{s_1} r_5^{s_2}$ rational; clearing the denominators gives n^6 integer equations in $K^2 = 4n^6$ unknowns, with entries of size at most $A = 30^{2n^5} H^{6n^5}$, and Siegel's lemma, with $B = 2 \cdot 4n^6 A + 1$, gives a solution with $|a_k| \leq 8n^6 \, 30^{2n^5} H^{6n^5} + 1$.

Extrapolation. Φ has $N = n^6$ zeros in $[0, R]$, $R = S' \log 30$, and $|\Phi^{(N)}| \leq K^2 \max |a_k| \, \Lambda^N e^{\Lambda R}$ with $\Lambda = K(1 + |d|)$. By the extrapolation tool, $|\Phi(x)| \leq K^2 \max |a_k| \, \Lambda^N e^{\Lambda R} R^N / N!$ on $[0, R]$.

Liouville step. At a point $\log m$ of the larger grid $s_j < S'$, Φ is a rational with denominator at most H^{12n^5}, so it is 0 or at least H^{-12n^5} in size. The growth tool makes the extrapolation bound smaller, so Φ vanishes at all $8n^6$ points of the larger grid.

Zero estimate. The frequencies $k_1 + k_2 d$ are $4n^6$ distinct reals, because d is irrational, and the $8n^6$ points are distinct, by unique factorization. The zero estimate gives every $a_k = 0$, a contradiction.

Part 2. Now $u_p = p^c$ satisfies $u_p + u_p^{-1} = t_p$ rational, so the values $\Phi(\log m)$ lie in the field generated by u_2, u_3, u_5, not in the rationals. Two repairs, with no field theory, restore the argument. Scale $U_p = \mathrm{den}(t_p) u_p$, a root of an integer quadratic $U^2 = TU - Q$; every monomial $\prod_p U_p^{l_p}$ has explicit integer coordinates in the eight products $\prod_p U_p^{e_p}$, $e \in \{0,1\}^3$, from the recursion $U^l = A_l U + B_l$, $A_{l+1} = TA_l + B_l$, $B_{l+1} = -QA_l$. In the Siegel step all eight coordinates are set to 0 at each of the n^6 points: $8n^6$ equations in $9n^6$ unknowns, with $K = 3n^3$. Here there are fewer than twice as many unknowns as equations, so Siegel's lemma is used with its general condition. For M equations and N unknowns with $8N = 9M$, and entries of size at most $A \geq 1$, the size $B = (2NA)^8$ works: $2NAB + 1 = (2NA)^9 + 1$, and with $x = 2NA \geq 1$,

$$(x^9 + 1)^8 = x^{72}(1 + x^{-9})^8 < x^{72}(1 + x^{-8})^9 = (x^8 + 1)^9,$$

so $(2NAB + 1)^M < (B + 1)^N$. The entries here are of size at most $n^a G^{n^5}$ for fixed a and G, so B is too, after enlarging a and G, and the growth tool applies as in part 1. In the Liouville step a nonzero value w with integer coordinates satisfies a nonzero integer polynomial of degree at most 8, found by Siegel's lemma on the coordinates of $1, w, \ldots, w^8$ (8 equations, 9 unknowns, the same size $B = (2NA)^8$ with $N = 9$); its lowest nonzero coefficient gives $1 \leq |w| \cdot 8B \max(1, |w|)^8$, a lower bound for $|w|$. No conjugate and no norm is used, so the cases in which some u_p is rational, or the square roots are dependent, need no separate treatment. The extrapolation runs on $[0, 3n^2 \log 30]$; the growth tool makes Φ vanish at all $27n^6$ points with $s_j < 3n^2$; and the zero estimate, with $9n^6$ distinct frequencies, kills every coefficient. Rationality at $n = 4$ is not used. □

The verdict needs one more step from the exponent. For $c > 0$, (V5) says that $J(q^c)$ is rational at every positive rational q, and (V6) that every positive rational is a rational cth power. The two premises leave different sets of exponents.

Proposition 22.57 (The exponent census)**.** *In classical mathematics, for $c > 0$:*

1. *J_c maps positive rationals to rationals exactly when c is a positive integer;*
2. *every positive rational is a rational cth power exactly when $c = 1/k$ for a positive integer k;*
3. *so both hold exactly when $c = 1$. Only part 1 uses the trace form of Theorem 22.55; part 2 uses its part 1, and the failure of part 1 of this proposition at $c = 1/k$ for $k \geq 2$ uses neither.*

Proof. We use one arithmetic step. *If a/b is a positive rational in lowest terms and $t = 2^{a/b} + 2^{-a/b}$ is rational, then $b = 1$.* Indeed $u = 2^{a/b}$ is a root of $X^2 - tX + 1$, so u lies in a field of degree at most 2 over the rationals, where the 2-adic valuation takes values in $\frac{1}{2}\mathbb{Z}$; it takes the value a/b

at u, so $b \le 2$. If $b = 2$, then a is odd and $t = 2^{a/2}(1 + 2^{-a})$ is a rational multiple of $\sqrt{2}$, which is irrational.

1. Integer exponents give rational costs. Conversely $J(n^c)$ rational for $n = 2, \dots, 5$ makes $n^c + n^{-c}$ rational, so $c = a/b$ is rational by the trace form, and $J(2^c)$ rational makes $2^c + 2^{-c}$ rational, so $b = 1$.

2. If $c = 1/k$, then $r = q^k$ gives $r^c = q$. Conversely, with $q = 2, 3, 5$ the premise makes $2^{1/c}$, $3^{1/c}$ and $5^{1/c}$ rational, so $1/c = a/b$ is rational by part 1 of Theorem 22.55; then $2^{a/b}$ and its inverse are rational, so their sum is, and $b = 1$: $c = 1/a$.

3. A positive integer of the form $1/k$ is 1. For $k \ge 2$, $J(2^{1/k})$ is irrational by the arithmetic step, since $2J(2^{1/k}) + 2 = 2^{1/k} + 2^{-1/k}$. □

Read physically, an exponent $c = k$ reads the kth power of a ratio: a coarser reading whose costs stay records. An exponent $c = 1/k$ reads a root: a finer reading that reaches every ratio, but whose costs leave the carrier. Only the unit reading does both.

Theorem 22.58 (The verdict of Recognition Science, with no cited premise)**.** *In classical mathematics, the premises (V1)–(V8) give the conclusions of Definition 22.54. No result of transcendental number theory is cited; the proof uses the textbook facts on measurable solutions of d'Alembert's equation [98] and Alexander duality.*

Proof. The cost. Put $F' = \frac{\kappa}{2}F$. By (V2), F' obeys the composition law (21.1). A solution of the law is either constant -1 or has $F'(1) = 0$ (Theorem 21.29, part 1, read classically), and (V3) excludes the constant; the law at $x = 1$ then gives $F'(x^{-1}) = F'(x)$. In logarithmic coordinates $H(t) = F'(e^t) + 1$ solves d'Alembert's equation and is even. By (V4) it is nondecreasing on $[0, \infty)$, hence measurable; measurable solutions of d'Alembert's equation are continuous, and the continuous ones with $H(0) = 1$ are $\cosh(c_0 t)$ and $\cos(c_0 t)$ [98], of which only the first is nondecreasing on $[0, \infty)$ for $c_0 \neq 0$. (V3) excludes $H \equiv 1$, and evenness lets us take $c = |c_0| > 0$. So $F' = J_c$. By (V5) and Proposition 22.57, part 1, c is a positive integer; by (V6) and part 2 it is $1/k$; so $c = 1$ and $\frac{\kappa}{2}F = J$.

The hierarchy. The adjacent ratios are all equal to $r = s_1/s_0 > 1$, and $s_2 = s_1 + s_0$ gives $r^2 = r + 1$, so $r = \varphi$, the only positive root; hence $s_n = \varphi^n s_0$ and $s_0/s_n = \varphi^{-n}$.

The dimension. By (V8) some embedded circle in S^D has a complement with nonzero first homology. For $D \le 1$ no circle has a complement that carries a loop: none embeds in S^0, and one fills S^1. For $D \ge 2$, Alexander duality identifies the first homology of the complement of an embedded circle with the reduced cohomology of the circle in degree $D - 2$, which is nonzero only for $D = 3$. So $D = 3$, and $2^D = 8$. Chapter 23 proves the corresponding statement on the line, natively and for free (Theorem 23.8). □

Conditions and scope.

Base and premises

Classical real numbers; the premises (V1)–(V8).

Conclusion

J at unit amplitude, the golden levels, $D = 3$ and the period 8, with no cited premise:

the transcendence step is Theorem 22.55, and the proof uses only the textbook facts on d'Alembert's equation [98] and Alexander duality.

Identification
The premises themselves: that physical costs compose by (V2), that the cost is native to the carrier and its character an automorphism, that the hierarchy exists, and that a completed recognition is kept. The theorem derives the conclusions from them; it does not supply them.

Not claimed
A price on $\mathbb{R}_\delta$; the price of the transcendence step on the line is treated in Proposition 22.61.

The census also settles which single premise selects the exponent.

Proposition 22.59 (The selection ledger)**.** *In classical mathematics, for $c > 0$:*

1. *$J(2^c) = \frac{1}{4}$ exactly when $c = 1$; and for each $x > 0$ with $x \neq 1$, $J(x^c) = J(x)$ exactly when $c = 1$;*
2. *the second derivative of $t \mapsto J_c(e^t)$ at 0 is 1 exactly when $c = 1$;*
3. *$J_c \leq J_m$ at every $x \neq 1$ for every positive integer m exactly when $c \leq 1$;*
4. *if J_c maps positive rationals to rationals, then (V6) holds exactly when $c = 1$, and J_c is least among the integer exponents exactly when $c = 1$.*

Proof. 1. J is strictly increasing on $[1, \infty)$ and $J(y) = J(y^{-1})$, so $J(x^c) = J(x)$ with $x \neq 1$ forces $x^c = x$ or $x^c = x^{-1}$, and $c > 0$ leaves $c = 1$; at $x = 2$, $J(2) = \frac{1}{4}$. 2. $J_c(e^t) = \cosh(ct) - 1$ has second derivative c^2 at 0. 3. J grows with $|\log x|$, so $J(x^c) \leq J(x^m)$ for all $m \geq 1$ exactly when $c \leq 1$. 4. By the census c is a positive integer; with (V6) it is also $1/k$; and least among integers with c an integer means $c \leq 1$. □

Part 1 is Recognition Science's bit at the classical level: the value of one binary distinction selects the exponent. Proposition 21.44 proves the same selection on $\mathbb{R}_\delta$ for free.

Why the ledger is $\mathbb{Z}[\varphi]$

The ledger of Section 21.5 lives in $\mathbb{Z}[\varphi]$. The reason is a universal property.

Proposition 22.60 (The free ring with a join scale)**.**

1. *No rational q has $q^2 = q + 1$.*
2. *For every commutative ring A and every $r \in A$ with $r^2 = r + 1$ there is exactly one ring map $\mathbb{Z}[\varphi] \to A$ that sends φ to r.*
3. *Every ring map from $\mathbb{Z}[\varphi]$ to a commutative ring of characteristic zero is injective.*

Parts 2 and 3 are free; part 1 is proved over the classical rationals.

Proof. 1. $(2q-1)^2 = 5$, and 5 is not the square of a rational, by descent as for 2. 2. Send $a + b\varphi$ to $a + br$; this respects the product because $r^2 = r + 1$, and a ring map is determined by the image of φ. 3. Let $f(a + b\varphi) = 0$. With the conjugate $\bar{x} = (a + b) - b\varphi$, $x\bar{x} = a^2 + ab - b^2$ is an integer, and $f(x)f(\bar{x}) = f(x\bar{x}) = a^2 + ab - b^2$, which is 0 in characteristic zero only if the integer is 0. By part 1 (in integers: $a^2 + ab - b^2 = 0$ forces $a = b = 0$), $x = 0$. □

A hierarchy with a costly initial join has ratio r with $r^2 = r + 1$ (Section 22.6). By part 2 the ring that r generates over the integers is the image of $\mathbb{Z}[\varphi]$, by part 3 that image is a faithful copy, and by part 1 no smaller ring will do: the rationals carry no join scale. So the level ratios of every such hierarchy are φ^n read faithfully, and $\mathbb{Z}[\varphi]$ is forced, not chosen.

The transcendence step on the line

Theorem 22.55 is classical. Its statement can be read on $\mathbb{R}_\delta$, and the question is what it costs there.

Proposition 22.61 (The six exponentials step on the line)**.** *Let ℓ_2, ℓ_3, ℓ_5 be points with $e^{\ell_p} = p$, and d a point such that $e^{d\ell_p}$ is a ratio for $p = 2, 3, 5$. Consider the conclusion*

$$d \text{ is an integer.} \tag{22.1}$$

1. *In classical mathematics,* (22.1) *holds.*
2. *With no choice principle: if $\neg\neg$*(22.1) *holds under these hypotheses, then* (22.1) *holds.*
3. *With no choice principle: the step reduces to its irrational core, the statement that under these hypotheses d cannot differ from every ratio. A ratio exponent a/b with $2^{a/b}$ a ratio is an integer by arithmetic alone.*

Proof. 1. Read through a bijective reading, the hypotheses are those of Theorem 22.55, part 1, so d is rational, and 2^d rational makes it an integer by the 2-adic argument of Proposition 22.57. 2. "d is an integer" is equivalent, with no choice, to "d is within $\frac{1}{3}$ of an integer z and $d = z$"; the integer z is found from one stage of a regular sequence naming d, and the equation is stable. 3. Under the core, $\neg\neg(d = a/b$ for some ratio a/b in lowest terms); and if $d = a/b$, the ratio $r = e^{d\ell_2}$ has $r^b = 2^a$, so $b \mid a$ by unique factorization and d is an integer. So $\neg\neg$(22.1), and part 2 finishes. □

Whether the irrational core holds on $\mathbb{R}_\delta$ with no omniscience principle and no choice principle is open. A free proof would replace each tool of Lemma 22.56 by a form proved on the line. Siegel's lemma is already free. Rolle's theorem on the line costs LLPO (Theorem 12.87), so a free extrapolation and a free zero estimate must avoid it. The next results do that for the extrapolation, and for the zero estimate in two cases.

Proposition 22.62 (Exponential sums on the line)**.** *On $\mathbb{R}_\delta$, with no omniscience principle and no choice principle:*

1. Newton's form. *In every commutative ring, for nodes $z_0, z_1, \dots$, every x and all N, k,*

$$x^k = \sum_{l<N} h_{k-l}(z_0, \dots, z_l) \prod_{i<l} (x - z_i) + \prod_{i<N} (x - z_i)\, h_{k-N}(z_0, \dots, z_{N-1}, x),$$

   with h_m the complete homogeneous symmetric polynomial of degree m ($h_m = 0$ for $m < 0$); the same holds for every polynomial by linearity.

2. The size of h. *If $0 \le z_i \le R$, then $0 \le h_m(z_0, \dots, z_n) \le \binom{n+m}{m} R^m$.*

3. Extrapolation. *Let $f(x) = \sum_{k<n} a_k e^{\lambda_k x}$ vanish at N increasing nodes in $[0, R]$. Then for $0 \le x \le R$,*

$$|f(x)| \le \Big(\sum_{k<n} |a_k|\, |\lambda_k|^N e^{|\lambda_k| R} \Big) \frac{R^N}{N!}.$$

4. Two terms. *If $\lambda - \mu$ is apart from 0, $z_1 < z_2$, and $ae^{\lambda z} + be^{\mu z}$ vanishes at z_1 and z_2, then $a = b = 0$.*

5. Frequencies in progression. *If d is apart from 0, $z_0 < \cdots < z_{n-1}$, and $\sum_{k<n} a_k e^{(\lambda_0 + kd)z}$ vanishes at every z_j, then every $a_k = 0$.*

Proof. 1. Induction on N with the exchange rule $h_m(z_0, \dots, z_{N-1}, x) = h_m(z_0, \dots, z_N) + (x - z_N) h_{m-1}(z_0, \dots, z_N, x)$.

2. $h_m(z_0, \dots, z_n)$ is a sum of $\binom{n+m}{m}$ monomials of degree m.

3. Expand each exponential as its power series and apply Newton's form to every monomial. The Newton coefficients of f at the nodes vanish, level by level, because f vanishes at the nodes; the remainder term is $\prod (x - z_i) \sum_k a_k \sum_j \lambda_k^j h_{j-N}(\dots)/j!$, and part 2 with $\binom{j}{N}/j! = 1/(N!(j-N)!)$ bounds it by the right side. The limit over the partial sums is taken with explicit moduli; no point is chosen.

4. Cramer's rule: the determinant $e^{\lambda z_1 + \mu z_2} - e^{\mu z_1 + \lambda z_2}$ is apart from 0, because the exponential is strictly increasing and $(\lambda - \mu)(z_2 - z_1)$ is apart from 0.

5. With $y = e^{dz}$ the sum is $e^{\lambda_0 z} P(y)$ for the polynomial $P(Y) = \sum_k a_k Y^k$; the points $y_j = e^{dz_j}$ are n points pairwise apart, and a polynomial of degree below n vanishing at them is 0, by Newton's form with the divided differences, which divide only by differences of nodes. □

The general zero estimate, for n frequencies with no arithmetic structure, and its case on the two-parameter lattice $s + td$ that the six exponentials need, remain open on the line: classically they follow from Rolle's theorem, and what is missing is a lower bound, free on the line, for the generalized Vandermonde determinant $\det(e^{\lambda_k z_j})$.

22.13 The brackets of the chain, closed

Three steps of the forcing chain that the earlier sections place only between two bounds have exact prices: the total meter costs exactly the LPO function (Theorem 22.6 brackets it), the rigid form of the deformation-erasure principle costs exactly the WLPO function (Proposition 22.25 bounds it above), and so does the winding number of the circle as data (Theorem 23.40 brackets it). A fourth step, dropping continuity and the order premises (T2.6), stays below the WLPO function (Section 22.11). The last two closures use one device: a map into a discrete set that is not constant on the line already decides as much as the WLPO function. The first reads a two-valued point as a bit.

Theorem 22.63 (The total inverse is the LPO function)**.** *A map $g : \mathbb{R}_\delta \to \mathbb{R}_\delta$ with $r\,g(r) = 1$ for every $r > 0$ exists if and only if the LPO function exists. Hence a total meter (Theorem 22.6) exists exactly when the LPO function does. No choice principle is used.*

Proof. Let g be given and α a binary sequence, with jump point $j_\alpha \geq 0$; put $t_\alpha = j_\alpha\, g(j_\alpha)$. If α has a 1, then $j_\alpha > 0$ and $t_\alpha = 1$; if α is all 0, then $j_\alpha = 0$ and $t_\alpha = 0$. Since $\neg\neg(\alpha$ has a 1 or is all 0) and equality is stable, $\neg\neg(t_\alpha = 0 \vee t_\alpha = 1)$, and the bit of Lemma 28.2, item 3, read at stage 7 of a regular sequence for t_α, is a map d on binary sequences: if $s_7 > \frac{1}{2}$ then $t_\alpha \neq 0$, so $t_\alpha = 1$; otherwise $t_\alpha \neq 1$, so $t_\alpha = 0$. If $d(\alpha) = 1$, then $j_\alpha\, g(j_\alpha) = 1$, so j_α is invertible and positive, and α has a 1; if α has a 1, then $t_\alpha = 1$ and $d(\alpha) = 1$. So d is the LPO function. The converse is Theorem 22.6(c), and (a) of that theorem carries the price to the meter. □

Theorem 22.64 (Integer readings of the line)**.**

1. *A map $P : \mathbb{R}_\delta \to \mathbb{Z}$ with $P(0) \neq P(1)$ gives the WLPO function.*
2. *The rigid form of the deformation-erasure principle, "for every point $x \neq 1$, DEP holds for the rigid kinematics of x", holds exactly when the WLPO function exists.*
3. *A map $F : [0,1] \to \mathbb{Z}$ with $F(0) = 0$ and $F(1) \neq 0$ exists exactly when the WLPO function exists.*

No choice principle is used.

Proof. 1. *Bisection on representatives.* Starting from $[a_0, b_0] = [0,1]$, given by explicit regular sequences, let m be the midpoint, computed from the sequences of a_n, b_n; keep $[m, b_n]$ if $P(m) = P(0)$ and $[a_n, m]$ otherwise, an integer test. Then $P(a_n) = P(0)$, $P(b_n) \neq P(0)$, $b_n - a_n = 2^{-n}$, and the intervals nest. The left ends form a sequence with an explicit modulus, given by explicit regular sequences, so their diagonal names a point c with $|c - a_n|, |c - b_n| \leq 2^{-n}$, and no representative is chosen. One integer test picks the side that disagrees with c: $y_n = b_n$ if $P(c) = P(0)$, else $y_n = a_n$; then $P(y_n) \neq P(c)$ and $|y_n - c| \leq 2^{-n}$.

Gluing by a stop time. For a binary sequence α let $\sigma(m) = m$ until α first takes the value 1, and frozen from then on. The sequence $y_{\sigma(m+1)}$ again has an explicit modulus; let r_α be its limit. If α is all 0, then $r_\alpha = c$; if $\alpha(n) = 1$, then $r_\alpha = y_{\sigma(n)}$ and $P(r_\alpha) \neq P(c)$. So $d(\alpha) = 1$ exactly when $P(r_\alpha) = P(c)$ defines the WLPO function: if $P(r_\alpha) = P(c)$, then α has no 1, so it is all 0; and if α

is all 0, then $r_\alpha = c$. Every point is the class of an explicit representative and every test is an equality of integers.

2. Given the WLPO function, Proposition 22.25 gives the rigid form. Conversely, DEP for the rigid kinematics of 2 gives a map P to $\mathbb{Z}$ with $P(1) = 0 \neq P(2)$, and $t \mapsto P(1+t)$ separates 0 from 1; part 1 applies.

3. Given F, the map $P(t) = F(\min(1, \max(0, t)))$ separates 0 from 1; part 1 applies. Conversely the WLPO function decides $s \leq \frac{1}{2}$ as data, and $F(s) = 0$ if $s \leq \frac{1}{2}$, $F(s) = 1$ otherwise, is such a map (Theorem 23.40, part 2). □

Part 1 says that the line admits no integer reading that is not constant, short of the WLPO function: a single integer-valued map that tells 0 from 1 already decides, as data, whether every binary sequence is identically zero. This is the device behind the circle.

Theorem 22.65 (The winding number as data costs exactly the WLPO function)**.** *Each of the following exists exactly when the WLPO function exists, with no choice principle in either direction: the data form of $H_1(S^1) = \mathbb{Z}$, a quarter-turn colouring of the circle, an antipodal two-colouring of the circle, and a map $F : [0,1] \to \mathbb{Z}$ with $F(0) = 0$ and $F(1) \neq 0$ (Definition 23.39). Moreover a quarter-turn colouring gives the data form through the WLPO function, and the WLPO function gives the data form without unique choice of path labels.*

Proof. Theorem 23.40, part 1, gives the chain data form ⇒ quarter-turn colouring ⇒ antipodal two-colouring ⇒ the non-constant unit principle, and Theorem 22.64, part 3, closes it at the WLPO function. It remains to go back up from the WLPO function.

A quarter-turn colouring from the WLPO function. The WLPO function decides $a = 0$ and $\neg(a > 0)$ as bits for every point a (Lemma 28.2). For $a \neq 0$ exactly one of $\neg(a > 0)$ and $\neg(-a > 0)$ holds: both would make a not apart from 0, hence 0; neither would give $\neg\neg(a > 0)$ and $\neg\neg(-a > 0)$, whose sum is 0, which is impossible. Colour $p = (x, y)$ by its quadrant: if $y = 0$, by the sign test of x (0 or 2); else if $x = 0$, by the sign test of y (1 or 3); else by both sign tests. The quarter turn $(x, y) \mapsto (-y, x)$ adds 1 modulo 4 in every case, using $x \neq 0$ when $y = 0$, from the circle equation.

The data form from the WLPO function. Theorem 23.40, part 2, needs one integer label $n(\gamma)$ for each path, with $4n(\gamma)$ the swept angle plus $\theta(\gamma(0)) - \theta(\gamma(1))$; it took the label by unique choice, because the swept angle exists only as a proposition. The WLPO function computes it. With it, $\leq$ on the line is decided as data, and "every dyadic point of cell k of a grid has chart coordinate at least $\frac{1}{8}$ in chart j" is one bit. A grid on which every cell passes exists, by the modulus of the path; the least such grid is found by a terminating search, and each cell's chart is the first that passes. Continuity carries the dyadic test to the whole cell, so the grid is admissible and the swept angle is the sum of the chart angles; the label is found by a decided search over the integers. The rest is the proof of Theorem 23.40, part 2.

The data form from a quarter-turn colouring. The colouring gives the WLPO function through the chain above, and the WLPO function gives the data form. □

Conditions and scope.

Base and premises
The line, the native circle and the reading of maps of Section 21.1.

Conclusion
The total meter: exactly the LPO function. The rigid form of DEP for every point other than 1: exactly the WLPO function. The data form of $H_1(S^1) = \mathbb{Z}$, the quarter-turn colouring, the antipodal two-colouring and the non-constant unit principle: each exactly the WLPO function. Unique choice of path labels is not needed.

Not claimed
Whether $\mathrm{SE}_{\mathbb{Z}}$ implies MP, which remains open (Theorem 22.24); and the exact price of dropping continuity and the order premises (T2.6), which stays below the WLPO function. Both readings of Theorem 23.40, part 3, stand: BU_2 and continuity on Cantor space each refute all four data forms.

With these closures, Table 22.1 reads: of 130 rows, 119 free, 10 with an exact price and 1 bracketed, none open. Read physically, one integer label on all records of motion around a circle, read as one function, is exactly as strong as deciding, as data, whether a binary record is blank; and so is a single integer reading of the line that tells two points apart.

22.14 The moral code, priced

Morality is the physics of relations between participants. It runs on the record, the relations and the cost J of this chapter: a relation out of balance carries the cost $J(x)$, and the moral code reads who wrote on each relation and what each end received [198]. On true books the code admits an act exactly when the act has consent, and it permits exactly the least costly acts with consent. This section reads that code on the line, at the scope of [198], and prices it. With the code's hypothesis in its free form (H3), every conclusion of its main theorem is free. A price appears only where a moral verdict is run as a decision on exact amounts over every conceivable record: deciding consent costs WLPO, and reading the writes off every record costs the WLPO function. Three steps of the usual proofs cost LLPO, MP and $\mathrm{MP}^{\vee}$: a decided alternative, a strict inequality from "not equal", and a finite De Morgan step. Each priced step has a free form beside it, and the code's theorems use only the free forms.

Amounts are points of $\mathbb{R}_\delta$ and ticks are natural numbers. Comparisons are those of this chapter: $a \geq 0$ means $\neg(a < 0)$, and $a \neq 0$ is the negation of $a = 0$. Where [198] reads a multiplier x, the line reads its log-flow t, with $x = e^t$; so $J(x) = \cosh t - 1$ (Definition 21.11), and $x = 1$ exactly when $t = 0$.

Definition 22.66 (The record of relations, on the line)**.** A *world* W has a finite set B of relations. A relation b has a source end and a destination end, held by participants $s(b)$ and $d(b)$, and each end holds a log-amount, $h_b(s)$ and $h_b(d)$. Its log-flow is $t_b = h_b(s) - h_b(d)$, its multiplier $x_b = e^{t_b}$ and its cost $J(x_b) = \cosh t_b - 1$; it is *at balance* when $x_b = 1$. Each end keeps an entry for b on its books, and the books are *true* when every entry is the multiplier. Each relation has a reserve θ_b, held by neither end. The *real cost* of W is $C(W) = \sum_{b \in B} J(x_b)$. The participants'

writes P are a set of pairs (participant, relation); b is *movable* when it is live and $(s(b), b)$ and $(d(b), b)$ both lie in P. The relations have *distinct ends* when $s(b) \neq d(b)$ for every b.

An *exchange* on b of amount a posts a at the source end and $-a$ at the destination end; one of the two ends emits it at a tick, and it is absorbed at a later tick, at least one tick after its emission. A *reserve post* on b adds an amount to θ_b; the source end, the destination end, both or neither emit it. An *act* α is a finite list of exchanges together with a finite list of reserve posts; doing nothing is the empty act. It reaches the world in which every holding has changed by the net of the posts at its end, so that t_b changes by twice the net posted at the source end, with true books, nothing ended, and every reserve changed by the net of its posts.

In α, an end k of b *absorbs* on b the sum of the posts at its end of the exchanges on b that the other end emits, and at b's reserve the net of the reserve posts on b that k did not emit. It *consents* on b when it emits on b, by an exchange or a reserve post, and both amounts it absorbs are ≥ 0. The act *has consent* when every end whose holding on a relation it changes, and each end of every relation whose reserve it changes, consents there.

A *recorded world* is a world with its reserves together with a record: a finite list of exchanges and reserve posts, each with its relation, amount and emitters. The recorded world R_α of α is the world it reaches, its reserves after it, and its own posts. *Writes* ω assign to each recorded world a set of pairs (participant, relation). They *meet* (W) on a set $\mathscr{R}$ of recorded worlds when, for every $R \in \mathscr{R}$, every relation b of W and each end of b, the pair (participant at that end, b) lies in $\omega(R)$ exactly when that end consents on b as the record of R shows.

Definition 22.67 (The code)**.** Let W have true books and every relation live, let $\mathscr{A}$ be a set of acts, and let ω be writes. An act $\alpha \in \mathscr{A}$ is *admissible* when both ends of every relation whose multiplier or reserve α changes write on that relation in $\omega(R_\alpha)$. Let W_α be the world α reaches and Φ the record's motion through one interval. An admissible act β *overtakes* α when $\sum_{n \leq N} C(\Phi^n W_\beta) < \sum_{n \leq N} C(\Phi^n W_\alpha)$ for every large enough N. The code *permits* the admissible acts of $\mathscr{A}$ that no admissible act of $\mathscr{A}$ overtakes, and *refuses* every other act of $\mathscr{A}$. The *balanced record* puts every movable relation at balance and keeps every other multiplier. The *balancing act* emits two exchanges on every movable relation b and nothing else: with $g = t_b$, $g^+ = \max(g, 0)$ and $g^- = \max(-g, 0)$, the source end emits one of amount $-g^+/2$ and the destination end one of amount $g^-/2$.

The code of [198, Definition 3.1] admits an act when four clauses hold: it moves only live relations; every new entry is written truthfully; it changes a relation's entry or its multiplier only when both ends of that relation write on it; and every live relation it ends is written on by one of its own ends. Admission in Definition 22.67 is these clauses on such worlds: an act of exchanges moves only live relations, ends nothing and writes true entries, so the clauses ask only that both ends of a changed relation write on it, and the code asks the same of every changed reserve. Where the record holds still between acts, Φ is the identity, so each act's world is the same at every checkpoint and one act overtakes another exactly when its world costs less; the code then permits α exactly when α is admissible and $C(W_\alpha) \leq C(W_\beta)$ for every admissible $\beta \in \mathscr{A}$ [198, Proposition 5.2]. On the line this reduction is free, because "no admissible act reaches a smaller cost" is the relation $\leq$ itself. In the balancing act each end gives half of what it holds above the other, and the end that holds less gives 0. It tests nothing: g^+ and g^- are defined at every point.

Theorem 22.68 (The moral code on the record is free)**.** *Let W have true books and every relation live, let the record the code reads hold still between acts, let P be participants' writes, $\mathscr{A}$ a set of acts and ω writes, and let G be a price on positive points with $G(x) \geq 0$, and $G(x) = 0$ exactly when $x = 1$. Let*

(H1) the code's menu be the recorded worlds of the acts of $\mathscr{A}$;

(H2) every exchange of every act of $\mathscr{A}$ be on a relation of W;

(H3) ω meet (W) on the recorded worlds of the acts of $\mathscr{A}$, with $\omega(R_\alpha) \subseteq P$ for every $\alpha \in \mathscr{A}$;

(H4) the balancing act be an act of $\mathscr{A}$.

Then, with no omniscience principle and no choice principle:

(a) An act of $\mathscr{A}$ is admissible exactly when it has consent.

(b) The code permits an act of $\mathscr{A}$ exactly when it has consent and reaches the balanced record; equivalently, when it has consent and its price $\sum_b G(x'_b)$, at the multipliers x'_b it reaches, is at most the price of every act of $\mathscr{A}$ with consent.

(c) The code permits the balancing act.

(d) No net taking is admitted or permitted: an act of $\mathscr{A}$ in which an end whose holding on b, or b's reserve, the act changes absorbs an amount < 0 on b or at b's reserve is neither admissible nor permitted.

(e) Love takes two: if the code permits an act of $\mathscr{A}$ that brings a relation with $x_b \neq 1$ to balance, both ends of that relation consent there.

(f) On every run of exchanges, let the code read at each tick the world that the posts made by then carry, let every exchange be absorbed within L ticks of its emission, and let $t \leq s$ be ticks that each come at least L ticks after every emission up to it. If no exchange is emitted after t and at or before s, the code reads the same world at s as at t. Under the motion that holds still, take k relations and a menu of single acts *on them: a set of admissible acts, each of which sets the log-flows of the k relations once, after which the motion carries each relation on its own and nothing else acts on them. If some act of the menu brings all k relations to balance, the code permits exactly the acts of the menu that reach balance.*

(g) Every exchange posts equal and opposite amounts and is absorbed at least one tick after its emission.

The same holds when ω meets (W) on every recorded world and $\omega(R_\alpha) \subseteq P$ for every $\alpha \in \mathscr{A}$, as in [198, Theorem 9.10], since that gives (H3) at once.

Proof. (a) By (H2) the act moves only live relations; it ends nothing and writes true entries. An exchange posts a at the source end and $-a$ at the destination end, so the act changes t_b by twice the net n_b it posts at the source end, and $2n_b = 0$ exactly when $n_b = 0$. So it changes x_b exactly when it changes the holdings at both ends, and admission asks that both ends of

every relation whose holdings or reserve change write on it in $\omega(R_\alpha)$. By (H3) that is that both ends consent there: consent. Every condition here is an implication from "$\neq 0$" to a finite membership, and nothing is decided.

(b) By (a) and (H3), an admissible act changes x_b only when both ends of b write on it inside P, that is only on a movable relation, every relation being live. So it keeps every other relation, and its world costs at least the balanced record's cost $\sum_{b \text{ not movable}} J(x_b)$. If it costs at most that, the costs $J(x'_b) \geq 0$ of its movable relations sum to at most 0, so each is 0 and each $x'_b = 1$ (Proposition 22.15). The balancing act attains the bound: each end emits on each movable relation; the source end absorbs $g^-/2 \geq 0$ and the destination end $g^+/2 \geq 0$; and the source end's net post is $(g^- - g^+)/2 = -g/2$, so t_b goes to 0. It has consent, so it is admissible by (a). With the reduction of Definition 22.67, the code permits exactly the acts with consent that reach the balanced record. For G the same bound holds term by term.

(c) follows from (b). (d) The end that absorbs an amount < 0 does not consent, so by (a) the act is not admissible, and the code permits only admissible acts. (e) A permitted act has consent by (a), and bringing $x_b \neq 1$ to 1 changes both holdings of b.

(f) At such a tick every exchange emitted by then has been absorbed, so the posts carry the record of completed exchanges, which no exchange changes between t and s. Under the motion that holds still, each act's cost on the k relations, $\sum_i J(x_i)$ at the multipliers it sets, is the same at every checkpoint, so β overtakes α exactly when β's cost is smaller. An act of the menu that brings the k relations to balance costs 0 and is admissible, so an act permitted on the menu is not overtaken by it and costs at most 0; each term $J(x_i) \geq 0$ is then 0, and every $x_i = 1$. Conversely an act of the menu that reaches balance costs 0, which no act undercuts, and it is admissible, so the code permits it. This argument is direct and free.

(g) is the definition of an exchange. The last sentence holds because (W) on every recorded world is (W) on the recorded worlds of the acts of $\mathscr{A}$, and $\omega(R_\alpha) \subseteq P$ is assumed. □

For comparison, here are the conclusions of [198, Theorem 9.10] in full. Its hypotheses are those of Theorem 22.68, with (H3) read as (W) on every recorded world and the writes on the recorded world of every act of $\mathscr{A}$ inside P, and with a price G that is zero exactly at balance. It concludes:

(a) an act of $\mathscr{A}$ is admissible exactly when it has consent;

(b) the code permits an act of $\mathscr{A}$ exactly when it has consent and leaves the balanced record, every movable relation at balance and the rest where they were; equivalently, when it has consent and its price $\sum_b G(x'_b)$ is least among the acts of $\mathscr{A}$ with consent;

(c) the code permits the balancing act;

(d) no net taking in $\mathscr{A}$ is admitted or permitted, on a relation or at its reserve: an act of $\mathscr{A}$ in which an end whose holding it changes, or an end of a relation whose reserve it changes, absorbs a net loss there is neither admissible nor permitted; nor is an act of $\mathscr{A}$ with a taking that its taker does not give back, that is, whose taker's other exchanges post less than the taking's amount at the victim's end on net, when it changes the victim's holding;

(e) love takes two: if the code permits an act of $\mathscr{A}$ that brings a relation from off balance to balance, both ends of that relation consent there, each emitting on it and neither absorbing a net loss on it or at its reserve;

(f) on every run of exchanges, with the timing of (f) above, the code reads the same world at s as at t; the motion that holds still keeps balance and repairs nothing, so balance leads under it, and the code permits, on relations each written by its participant and carried by this motion on its own, exactly the act to balance on every menu of single acts that offers it;

(g) every exchange posts equal and opposite amounts, absorbed at least one tick after its emission.

Theorem 22.68 proves (a), (b), (c), (e) and (g) as they stand, for $G \geq 0$, and the first sentence of (d). The second sentence of (d) is a case of the first: the victim's end absorbs on the relation the net of the taker's exchanges, which is the taker's other posts there less the taking's amount, an amount < 0. In (f), the reading of the world and the code law are Theorem 22.68(f), proved directly; "balance leads" is free when it is read with "apart" and costs MP when it is read with "$\neq$" (Theorem 22.72(vi)).

Corollary 22.69 (The record fixes the emitters, and the duty to help)**.** *Free:*

(a) Two acts with one recorded world have the same emitters: at every end of every relation, one emits there, by an exchange or a reserve post, exactly when the other does.

(b) Under the hypotheses of Theorem 22.68, with doing nothing an act of $\mathscr{A}$, let every movable relation be at balance. Then the code permits doing nothing and the balancing act; it permits exactly the acts of $\mathscr{A}$ with consent that keep every multiplier; and no act of $\mathscr{A}$ without consent is admissible or permitted.

(c) Under the hypotheses of Theorem 22.68, with doing nothing an act of $\mathscr{A}$, the code permits doing nothing exactly when every movable relation is at balance, and refuses it exactly when not every movable relation is at balance.

(d) Let W have true books, every relation live and distinct ends, and let P be any participants' writes. Take $\mathscr{A}$ to be doing nothing and the balancing act, and ω the emitter writes*: the pairs (participant at an end, b) for the ends whose record shows an emission on b. Then (H1)–(H4) hold. So on every such world, with the record holding still between acts, the code refuses doing nothing exactly when not every movable relation is at balance.*

Proof. (a) The record lists every post with its emitters. (b) The balanced record now keeps every multiplier; doing nothing has consent, and the balancing act posts only amounts 0 and has consent; apply Theorem 22.68(a) and (b). (c) Doing nothing has consent and keeps every multiplier, so by Theorem 22.68(b) it is permitted exactly when W is the balanced record; the second half is the negation of the first. (d) Doing nothing's record shows no emission, so its writes are empty. In the balancing act's record the emitting ends are the two ends of the movable relations, and each absorbs no loss, so with distinct ends the emitter writes are exactly the consenting ends and lie in P. Whether a finite record shows an emission is a finite search. □

Part (c) is the duty to help: where a movable relation is off balance, doing nothing is forbidden. Part (d) states the duty on every world with distinct ends, with writes that cost nothing to read. Its last form, [198, Corollary 9.14], "some movable relation is off balance", costs $\mathrm{MP}^{\vee}$ when (W) holds on the menu only (Theorem 22.72(vii)); with (W) on every recorded world it is free, because that hypothesis already decides whether each movable relation is at balance. That hypothesis is not free to supply: writes meeting (W) on every recorded world exist only with the WLPO function (Theorem 22.72(iii)).

The code's two clauses produce consent. Read the record of an act α at an end k of a relation b: $u = (u_1, u_2)$ is what k sent, the net of its own posts on b at its holding and at the reserve; $v = (v_1, v_2)$ is what it received, the net of the posts on b it did not emit, at the same two places; and its change is $\Delta = u + v$. A *book* of k on b is a pair ψ that meets the three cases of [198, Definition 9.5]: $\psi = (0, 0)$ if $\Delta_1 = 0$ and $\Delta_2 = 0$; $\psi = u + v$ if $\Delta_1 \neq 0$ or $\Delta_2 \neq 0$, and $v_1 \geq 0$ and $v_2 \geq 0$; $\psi = u$ if $\Delta_1 \neq 0$ or $\Delta_2 \neq 0$, and $v_1 < 0$ or $v_2 < 0$. The book is *true* when $\psi = \Delta$. The truth clause asks that the books of both ends of a relation be true; the both-ends clause, with the emitters as writes, asks that both ends of a relation that moved emit on it.

Proposition 22.70 (Consent from the two clauses, and consent forced)**.** *Free:*

(a) Two books of one end on one relation are equal, and a book is true exactly when, if $\Delta_1 \neq 0$ or $\Delta_2 \neq 0$, then $v_1 \geq 0$ and $v_2 \geq 0$.

(b) Let the relations of W have distinct ends, and take a book of each end on each relation on the record of α. Then α has consent exactly when the truth clause and the both-ends clause hold on every relation of its recorded world. Under the hypotheses of Theorem 22.68, an act of $\mathscr{A}$ is admissible exactly when the two clauses hold there.

(c) The third case cannot be replaced by the true book: on one relation, let the source end emit an exchange of amount 1, a taking of 1, and the destination end an exchange of amount 0. With Δ as every book and the emitters as writes both clauses hold, yet the destination end absorbs -1 and the act lacks consent.

(d) On one relation, call a history of exchanges a net taking *when some end whose holding it changes absorbs an amount < 0, and an* unrequested gift *when some end whose holding it changes emits nothing. A history has consent exactly when it is neither. So consent is the greatest condition on histories that refuses every net taking and every unrequested gift, and a condition on histories is consent exactly when it refuses those and passes every other history.*

Proof. (a) Equality of points is stable under double negation, and under double negation one of the three cases applies, so two books coincide. If the relation did not move, $\psi = (0, 0) = \Delta$. If it moved and $v \geq 0$, then $\psi = u + v = \Delta$. If it moved and some $v_i < 0$, then $\psi = u$, and $\psi = \Delta$ would give $v = 0$; so a true book excludes $v_i < 0$, which is $v_i \geq 0$. (b) By (a), at an end of a moved relation the book is true exactly when the end received no net loss, and the both-ends clause asks that both ends emitted: together, that both ends consent. A relation moves exactly when the holding of either end or its reserve changes, and then both holdings or the reserve change; so the clauses on every relation are consent. The second sentence is this with Theorem 22.68(a). (c) Both ends emitted, and the true book is true by definition. (d)

Absorbing no net loss is by definition the negation of absorbing an amount < 0, and whether an end emitted on the relation is a finite search, so its double negation gives it. □

The price at the multiplier [198, Section 9.6] reaches the same verdicts from the shape of J. A taking moves a relation from e^s to e^t while the silent end's entry stays at e^s; charge it the absolute slope of the cost at s, $\sinh|s|$, times the distance moved.

Proposition 22.71 (The price at the multiplier)**.** *Free:*

(a) For all points s and t, $\cosh s - 1 \le \cosh t - 1 + \sinh|s| \cdot |s - t|$, strictly when t is apart from s, and equality holds only if $t = s$. With $r = e^s$ and $y = e^t$ this reads $J(r) \le J(y) + \sinh|\log r| \cdot |\log(r/y)|$.

(b) Let B be a finite set of relations with log-flows t_b, $\mathscr{A}$ a set of acts with log-flows $t_b(\alpha)$ after each act, "silent" any rule on acts and relations, and $M \subseteq B$, such that every act that changes a relation outside M is silent on it, and some act changes no relation with a silent end and puts every relation of M at balance and keeps the rest. Let $c_b(\alpha)$ be any values meeting the cases $c_b(\alpha) = \sinh|t_b| \cdot |t_b - t_b(\alpha)|$ if $t_b(\alpha) \neq t_b$ and b is silent in α, and $c_b(\alpha) = 0$ otherwise, and let $p(\alpha) = \sum_b \big(\cosh t_b(\alpha) - 1 + c_b(\alpha)\big)$. Then $p(\alpha) \le p(\beta)$ for every $\beta \in \mathscr{A}$ exactly when α changes no relation with a silent end, puts M at balance and keeps the rest.

(c) Read Theorem 22.68 on worlds: the menu is the worlds the acts of $\mathscr{A}$ reach, the writes on each are the ends that consent in the act reaching it, and b is silent in α when an end of b does not consent there. An act of $\mathscr{A}$ whose reserve posts are consented has least charged price exactly when the code permits it; so does every act with no reserve post. On one relation with the source end holding 1 and the destination end 0, no participant writing on it, and $\mathscr{A}$ doing nothing and a taking of 1 from the reserve by neither end, every hypothesis holds, the taking has least charged price for every charge meeting the cases, and the code refuses it and permits doing nothing.

Proof. (a) Put $d = t - s$. Then

$$\cosh t - \cosh s - d\sinh s = \tfrac{1}{2}e^s\big(e^d - 1 - d\big) + \tfrac{1}{2}e^{-s}\big(e^{-d} - 1 + d\big),$$

a sum of two terms ≥ 0, both positive when d is apart from 0; and $d\sinh s \ge -\sinh|s| \cdot |d|$. Equality makes d apart from 0 impossible, so $d = 0$. (b) Compare term by term with the balanced price. A relation outside M that α changes is silent, so by (a) it contributes at least its old cost, and exactly that only if it is unchanged; a relation of M contributes $\cosh t_b(\alpha) - 1 + c_b(\alpha) \ge 0$, which is 0 exactly when it is at balance with no charge. The act of the hypothesis attains the bound. (c) On these worlds a relation outside the movable ones cannot change with both ends consenting, so (b) applies with the balancing act; an act has consent exactly when it changes no relation with a silent end and its reserve posts are consented, and Theorem 22.68(b) finishes. In the example the taking changes no multiplier and carries no charge, while no end consents at the reserve. □

Consent at the reserve refuses what the charge cannot see: the charge reads multipliers, and a reserve moves none.

Here are the prices. Each priced step is stated as a statement about every case, and each is beside a free form proved above.

Theorem 22.72 (The priced steps of the moral code)**.** *Each of the following assertions is equivalent to the principle named, with no choice principle in either direction.*

(i) For every world and every act, the act has consent or it does not: WLPO. For every act and relation, the relation is silent in the act or it is not: WLPO. Free form: consent stated, not decided (Theorem 22.68).

(ii) For every recorded world, relation and end, some book meets the cases: WLPO. Free form: books on the act's own record (Proposition 22.70(b)).

(iii) For a world with at least one relation, whose relations all have distinct ends: writes meeting (W) on every recorded world exist, exactly when the WLPO function exists. Free form: (W) on the menu's recorded worlds, which the emitter writes meet with no decision (Corollary 22.69(d)).

(iv) A rule f from points to $\{0,1\}$ naming an end that holds at least as much, $f(g)=1$ giving $g\geq 0$ and $f(g)=0$ giving $g\leq 0$, exists exactly when the WLPO function exists; so does an exact test, $f(g)=1$ exactly when $g\geq 0$. Free form: the balancing act, which tests nothing.

(v) For every history of exchanges and reserve posts on one relation and each end, let U say that the end's holding and the reserve are unchanged and N that both amounts the end absorbs are ≥ 0. Then $(\neg U\to N)$ gives $U\vee N$: LLPO. Free form: the implication $\neg U\to N$.

(vi) For all points s,t with $t\neq s$, $\cosh s-1<\cosh t-1+\sinh|s|\cdot|s-t|$: MP. So is balance leading under the motion that holds still [198, Lemma 5.11(a)]: for every $t\neq 0$, $\sum_{n\leq N}J(e^0)<\sum_{n\leq N}J(e^t)$ for every large enough N. Free forms: Proposition 22.71(a), and the code law of Theorem 22.68(f), proved directly.

(vii) For every world and participants' writes, if not every movable relation is at balance, then some movable relation has $x_b\neq 1$: $\mathrm{MP}^{\vee}$. Free form: Corollary 22.69(c) and (d).

Proof. (i) WLPO decides $a=0$ and $a\geq 0$ for every point (Table 12.2); consent is a finite conjunction, over the relations and their two ends, of implications between such statements and a finite search for an emission, so it is decided. Conversely, on one relation let the source end emit an exchange of amount 0 and the destination end one of amount z. Both ends emit; the source end absorbs z and the destination end 0. So the source end consents, and the act has consent, exactly when $z\geq 0$: $z<0$ would make $z\neq 0$ and the absorbed amount negative. Deciding consent, or silence, decides $z\geq 0$ for every z, which is WLPO (Table 12.2).

(ii) Given WLPO the tests of the cases are decided and a book exists. Conversely, let the source end emit an exchange of amount $1+|x|$ and the destination end one of amount -1. The source end's holding changes by $|x|$ and it absorbs -1, so a book is $(0,0)$ if $x=0$ and $(1+|x|,0)$ if $x\neq 0$. Its first entry p satisfies $0<p$ or $p<1$; the first excludes $x=0$, the second excludes $x\neq 0$, and $x=0$ is stable. So $x=0$ or $x\neq 0$.

(iii) Let ω meet (W) everywhere and let b be a relation. For a point z, let R_z be W with zero reserves and the record in which the source end of b emits an exchange of amount 0 and the destination end one of amount z. As in (i), the source end consents on b in R_z exactly when $z\geq 0$. Membership in the finite set $\omega(R_z)$ is a bit, so $z\mapsto[(s(b),b)\in\omega(R_z)]$ is a map from the

line to $\{0,1\}$ with value 1 at 0 and 0 at -1; by Theorem 22.64, part 1, applied at $u \mapsto u-1$, it gives the WLPO function. Conversely the WLPO function decides $\leq$ as data (Theorem 28.3, part 2); list, relation by relation, each end whose record passes the test. With distinct ends each pair (participant, relation) names one end, so these writes meet (W) on every recorded world.

(iv) $f(1) = 0$ would give $1 \leq 0$, so $f(1) = 1$, and likewise $f(-1) = 0$; so f is a map with two values, and Theorem 22.64, part 1, gives the WLPO function. Conversely the WLPO function decides $g \geq 0$ as data (Theorem 28.3, part 2), an exact test.

(v) Let the source end emit an exchange of amount $-z$ and the destination end one of amount $-z^-$. The source end's holding changes by $-z^+$ and it absorbs $-z^-$, so U is $z \leq 0$ and N is $z \geq 0$. And $\neg U \to N$ holds: $z^- > 0$ would give $z < 0$ and $z^+ = 0$. So the assertion gives $z \leq 0$ or $z \geq 0$ for every z, which is LLPO (Corollary 12.18). Conversely, put $a = |\Delta_1| + |\Delta_2|$ and $l = v_1^- + v_2^-$, both ≥ 0, from the change Δ and the absorbed amounts v. LLPO gives $a \leq l$ or $l \leq a$. If $a \leq l$ and $a > 0$, then $\neg U$, so N, so $l = 0$, which is impossible; so $a = 0$, and U. If $l \leq a$ and $l > 0$, then $a > 0$ and the same argument gives $l = 0$; so $l = 0$, and N.

(vi) At $s = 0$ the assertion is: $t \neq 0$ gives $J(e^t) > 0$, which is Theorem 22.16(i); so it gives MP. Conversely MP makes $t \neq s$ apart (Table 12.2), and Proposition 22.71(a) applies. Under the motion that holds still the two sums are 0 and $(N+1)J(e^t)$, so balance leads exactly when every $t \neq 0$ has $J(e^t) > 0$: MP again.

(vii) For a point $r \neq 0$, take two relations from one participant to another, both ends writing on both, at log-flows r^+ and r^-, so $r = r^+ - r^-$. Both at balance would give $r = 0$, so not both are; the assertion names one with $x_b \neq 1$. If it is the first, $r^+ \neq 0$, and $r < 0$ would give $r^+ = 0$, so $r \geq 0$; if the second, $r \leq 0$. So every nonzero point has a weak sign, which is $\mathrm{MP}^\vee$ (Theorem 14.19). Conversely, let the movable relations have log-flows $t_1, \dots, t_m$, not all 0, and argue by induction on m; for $m = 1$ there is nothing to prove. Fix regular sequences for them; let $e(2k) = 1$ when stage k of t_1 witnesses $t_1 \# 0$ and $e(2k+1) = 1$ when stage k of some t_i with $i \geq 2$ witnesses $t_i \# 0$, and let f mark the first event of e. Then f has at most one 1, and it is not all 0, since then every t_i would be 0. By $\mathrm{MP}^\vee$ its odd entries are all 0, and then $t_1 = 0$ would leave no event at all, so $t_1 \neq 0$; or its even entries are all 0, and then $t_2, \dots, t_m$ are not all 0, and the induction applies. □

The first theorem of [198] fixes the judgment itself. A *case* (S, o, c) is a set S of acts, an act o, doing nothing, and a real price $c(s)$ for every act; a *judgment form* $\mathcal{F}$ returns the set $\mathcal{F}(S,o,c)$ of acts it permits, and the least form is $\mathcal{L}(S,o,c) = \{s \in S : c(s) \leq c(t) \text{ for every } t \in S\}$. The joint case of (S,o,c) and (T,o',d) is $(S \times T, (o,o'), c \oplus d)$, with $(c \oplus d)(a,b) = c(a) + d(b)$.

Theorem 22.73 (The judgment is unique; quoted from [198, Theorem 6.2], not proved here)**.** *In classical mathematics, let a judgment form $\mathcal{F}$ meet: (J1) if $o \in S$ then $\mathcal{F}(S,o,c) \subseteq S$; (J2) if $s, t \in S$ differ from o, $c(s) = c(t)$ and $s \in \mathcal{F}(S,o,c)$, then $t \in \mathcal{F}(S,o,c)$; (J3) $\mathcal{F}$ of a joint case is the product of the two judgments; (J4) if $\mathcal{F}$ permits o, then $c(o) \leq c(t)$ for every $t \in S$; (J5) $\mathcal{F}$ permits some act on every situation the record allows. Then on every situation σ the record allows, $\mathcal{F}(A_\sigma, o_\sigma, c_\sigma) = \mathcal{L}(A_\sigma, o_\sigma, c_\sigma)$: $\mathcal{F}$ permits exactly the admissible acts of least real cost, the acts the code permits where the record holds still between acts, on true books.*

Here a situation the record allows, its admissible acts A_σ and the prices c_σ, the real costs of the worlds the acts reach, are those of [198, Section 6.1]: a world whose menu is every act executable with some available energy, every act's writes inside some participants' writes P, with the balancing act of P on the menu. The theorem is quoted from [198], where it is proved in classical mathematics; this book does not prove it, and its price on the line is not determined here.

Conditions and scope.

Base and premises

The line, the cost J, and the worlds, acts, records and code of Definitions 22.66 and 22.67, at the scope of [198]: true books, every relation live, and the record the code reads holding still between acts where a theorem says so. The identification (W) of the code's writes with the ends that consent is a hypothesis of Theorem 22.68, as in [198, Theorem 9.10]; on the menu of Corollary 22.69(d) the emitter writes meet it.

Conclusion

With the code's hypothesis in its free form (H3), every conclusion of [198, Theorem 9.10], listed in full after Theorem 22.68, with [198, Proposition 9.2, Theorem 9.6(b), Proposition 9.7(d), Corollaries 9.11, 9.13 and 9.14, Theorem 9.12 and Theorem 9.16] and consent forced as the greatest condition [198, Section 8.4], is free in the forms stated here. Deciding consent or silence, and a total book rule, cost exactly WLPO; on a world with at least one relation whose relations all have distinct ends, writes meeting (W) on every recorded world cost exactly the WLPO function, and so does any rule that names the end holding more; "no change or no net loss" costs LLPO; the strict inequality from "$\neq$", and balance leading read with "$\neq$", cost MP; and the finite De Morgan step in the duty to help costs $\mathrm{MP}^\vee$.

Not claimed

A proof or a price on the line for Theorem 22.73, which is quoted, classical and unpriced; any statement of the moral code beyond [198]; and the physical premises that [198, Section 11] lists as steps not yet derived, among them that the code's writes are the emitters and that its records are the books of the book rule, which enter here as stated hypotheses.

Read physically, a world that keeps its record carries, with its holdings, the posts that reached it and who emitted each one. That record tells apart two acts that reach the same holdings with different emitters, and every verdict of the code follows from it with no decision. What costs something is a rule written as a function over every conceivable record: it has to decide whether an absorbed amount is a loss, a weak sign on the line. The code never needs that rule beyond the records its own acts produce.

Questions to work through

1. (Theorem 22.16.) Give a second proof that assertion (ii) implies MP, without the jump point: apply (ii) at $x = 1 + r^2$ and use the row of Table 12.2 that prices $x \neq 0 \to x < 0 \vee x > 0$.

2. (Theorem 22.20 and Proposition 22.21.) In the model, compute $\ell(n) = A^n(0,1)$ in terms of Fibonacci numbers, check $\nu(\ell(n)) = \varphi^n$ directly from Proposition 22.37(d), and verify each hypothesis of Theorem 22.20(b) for the state $s_* = 0$.

3. (Theorem 22.31.) Show, with no principle, that for $x, y \geq 1$ the equation $J(x) = J(y)$ implies $x = y$. Explain why LLPO enters the general statement only through the reciprocal branch $xy = 1$.

4. (Theorem 22.44.) Using the brackets for π and $\log \varphi$ in Section 22.9, show that the clock ratio $\pi/(4 \log \varphi)$ lies between 1.631 and 1.633, and that it differs from $K = \sqrt{\varphi}$ by more than $1/10$.

5. (Theorem 22.42(b).) Let $h : \mathbb{R}_\delta \to \mathbb{R}_\delta$ have uniform derivative 0 on every bounded interval. Show by the telescoping argument that h is constant, and deduce from (b) that a function g satisfying its hypotheses has $g(x)\, g(-x) = \sigma^2$ for every x.

6. (Proposition 22.49(b).) Let $D \geq 1$. Show, with no principle, that a sequence of points of $\{0,1\}^D$ with period $p > 0$ that reaches every point has $p \geq 2^D$, and write down one such sequence with $p = 2^D$ in which consecutive points differ in exactly one coordinate.

Chapter 23

Why three dimensions

Why should a world of distinctions have three spatial dimensions? Recognition Science answers through records that keep a pair. Two linked loops of string cannot be pulled apart without cutting one of them: the link is a record that no continuous deformation erases. Recognition Science identifies such a kept pair with a closed curve linked in space. That identification is a premise of its forcing chain, and from it the dimension of space must be one in which a closed curve can be linked. That this dimension is three is the topological fact on which the step rests; Chapter 22 lists the step in its forcing chain. This chapter proves that fact on $\mathbb{R}_\delta$, and asks what it costs.

Classically the fact goes back to Alexander: a circle embedded in the D-sphere has a complement whose first homology group is $\mathbb{Z}$ when $D = 3$ and zero for every other $D \geq 2$ [191], [194, Proposition 2B.1]. The D-sphere is D-dimensional space closed up by one point at infinity, so $D = 3$ is ordinary space. The classical proofs bisect an arc again and again, keeping a half in whose complement some cycle fails to bound, and finish with a compactness argument; along the way they decide freely whether a point lies on the curve or off it. None of these moves is free on the line. Bisection decides at every stage which half to keep; the compactness argument has the prices that Chapter 13 computes; and deciding membership in a closed set is an omniscience principle.

Here is the smallest case, and it shows how the decisions disappear. In the 2-sphere S^2 of points (x_0, x_1, x_2) with $x_0^2 + x_1^2 + x_2^2 = 1$, the plane closed up by one point, take the equatorial circle C where $x_2 = 0$. Is C linked: does some loop that keeps away from C fail to bound a surface that also keeps away from C? Let γ be a loop that keeps a distance $r > 0$ from C. Its third coordinate never comes near zero: $|\gamma_2(t)| \geq c = \min(r/2, 1/4)$ at every time t, since a point with a small third coordinate lies close to the point of C obtained by rescaling its first two coordinates. Whether γ runs above or below C looks like a sign decision, and signs of points are not free (Corollary 12.18). Here none is needed. At $t = 0$ the number $\gamma_2(0)$ is apart from 0, so it is positive or negative, and that much is free. The sign then cannot change. The loop is uniformly continuous, so over every time step shorter than its modulus at c the third coordinate moves by less than c, while passing from at least c to at most $-c$ takes a move of $2c$; finitely many such steps cover $[0, 1]$. Say the loop runs above, so $\gamma_2(t) \geq c$ for every t. The map

$$H(s, p) = \Big(s\, p_0,\ s\, p_1,\ \sqrt{1 - s^2\big(p_0^2 + p_1^2\big)} \Big), \qquad 0 \leq s \leq 1,$$

slides each point of the upper hemisphere along its meridian to the pole $(0, 0, 1)$: $H(1, p) = p$ there, $H(0, p)$ is the pole, and the third coordinate only grows, so nothing approaches C. The square of pairs (s, t), cut along its diagonal, gives two triangles $(s, t) \mapsto H(s, \gamma(t))$. Their boundaries, with the boundary of the constant triangle at the pole, add up to γ, because the two remaining edges are the paths of the same point $\gamma(0) = \gamma(1)$ and cancel. Every loop of the complement bounds. The equatorial circle of S^2 is not linked, and nothing was decided.

What made the case free is a sign that cannot flip. The complement of C reads into two points, above and below, which form the 0-sphere $S^0 = \{-1, 1\}$, and a uniformly continuous path in S^0 is constant. That needs no decision either: two points of S^0 closer than 1 are equal. The general argument lowers the dimension of the sphere step by step (Section 23.4). For $D = 2$ the descent ends at exactly this fact about S^0. For $D \geq 4$ it ends at a sphere of positive dimension, in which any two points are joined by a path. For $D = 3$ it ends at the circle, whose winding number stops it; there an explicit loop around the equatorial circle of S^3 sweeps four quarter turns and bounds nothing (Section 23.7).

Theorem 23.8 states the result: for every natural number D, some natively embedded circle in the native D-sphere is linked if and only if $D = 3$, with no omniscience principle and no choice principle. The definitions are those of singular homology, built from the line (Section 23.1). The proof replaces bisection by explicit moduli, compactness by finitely many comparisons and Lebesgue numbers computed from moduli, and the winding function by a relation between chains and values. The one price in the chapter belongs to a different question: whether the winding number of the circle can be given as one integer-valued function on all chains of paths. Section 23.10 relates that function to colourings of the circle and to the WLPO function, and Theorem 22.65 shows that it costs exactly the WLPO function. It is refuted by the Borsuk–Ulam property for two-colourings of the circle, and the WLPO function by the continuity of Boolean functions on Cantor space; both properties hold in Brouwer's intuitionistic mathematics and fail classically.

Two conventions hold throughout. A ratio used as a point stands for its point, as in Chapter 13. For points of the line, $x \leq y$ means $\neg(y < x)$, as in Proposition 12.19.

23.1 Spheres, simplices and chains built from the line

Everything in this section is built from $\mathbb{R}_\delta$ and its ordered field structure, which costs nothing (Proposition 12.19): sums, products, max, min, $|x|$, nonnegative square roots, inverses of points apart from 0, and cotransitivity of $<$. Equality of points is equality on the line. Deciding it costs WLPO (Corollary 12.18), and no definition below asks for it.

Definition 23.1 (Native spheres)**.** Let D be a natural number. The *native D-sphere* S^D is the set of tuples $x = (x_0, \dots, x_D)$ of points of $\mathbb{R}_\delta$ with $x_0^2 + \cdots + x_D^2 = 1$, with the sup distance $d(x, y) = \max_i |x_i - y_i|$. We write $\langle x, y\rangle = \sum_i x_i y_i$ and $|x|^2 = \langle x, x\rangle$, so that $d(x, y)^2 \leq |x - y|^2 \leq (D{+}1)\, d(x, y)^2$. The *native circle* is S^1. The *poles* of S^D are $N = (1, 0, \dots, 0)$ and $S = (-1, 0, \dots, 0)$; for $D \geq 1$ its *equator* is the set of points with $x_0 = 0$, a copy of S^{D-1}. A *removed set* is given as the image of a map $K : X \to S^D$ from any set X. A point y is *r-apart* from K when $d(y, K(x)) \geq r$ for every x, and *apart* from K when it is r-apart for some $r > 0$.

Definition 23.2 (Uniform continuity, apartness and embeddings)**.** A map g between sets with distances d_A and d_B is *uniformly continuous* when there is a map ω from the line to the line, a *modulus*, such that $\varepsilon > 0$ implies $\omega(\varepsilon) > 0$ and $d_A(a, b) < \omega(\varepsilon)$ implies $d_B(g(a), g(b)) < \varepsilon$. A map g into S^D is *uniformly apart* from a removed set K when a single $r > 0$ has $d(g(a), K(x)) \geq r$ for every a and every x. A *native embedding* of the circle is a uniformly continuous $f : S^1 \to S^D$ with a second modulus ω' such that $d(f(a), f(b)) < \omega'(\varepsilon)$ implies $d(a, b) < \varepsilon$.

The definitions assert that the moduli and the radius r exist. A map does not carry them as data; this matters in Section 23.10.

Definition 23.3 (Model simplices and native singular simplices)**.** For $k \geq 1$ the *model k-simplex* Δ^k is the set of tuples $(y_1, \dots, y_k)$ of points of the line with $0 \leq y_1 \leq y_2 \leq \cdots \leq y_k \leq 1$, with the sup distance; Δ^0 is a single point, and $\Delta^1 = [0, 1]$. Its *faces* $d_0, \dots, d_k : \Delta^{k-1} \to \Delta^k$ insert one coordinate: d_0 appends 1 at the end, d_k puts 0 in front, and for $0 < i < k$ the face d_i repeats the coordinate y_{k-i}. Thus $d_0 = 1$ and $d_1 = 0$ on Δ^1, and

$$d_0(s) = (s, 1), \qquad d_1(s) = (s, s), \qquad d_2(s) = (0, s)$$

on Δ^2, whose vertices are $(0, 0)$, $(0, 1)$ and $(1, 1)$. A *native singular k-simplex* of $S^D \setminus K$ is a uniformly continuous map $\sigma : \Delta^k \to S^D$ that is uniformly apart from K; a 0-simplex is a point apart from K. When X is empty nothing is removed, and we speak of simplices of S^D.

Each face map preserves sup distances, so every face $\sigma \circ d_i$ of a simplex of $S^D \setminus K$ is again one, with the same modulus and radius.

Definition 23.4 (Native chains, cycles and boundaries)**.** Let M be a set. A *combination* of members of M is a finite list of terms (n, σ) with $n \in \mathbb{Z}$ and $\sigma \in M$. Two combinations are *equivalent*, $a \sim b$, when one is reached from the other by finitely many moves, each made anywhere in the list and in either direction: exchange two neighbouring terms; merge two neighbouring terms (n, σ) and (m, σ) that carry the same member into $(n + m, \sigma)$; delete a term $(0, \sigma)$. The classes form the *free abelian group* on M, added by concatenation; $-a$ is a with every coefficient negated, and na is defined from these. A *native k-chain* of $S^D \setminus K$ is a combination of native singular k-simplices of $S^D \setminus K$. For $k \geq 1$ its *boundary* is computed term by term:

$$\partial(n, \sigma) = (n, \sigma \circ d_0),\ (-n, \sigma \circ d_1),\ \dots,\ \big((-1)^k n, \sigma \circ d_k\big).$$

A k-chain z with $k \geq 1$ is a *cycle* when $\partial z \sim \emptyset$, the empty list. It *bounds* in $S^D \setminus K$ when $z \sim \partial L$ for a $(k + 1)$-chain L of $S^D \setminus K$. We write $H_k(S^D \setminus K) = 0$ for the statement that every k-cycle of $S^D \setminus K$ bounds there, and $\tilde{H}_0(S^D \setminus K) = 0$ for the statement that every 0-chain of $S^D \setminus K$ whose coefficients sum to 0 is the boundary of a 1-chain of $S^D \setminus K$.

Two terms carry the same member when the two maps are equal, that is, equal at every point; a merge needs a proof of that equality, never a decision. This is why chains are lists. The usual description, a formal sum with the coefficients of each simplex collected, would have to decide which simplices coincide, and maps into the line have no such decision. The boundary of an equivalent chain is equivalent, because each move on a chain becomes a few moves on its boundary. The presentation does not collapse: every move keeps the sum of the coefficients, so $(1, \sigma)$ is never equivalent to the empty list. Statements such as $H_k(S^D \setminus K) = 0$ speak about cycles and boundaries only; we never form a quotient group.

Definition 23.5 (Linking)**.** Let f be a native embedding of the circle into S^D, and write $S^D \setminus f$ for S^D with the image of f removed. A *loop* of the complement is a native 1-simplex γ of $S^D \setminus f$ with $\gamma(0) = \gamma(1)$. The embedding f is *linked* when some loop of its complement does not bound there: no 2-chain L of $S^D \setminus f$ has $\partial L \sim (1, \gamma)$. The dimension D *detects linking* when some native embedding of the circle into S^D is linked.

Remark 23.6 (The notions are not empty)**.** For every $D \geq 1$ the *equatorial circle* $e(x, y) = (x, y, 0, \dots, 0)$ is a native embedding of S^1 into S^D, with both moduli the identity, since it preserves distances. (It is not the equator $x_0 = 0$ of Definition 23.1.) For $D \geq 2$ the point $(0, 0, 1, 0, \dots, 0)$ is 1-apart from it, so its complement has points, and constant loops there. Every constant loop bounds: the constant 2-simplex has three equal faces, and the boundary $c - c + c$ is equivalent to c. So "does not bound" is a genuine condition.

Remark 23.7 (The classical reading)**.** Classically each native notion agrees with its usual counterpart. A continuous map on a compact model simplex is uniformly continuous (Heine–Cantor); a continuous injective map on the compact circle has a uniformly continuous inverse on its image; a compact curve and a point off it have positive distance, so "uniformly apart from the curve" describes simplices of the open complement; every singular 1-cycle is homologous to a sum of loops, so the first homology group is nonzero exactly when some single loop does not bound [194, Section 2.A]; the list presentation is the free abelian group; and the ordered model simplices are the standard simplices of singular homology [193], [194, Section 2.1]. These agreements are classical theorems, and we do not prove them natively. The theorem below concerns the native notions, and none of them mentions the number three.

23.2 The theorem: a circle links only in the 3-sphere

Theorem 23.8 (Three dimensions are forced, with no omniscience and no choice)**.** *For every natural number D, some native embedding of the circle into the native D-sphere has a loop in its complement that bounds no native 2-chain of the complement if and only if $D = 3$. The proof uses no omniscience principle and no choice principle.*

Conditions and scope.

Base and premises
The line $\mathbb{R}_\delta$ with its ordered field structure, and the native notions of Definitions 23.1–23.5. Nothing else: no omniscience principle, no countable or unique choice, no decision of equality or order on the line.

Conclusion
Three is the only dimension in which some natively embedded circle is linked. In S^3 the equatorial circle is linked (Theorem 23.34); in every other S^D every loop of the complement of every natively embedded circle bounds there.

Identification
Recognition Science reads a kept pair of records, a pairing that no deformation erases, as a linked curve in space, and reads the dimension of space as D. These readings belong to the forcing chain (Chapter 22); the theorem does not supply them. The classical meaning of the native notions (Remark 23.7) is likewise a reading, not a native theorem.

Not claimed

That every natively embedded circle in S^3 is linked: the theorem exhibits one, the equatorial circle. The homology groups as quotient groups. An integer-valued winding function on chains, which costs exactly the WLPO function (Section 23.10 and Theorem 22.65).

The proof has two halves that meet at the third homology of the sphere. The first half turns a linked circle into a cycle of the sphere that does not bound. Cut the circle into two arcs that meet in two points. The complement of an arc has no first homology (Lemma 23.20). A Mayer–Vietoris argument then shows that a linked circle needs a 2-cycle of the sphere minus the two meeting points that bounds nothing there, and a second one turns that into a 3-cycle of the sphere that bounds nothing (Proposition 23.23). The second half shows that every 3-cycle of S^D bounds when $D = 2$ or $D \geq 4$, by a descent through lower spheres, each step lowering the degree of homology or the dimension of the sphere:

$$\begin{aligned} H_3(S^D) \Leftarrow H_2(S^D \setminus \{N, S\}) \Leftarrow H_2(S^{D-1}) \Leftarrow H_1(S^{D-1} \setminus \{N, S\}) \\ \Leftarrow H_1(S^{D-2}) \Leftarrow \tilde{H}_0(S^{D-2} \setminus \{N, S\}) \Leftarrow \tilde{H}_0(S^{D-3}), \end{aligned} \tag{23.1}$$

where each arrow reads "if the right side is 0, so is the left". The steps alternate. A Mayer–Vietoris step covers the sphere by the complements of its two poles, each of which is acyclic (Lemmas 23.12 and 23.15). A retraction step slides the complement of the poles onto the equator, a sphere one dimension lower (Lemma 23.16). Dimensions 0 and 1 are settled directly (Proposition 23.24), and in S^3 an explicit loop is linked (Theorem 23.34).

23.3 Tools that work in every dimension

Six tools carry the proof. None depends on D, and none uses a decision. The first is algebra of the free abelian group. The next two are the subdivision and prism operators of singular homology [194, Section 2.1], built on the model simplices. The last three concern the sphere: a sphere with one point removed is acyclic; a point far from the two places where two arcs meet is far from one of the arcs; and a Mayer–Vietoris gluing.

Lemma 23.9 (Combinations that agree lie in the intersection)**.** *Let M be a set and A, B properties of its members.*

1. *If a combination a of members with property A is equivalent, as a combination of members of M, to a combination b of members with property B, then a is equivalent to a combination c of members with both properties.*
2. *If two combinations of members with property A are equivalent as combinations of members of M, they are equivalent through moves whose lists contain only members with property A.*

Proof. Label the terms of a combination by natural numbers. A labelling is *good* when terms with equal labels carry the same member and, for each label, the coefficients of the terms carrying it sum to 0; a combination is *grouped* when it has a good labelling. A grouped combination is equivalent to the empty list: exchanges bring the terms of one label together, merges collapse them into one term with coefficient 0, and a deletion removes it.

Each move preserves grouping, in both directions, whatever surrounds it. An exchange permutes the labels. Splitting $(n+m,\sigma)$ into (n,σ) and (m,σ) gives both parts the label of the whole. When (n,σ) and (m,σ) with labels i and j are merged, the merged term keeps i if $i=j$; otherwise every term labelled j is relabelled i, which keeps the labelling good, since all terms of both labels carry σ and two sums 0 add to 0. Whether $i=j$ is a comparison of natural numbers. Deleting a term with coefficient 0 changes no sum, and an inserted one gets a label not used before. Now $-b$ followed by b is grouped: give the ith terms of $-b$ and of b the label i. If $a\sim b$, the moves that turn b into a, made after the prefix $-b$, preserve grouping, so $-b$ followed by a is grouped.

For part 1, take a good labelling of $-b$ followed by a. Whether the label of a term of a also occurs on a term of b is decided by comparing finitely many natural numbers. Let c be the terms of a whose labels occur in b, in their order, and r the other terms of a. Each term of c carries the same member as a term of b, so its member has both properties. Each label of r occurs only in r, so r is grouped and $r\sim\emptyset$. Exchanges give $a\sim c$ followed by r, hence $a\sim c$.

For part 2, let a and b have property A. A good labelling of $-b$ followed by a is good when the members are read as members with property A, because two such members that are equal as members of M are equal. So $-b$ followed by a is grouped among members with property A, and so is b followed by $-b$. Hence, within such members, a is equivalent to b followed by $-b$ followed by a (insert the grouped list $b,-b$ in front), and that is equivalent to b (remove the grouped list $-b,a$). □

Part 1 is the algebraic heart of every Mayer–Vietoris argument below: a chain written once with simplices that avoid one set and once with simplices that avoid another can be written with simplices that avoid both. Part 2 lets us compute equivalence among all maps into the sphere, whatever property the simplices of a particular complement carry.

Lemma 23.10 (Subdivision)**.** *For $k=1,2,3,4$ there are operators Sd taking each map $\sigma:\Delta^k\to S^D$ to a k-chain, and for $k=1,2,3$ operators T taking it to a $(k+1)$-chain, extended to chains term by term, such that:*

1. *$\partial\,\mathrm{Sd}\,c\sim\mathrm{Sd}\,\partial c$ for $k\geq 2$;*
2. *$\partial Tc\sim c-\mathrm{Sd}\,c$ for $k=1$, and $\partial Tc+T\partial c\sim c-\mathrm{Sd}\,c$ for $k=2,3$;*
3. *every simplex occurring in $\mathrm{Sd}\,\sigma$ or $T\sigma$ is σ composed with a map between model simplices, so its values are values of σ, and it is uniformly continuous when σ is;*
4. *for every uniformly continuous σ and every $\varepsilon>0$ some m makes every simplex τ of $\mathrm{Sd}^m\sigma$ small: $d(\tau(x),\tau(y))<\varepsilon$ for all x,y.*

The operators respect equivalence of chains.

Proof. The construction is the cone construction of barycentric subdivision [194, Section 2.1], carried out with ratio weights. A linear simplex in a model is a list of vertices of the model; it names the affine map that sends the vertices of the standard simplex to them. Each linear simplex gets an interior point b: the convex combination of its vertices with weights $(c,1-c)$, $(c,c,1-2c)$ and $(c,c,c,1-3c)$ in degrees 1, 2 and 3, where $c=1/4$, and weights $(c,c,c,c,1-4c)$

with $c = 1/5$ in degree 4. The cone $b \cdot [w_0, \dots, w_j] = [b, w_0, \dots, w_j]$ satisfies $\partial(b \cdot u) = u - b \cdot \partial u$. Linear subdivision is $S[w_0] = [w_0]$ and $S\tau = b(\tau) \cdot S(\partial\tau)$, and the homotopy is $T\tau = b(\tau) \cdot (\tau - T\partial\tau)$ with $T = 0$ on points. Then $\partial S = S\partial$ follows from the cone formula and $\partial\partial = 0$ alone, by cancelling identical vertex lists; and

$$\partial T\tau = \tau - T\partial\tau - b \cdot \partial(\tau - T\partial\tau) = \tau - T\partial\tau - b \cdot S\partial\tau = \tau - T\partial\tau - S\tau,$$

using $\partial T\partial\tau = \partial\tau - S\partial\tau$ one degree lower. For a map σ, $\mathrm{Sd}\,\sigma$ and $T\sigma$ compose σ with the affine maps of the linear subdivision of the identity simplex; faces commute with these maps because the face maps are affine, so the identities transfer. With these weights every affine identity used is a ring identity among ratios. Affine maps between models are Lipschitz for the sup distances, with constant 3 (constant 4 in degree 4), so composition keeps uniform continuity, with a modulus divided by that constant. One subdivision shrinks every coordinate spread of the vertices by the factor $3/4$ ($4/5$ in degree 4). After m steps the vertex coordinates of every piece spread at most $(3/4)^m$ ($(4/5)^m$ in degree 4), and so do the points of its affine image, which are convex combinations of the vertices. Bernoulli's inequality gives $(3/4)^m(3+m) \le 3$ and $(4/5)^m(4+m) \le 4$, so by the Archimedean property of the line (Proposition 12.19) some m makes the spread smaller than the modulus of σ at ε; two values of a piece of $\mathrm{Sd}^m\sigma$ are values of σ at two such points, which gives item 4. Each operator acts term by term, so it respects the three moves. The number m is found inside the proof of a statement; nothing is chosen. □

Lemma 23.11 (Prisms). *For $k = 1, 2, 3$, let $F : [0,1] \times \Delta^k \to S^D$, write $F_t = F(t, \cdot)$, and let ∂F be the alternating list of the face homotopies $F \circ (\mathrm{id} \times d_i)$; the prism of a homotopy of a point is its path. There is a $(k+1)$-chain PF, the* prism *of F, with*

$$\partial PF + P(\partial F) \sim F_1 - F_0.$$

Every simplex of PF takes only values of F, and it is uniformly continuous when F is uniformly continuous for the distance $\max(|t - t'|, d(y, y'))$.

Proof. A point of Δ^{k+1} is $(y_1, \dots, y_{k+1})$. For $j = 0, \dots, k$ the jth piece reads the time from the coordinate y_{k+1-j} and the point of Δ^k from the other k coordinates, which remain in order: $\pi_j(y) = F\big(y_{k+1-j}, (y_1, \dots, \widehat{y_{k+1-j}}, \dots, y_{k+1})\big)$; the prism is $PF = \sum_j (-1)^j \pi_j$. For $k = 1$ this is $\pi_0(a,b) = F(b,a)$ and $\pi_1(a,b) = F(a,b)$, and the faces of Definition 23.3 give

$$\partial(\pi_0 - \pi_1) = \big(F_1 - \delta + F(\cdot, 0)\big) - \big(F(\cdot, 1) - \delta + F_0\big) = F_1 - F_0 - \big(F(\cdot, 1) - F(\cdot, 0)\big),$$

where $\delta(s) = F(s,s)$ is the diagonal and $F(\cdot, 0)$, $F(\cdot, 1)$ are the paths of the two ends of the 1-simplex; the last bracket is $P(\partial F)$. In every degree each face of each piece is a face of F_1 or of F_0 (the top and bottom), a diagonal shared by two neighbouring pieces with opposite signs, or a piece of the prism of a face homotopy with the sign of that face; collecting them gives the law. Coordinate maps are 1-Lipschitz for sup distances, so every piece is uniformly continuous with the modulus of F. □

Lemma 23.12 (A sphere with one point removed is acyclic)**.** *For every D and every $r > 0$ there is $\rho > 0$ such that, for every point p of S^D:*

1. *every uniformly continuous loop that is r-apart from p is the boundary of a 2-chain of S^D whose simplices are ρ-apart from p;*
2. *every 2-cycle of S^D whose simplices are r-apart from p is the boundary of a 3-chain of S^D whose simplices are ρ-apart from p;*
3. *for $k = 1, 2, 3$, every k-cycle of S^D whose simplices are apart from p is the boundary of a $(k+1)$-chain of S^D.*

Proof. Push points away from p along great circles. For x in S^D put $c = \langle x, p\rangle$ and $m = 1 - c$, so that $|x - p|^2 = 2m$. For $t \in [0, 1]$ put

$$A = t^2(1 + c), \qquad Q = A + m, \qquad k = A - 2tc - m, \qquad H(t, x) = \frac{2t\,x + k\,p}{Q}.$$

No square root is needed. Since $k = (A - m) - 2tc$,

$$|2tx + kp|^2 = 4t^2 + 4tkc + k^2 = 4t^2(1 - c^2) + (A - m)^2 = 4Am + (A - m)^2 = Q^2,$$

so $H(t, x)$ lies on S^D whenever $Q > 0$. At $t = 1$, $k = 0$ and $Q = 2$, so $H(1, x) = x$; at $t = 0$, $H(0, x) = -p$ when $m > 0$. Moreover $\langle H, p\rangle = (2tc + k)/Q = (A - m)/Q$, so

$$|H(t, x) - p|^2 = 2 - \frac{2(A - m)}{A + m} = \frac{4m}{Q} \geq 2m = |x - p|^2,$$

because $Q \leq (1 + c) + m = 2$: the homotopy never moves a point towards p.

To have one homotopy on the whole sphere, slow it down near p. Put $e = \min(r^2, 1)$, $\phi(x) = \min(1, 2m/e)$ and $G(s, x) = H(1 - s\phi(x), x)$ for $s \in [0, 1]$. Suppose $Q < e/4$ at some (s, x). Then $m \leq Q < e/4$, so $\phi < 1/2$, the time $t = 1 - s\phi$ exceeds $1/2$, and $c = 1 - m > 3/4$; hence $Q \geq A > \frac{1}{4} \cdot \frac{7}{4} \geq e/4$, a contradiction. So $Q \geq e/4$ everywhere, G uses the inverse of a point at least $e/4$, and G is uniformly continuous on $[0, 1] \times S^D$. We have $G(0, x) = x$. If x is r-apart from p then $2m \geq d(x, p)^2 \geq r^2 \geq e$, so $\phi(x) = 1$ and $G(1, x) = -p$; and $|G(s, x) - p|^2 \geq r^2$ along the way, so $G(s, x)$ is ρ-apart from p with $\rho = r/(D + 1)$.

For item 1, let γ be the loop and $F(s, t) = G(s, \gamma(t))$. The prism law gives $\partial PF \sim F_1 - F_0 - P(\partial F)$. Here $F_0 = \gamma$, F_1 is the constant path c_{-p} at $-p$, and $P(\partial F)$ is the path of $\gamma(1)$ minus the path of $\gamma(0)$, which cancel. The constant 2-simplex at $-p$ has boundary $c_{-p} - c_{-p} + c_{-p} \sim c_{-p}$. Hence $\gamma \sim \partial(\text{constant} - PF)$, and every simplex here is ρ-apart from p.

For item 2, let z be the 2-cycle and apply the same homotopy to each of its simplices; summing the prism laws, $\partial Pz + P(\partial z) \sim G_1 \circ z - z$. The boundary of one 2-simplex has coefficient sum $1 - 1 + 1 = 1$, so the coefficient sum of z equals that of $\partial z \sim \emptyset$, which is 0; thus $G_1 \circ z$, a combination of copies of one constant simplex, merges to the empty list. The prism operator acts term by term and respects equivalence, so $P(\partial z) \sim P(\emptyset) = \emptyset$. Hence $z \sim \partial(-Pz)$.

For item 3, take for r the least of the radii of the simplices of z. The same computation gives $z \sim G_1 \circ z - \partial Pz$, and $G_1 \circ z$ is the coefficient sum of z times the constant k-simplex at $-p$. For $k = 2$ that sum is 0, as above. For odd k the constant k-simplex is a boundary: the constant $(k + 1)$-simplex has $k + 2$ equal faces with alternating signs, which merge to one copy. □

The next two tools work with two removed sets at once. The Lebesgue number of a cover is classically produced by compactness; here it is computed from the moduli of the embedding.

Lemma 23.13 (Lebesgue numbers for two arcs). *Let $f : S^1 \to S^D$ be a native embedding, and let R_1, R_2 be properties of points of the circle, the two pieces, with meeting points $j(x)$, $x \in X$, that have both properties. Assume the pieces are separated near the meeting points (for every $\varepsilon > 0$ some $\eta > 0$ has: if a has R_1, b has R_2 and $d(a,b) < \eta$, then $d(a, j(x)) < \varepsilon$ for some x) and have finite nets (for every $\eta > 0$ each piece has a finite list of its points within η of each of its points). Then for every $r > 0$ there is $\delta > 0$ such that every point y of S^D that is r-apart from all the $f(j(x))$ is δ-apart from $f(R_1)$ or δ-apart from $f(R_2)$.*

Proof. Let ω and ω' be the moduli of f. Put $\varepsilon = \omega(r/2)$, let η be given by the separation at ε, and put $m = \min(r/2, \omega'(\eta))$, $b = m/2$ and $\delta = b/4$. Take nets of both pieces of fineness $\omega(\delta)$. For each net point c, cotransitivity of $<$ at $b/2 < b$ gives $b/2 < d(y, f(c))$ or $d(y, f(c)) < b$. Going through the two finite lists, each piece has either all its net points $b/2$-far from y, or some net point b-near. If all net points of a piece are $b/2$-far, then every point a of the piece is within $\omega(\delta)$ of a net point c, so $d(f(a), f(c)) < \delta$ and $d(y, f(a)) > b/2 - \delta = \delta$: the point y is δ-apart from that piece. If both pieces have b-near net points c_1 and c_2, then $d(f(c_1), f(c_2)) < 2b \le \omega'(\eta)$, so $d(c_1, c_2) < \eta$, so $d(c_1, j(x)) < \varepsilon$ for some x, so $d(f(c_1), f(j(x))) < r/2$, and $d(y, f(j(x))) < b + r/2 < r$, which is impossible. Only finitely many comparisons were made, each by cotransitivity. □

Lemma 23.14 (Mayer–Vietoris gluing). *Let K_1, K_2 and K_{12} be removed sets in S^D, every point of K_{12} a point of K_1 and of K_2. Assume the Lebesgue condition (for every $r > 0$ some $\delta > 0$ makes every point r-apart from K_{12} δ-apart from K_1 or from K_2) and $H_2(S^D \setminus K_{12}) = 0$. Let γ be a uniformly continuous loop apart from K_1, K_2 and K_{12} that bounds in $S^D \setminus K_1$ and bounds in $S^D \setminus K_2$. Then γ is the boundary of a 2-chain whose simplices are apart from K_1 and from K_2.*

Proof. This is the classical argument [194, Section 2.2] with every step made explicit. Let $\gamma \sim \partial a$ with a apart from K_1 and $\gamma \sim \partial b$ with b apart from K_2. Then $a - b$ is a 2-cycle whose simplices are apart from K_{12}, so $a - b \sim \partial e$ for a 3-chain e apart from K_{12}, with some radius r. Let δ be the Lebesgue number for r. Subdivide e by Lemma 23.10, m times, until every simplex τ of $\mathrm{Sd}^m e$ has its values within $\delta/2$ of one another. The first vertex of τ is a value of e, hence r-apart from K_{12}, hence δ-apart from K_1 or from K_2; then every value of τ is $\delta/2$-apart from the same set. Sorting the terms by this outcome gives $\mathrm{Sd}^m e = e_1 + e_2$, with e_1 apart from K_1 and e_2 apart from K_2. Since $\partial \mathrm{Sd}^m e \sim \mathrm{Sd}^m \partial e \sim \mathrm{Sd}^m a - \mathrm{Sd}^m b$,

$$\mathrm{Sd}^m a - \partial e_1 \sim \mathrm{Sd}^m b + \partial e_2,$$

the left side apart from K_1 and the right side apart from K_2, because subdivision keeps values. Lemma 23.9 writes both as one chain c apart from K_1 and from K_2, and $\partial c \sim \mathrm{Sd}^m \partial a \sim \mathrm{Sd}^m \gamma$. Finally $\gamma - \mathrm{Sd}^m \gamma \sim \partial \sum_{i<m} T(\mathrm{Sd}^i \gamma)$, by Lemma 23.10, and these simplices take values of γ. So $\gamma \sim \partial\big(c + \sum_{i<m} T(\mathrm{Sd}^i \gamma)\big)$. Part 2 of Lemma 23.9 moves between chains of the complements and chains of all maps. □

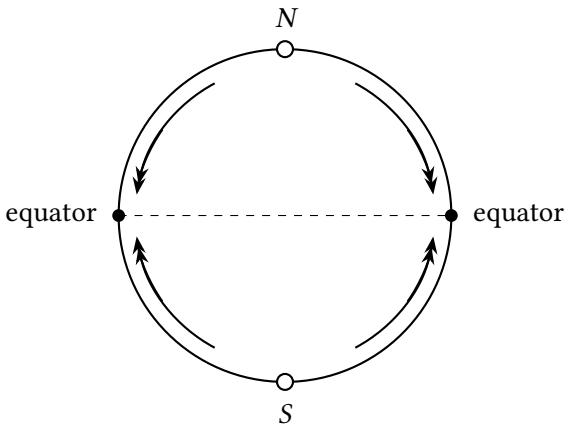

Figure 23.1. A section of S^D through its poles. The complements of N and of S (open circles) cover the sphere. The points of their intersection slide along meridians onto the equator (arrows), which is a sphere one dimension lower; near the poles the slide is slowed down, and points a given distance from both poles reach the equator.

Table 23.1. The three endings of the descent (23.1). Each row lists the last statement the descent needs and why it holds or fails.

Dimension	Last statement needed	Status
$D = 2$	$H_1(S^0) = 0$	Holds: uniformly continuous paths in the two points of S^0 are constant (Lemma 23.17).
$D \geq 4$	$\tilde{H}_0(S^{D-3}) = 0$	Holds: S^{D-3} has positive dimension, and any two of its points are joined by a path (Lemma 23.18).
$D = 3$	$H_1(S^1) = 0$	Fails: every cycle of the circle carries a winding number, and a cycle of winding number 1 bounds nothing (Theorem 23.38), so the descent stops. Separately, $H_3(S^3)$ does not vanish (Corollary 23.37, from the linked equatorial circle).

23.4 The suspension ladder

The sphere S^D is covered by the complements of its two poles, $S^D \setminus \{N\}$ and $S^D \setminus \{S\}$. Each is acyclic (Lemma 23.12). Their intersection, the sphere without its poles, slides along meridians onto the equator, a copy of S^{D-1} (Figure 23.1). Classically these two facts make S^D the suspension of S^{D-1}, and the Mayer–Vietoris sequence gives $H_k(S^D) \cong H_{k-1}(S^{D-1})$ [194, Section 2.2]. We prove the two implications that the ladder (23.1) uses. A Mayer–Vietoris step lowers the degree; a retraction step lowers the dimension; one of each lowers the degree and the dimension together. The descent can end in three ways, which Table 23.1 lists.

Lemma 23.15 (Mayer–Vietoris for two point complements)**.** *Let a and b be points of S^D with $d(a,b) > 0$, and let $k \in \{1,2,3\}$. If $\tilde{H}_0(S^D \setminus \{a,b\}) = 0$ when $k = 1$, or $H_{k-1}(S^D \setminus \{a,b\}) = 0$ when $k = 2,3$, then $H_k(S^D) = 0$.*

Proof. Every point y is $d(a,b)/4$-apart from a or from b: from $d(a,y) + d(y,b) \geq d(a,b) > d(a,b)/2$, cotransitivity gives $d(a,y) > d(a,b)/4$ or $d(y,b) > d(a,b)/4$. Let z be a k-cycle of S^D.

1. By Lemma 23.10, one number m of subdivisions makes every simplex of $\mathrm{Sd}^m z$ smaller than $d(a,b)/8$; there are finitely many simplices, and one m serves all.

2. The first vertex of each simplex is $d(a,b)/4$-apart from a or from b, and then the whole simplex is $d(a,b)/8$-apart from the same point. Sorting gives $\mathrm{Sd}^m z = x_a + x_b$, with x_a apart from a and x_b apart from b.

3. Since $\mathrm{Sd}^m z$ is a cycle, $\partial x_a \sim -\partial x_b$. By Lemma 23.9, $\partial x_a \sim w$ for a $(k-1)$-chain w apart from both points. It is a cycle, since $\partial\partial = 0$; for $k = 1$ its coefficients sum to 0, as those of every boundary of a 1-chain do. By hypothesis $w \sim \partial e$ with e apart from both points.

4. Then $x_a - e$ is a k-cycle apart from a and $x_b + e$ a k-cycle apart from b. By Lemma 23.12, item 3, they bound in S^D: $x_a - e \sim \partial F_a$ and $x_b + e \sim \partial F_b$.

5. By Lemma 23.10, $z - \mathrm{Sd}^m z \sim \partial T'$, where T' telescopes the subdivision homotopies of $z, \mathrm{Sd}\, z, \dots, \mathrm{Sd}^{m-1} z$; the terms $T\partial$ vanish because each $\mathrm{Sd}^i z$ is a cycle.

So $z \sim \partial(F_a + F_b + T')$, a boundary of uniformly continuous simplices. Steps 3 and 4 use only that ∂ is linear, and are done once for all degrees. □

Lemma 23.16 (The complement of the poles slides onto the equator)**.** *Let D be a natural number. If $\tilde{H}_0(S^D) = 0$, then $\tilde{H}_0(S^{D+1} \setminus \{N, S\}) = 0$. If $H_1(S^D) = 0$, then $H_1(S^{D+1} \setminus \{N, S\}) = 0$. If $H_2(S^D) = 0$, then $H_2(S^{D+1} \setminus \{N, S\}) = 0$.*

Proof. Write a point of S^{D+1} as $x = (c, x')$ with $c = x_0$, and put $u = |x'|^2 = 1 - c^2$. For a scale κ with $0 < \kappa \le 1$ put $\phi(x) = \min(1, u/\kappa)$ and, for $t \in [0,1]$,

$$H(t,x) = \frac{\big((1 - t\phi)\, c,\ x'\big)}{\sqrt{n}}, \qquad n = (1 - t\phi)^2 c^2 + u.$$

Suppose $n < \kappa/8$. Then $u \le n < \kappa/8$, so $\phi < 1/8$ and $1 - t\phi > 7/8$, while $c^2 = 1 - u > 7/8$; hence $n \ge (1 - t\phi)^2 c^2 > (7/8)^3 > 1/8 \ge \kappa/8$, a contradiction. So $n \ge \kappa/8$ everywhere. The square root of the line (Proposition 12.19) then has an inverse bounded by $\sqrt{8/\kappa}$, so H is defined on all of $[0,1] \times S^{D+1}$, lands on the sphere, and is uniformly continuous. Four facts about it are short computations.

1. $H(0,x) = (c, x')/\sqrt{c^2 + u} = x$.

2. Where $u \ge \kappa$, $\phi = 1$ and $H(1,x) = (0, x')/\sqrt{u}$ lies on the equator.

3. Along H the quantity u does not decrease: the last coordinates of $H(t,x)$ have squared length $u/n \ge u$, because $n \le c^2 + u = 1$.

4. A point with $u \ge \kappa$ is $\kappa/2$-apart from both poles: its first coordinate has square $1 - u \le 1 - \kappa \le (1 - \kappa/2)^2$, so $|x_0 \mp 1| \ge \kappa/2$. Conversely, a point r-apart from both poles, with $r \le 1$, has $u \ge r^2$. For if $u < r^2$, every $|x_i|$ with $i \ge 1$ is below r and $c^2 > 1 - r^2 > 0$, so c is apart from 0 and has a sign; if $c > 0$ then $|c - 1| \le 1 - c^2 = u < r$, so $d(x, N) < r$, and if $c < 0$ likewise $d(x, S) < r$; both are impossible.

Let z be a k-cycle of $S^{D+1}\setminus\{N,S\}$, $k=1,2$, its simplices r-apart from both poles, where we may take $r\le 1$; put $\kappa=r^2$. Every value of z has $u\ge\kappa$. Summing the prism laws of Lemma 23.11 over the terms of z, with $F=H\circ(\mathrm{id}\times\sigma)$ for each simplex σ,

$$\partial Pz + P(\partial z) \sim H_1\circ z - z,$$

and $P(\partial z)\sim\emptyset$ because $\partial z\sim\emptyset$ and the prism acts term by term. By items 3 and 4 every simplex of Pz is $\kappa/2$-apart from both poles, and by item 2 the cycle $H_1\circ z$ lies on the equator. Dropping the first coordinate maps the equator onto S^D, preserving distances and commuting with faces, so it carries $H_1\circ z$ to a k-cycle z' of S^D (Lemma 23.9, part 2, transports the equivalences). By hypothesis $z'\sim\partial L$ in S^D. Putting 0 in front again carries L into the equator of S^{D+1}, at distance 1 from both poles, with boundary equivalent to $H_1\circ z$. Hence $z\sim\partial(L-Pz)$ in $S^{D+1}\setminus\{N,S\}$.

In degree 0 the prism of a point x is the path $t\mapsto H(t,x)$. For a 0-chain z of points apart from the poles with coefficient sum 0, these paths give $\partial Pz\sim H_1\circ z-z$; the dropped 0-chain has the same coefficient sum 0, bounds in S^D by hypothesis, and the argument closes as before. □

Physically read, Lemma 23.16 says that a loop or a membrane that keeps away from two antipodal events can be slid, without approaching them, onto the sphere of points midway between them.

The ladder needs two foundations, one for each way it can end.

Lemma 23.17 (On the 0-sphere every uniformly continuous simplex is constant)**.** *Every uniformly continuous map $g:[0,1]\to S^0$ is constant: $g(t)=g(0)$ for every t. Hence every 1-chain of S^0 is a boundary; in particular $H_1(S^0)=0$.*

Proof. The 0-sphere consists of the points v of the line with $v^2=1$. Two of them closer than 1 are equal. Indeed $(v-1)(v+1)=0$ and the two factors differ by 2, so by cotransitivity one of them exceeds $1/2$ in absolute value; it has an inverse, so the other factor is 0, and $v=1$ or $v=-1$. The same holds for w, and if the signs differed, $|v-w|$ would be 2. Now let ω be a modulus of g, put $h=\omega(1)/2$, and take N with $Nh\ge 1$. The points $s_n=\min(t,nh)$, $n=0,\dots,N$, run from $s_0=0$ to $s_N=t$ in steps of at most $h<\omega(1)$, so neighbouring values of g are closer than 1 and therefore equal; hence $g(t)=g(0)$. For a 1-chain, replace each term (n,g) by n times the constant 2-simplex at $g(0)$: its boundary is $n(c-c+c)\sim(n,c)=(n,g)$. □

Lemma 23.18 (Spheres of positive dimension are connected)**.** *For every $n\ge 1$, $\tilde H_0(S^n)=0$: every 0-chain of S^n whose coefficients sum to 0 is the boundary of a 1-chain of S^n.*

Proof. The poles are 2 apart, so every point x is $1/2$-apart from N or from S (the first line of the proof of Lemma 23.15). If x is apart from N, the homotopy of Lemma 23.12 for $p=N$ is a uniformly continuous path from x to $-N=S$; if x is apart from S, the same construction gives a path from x to N. By induction on the length of a 0-chain z, there are integers α,β whose sum is the coefficient sum of z, and a 1-chain L with $\partial L\sim\alpha N+\beta S-z$. If the coefficient sum is 0 then $\beta=-\alpha$, and $\alpha N-\alpha S$ is the boundary of α times a path from $e_1=(0,1,0,\dots,0)$ to N minus α times a path from e_1 to S; the point e_1 exists because $n\ge 1$, and it is 1-apart from both poles. So z is a boundary. □

Proposition 23.19 (The ladder)**.** *$H_3(S^D) = 0$ for $D = 2$ and for every $D \geq 4$. On the way, $H_1(S^m) = 0$ for every $m \geq 2$, and $H_2(S^m) = 0$ for $m = 1$ and every $m \geq 3$. No omniscience principle and no choice principle is used.*

Proof. Write MV for Lemma 23.15, applied to the poles, which are 2 apart, and R for Lemma 23.16. For $D = 2$:

$$H_1(S^0) = 0 \overset{\mathrm{R}}{\Longrightarrow} H_1(S^1 \setminus \{N, S\}) = 0 \overset{\mathrm{MV}}{\Longrightarrow} H_2(S^1) = 0$$
$$\overset{\mathrm{R}}{\Longrightarrow} H_2(S^2 \setminus \{N, S\}) = 0 \overset{\mathrm{MV}}{\Longrightarrow} H_3(S^2) = 0,$$

starting from Lemma 23.17. For $D = m + 4$, starting from Lemma 23.18 for S^{m+1}:

$$\tilde{H}_0(S^{m+1}) = 0 \overset{\mathrm{R}}{\Longrightarrow} \tilde{H}_0(S^{m+2} \setminus \{N, S\}) = 0 \overset{\mathrm{MV}}{\Longrightarrow} H_1(S^{m+2}) = 0 \overset{\mathrm{R}}{\Longrightarrow} H_1(S^{m+3} \setminus \{N, S\}) = 0$$
$$\overset{\mathrm{MV}}{\Longrightarrow} H_2(S^{m+3}) = 0 \overset{\mathrm{R}}{\Longrightarrow} H_2(S^{m+4} \setminus \{N, S\}) = 0 \overset{\mathrm{MV}}{\Longrightarrow} H_3(S^{m+4}) = 0.$$

The intermediate statements are the byproducts. □

The ladder has three endings (Table 23.1). For $D \geq 4$ it reaches the reduced zeroth homology of a sphere of positive dimension, which is a statement about paths: any two points can be joined. For $D = 2$ it stops one rung earlier, at the first homology of the 0-sphere, and holds there for the reason of the opening example: a uniformly continuous path cannot jump between the two points. For $D = 3$ it needs $H_1(S^1) = 0$, the first homology of the circle, and that is false: the circle carries a winding number. The descent breaks exactly where a cycle can wind, and this is why three is the dimension that links.

23.5 From a linked circle to the third homology of the sphere

Cut the circle into its right half $R = \{x_0 \geq 0\}$ and its left half $L = \{x_0 \leq 0\}$, which meet at the two *junctions* $(0, 1)$ and $(0, -1)$. For a native embedding f, the images $f(R)$ and $f(L)$ are removed sets (given by f on the points of each half), and so is the pair $J_f = \{f(0, 1), f(0, -1)\}$. The circle is the union of its halves only up to a double negation: "$x_0 \geq 0$ or $x_0 \leq 0$" for every point costs LLPO (Corollary 12.18). The argument never uses the union itself.

Lemma 23.20 (The complement of an arc is acyclic)**.** *For every D and every native embedding $f : S^1 \to S^D$, every uniformly continuous loop apart from $f(R)$ bounds in $S^D \setminus f(R)$, and every uniformly continuous loop apart from $f(L)$ bounds in $S^D \setminus f(L)$.*

Proof. The classical proof [194, Proposition 2B.1] bisects the arc until it finds a piece whose complement carries a non-bounding cycle, and the choice of the bad half at each stage is a decision. We glue instead of bisecting. The right half is parametrized by

$$w(u) = \Big(\frac{1 - u^2}{1 + u^2},\ \frac{2u}{1 + u^2}\Big), \qquad -1 \leq u \leq 1,$$

which is onto, with inverse $u = x_1/(1 + x_0)$; it is 4-Lipschitz, and $|u - v| \leq 2\, d(w(u), w(v))$. Let γ be a loop r-apart from $f(R)$, and let ρ be given by Lemma 23.12, item 1, for r: for every point

q of the arc, γ bounds a 2-chain ρ-apart from q. By uniform continuity of $f \circ w$ there is n such that, with $u_k = -1 + 2k/(n+1)$, each image piece $f(w[u_k, u_{k+1}])$ lies within $\rho/2$ of $f(w(u_k))$. Then γ bounds in the complement of each piece: the 2-chain that avoids $f(w(u_k))$ by ρ avoids the whole piece by $\rho/2$. Now glue. Suppose γ bounds in the complement of $f(w[u_0, u_{k+1}])$. Apply Lemma 23.14 with $K_1 = f(w[u_0, u_{k+1}])$, $K_2 = f(w[u_{k+1}, u_{k+2}])$ and K_{12} the single point $f(w(u_{k+1}))$. Its hypotheses hold: H_2 of the sphere minus a point vanishes by Lemma 23.12, item 2; the two pieces have finite nets from a grid in u, and they are separated near u_{k+1}, since points $w(u)$ and $w(v)$ with $u \le u_{k+1} \le v$ satisfy $|u - u_{k+1}| \le |u - v| \le 2\,d(w(u), w(v))$; so Lemma 23.13 supplies the Lebesgue condition. Lemma 23.14 gives a 2-chain with boundary equivalent to γ whose simplices are r_1-apart from the first piece and r_2-apart from the second. They are $\min(r_1, r_2)$-apart from the union $f(w[u_0, u_{k+2}])$. For a parameter u in $[u_0, u_{k+2}]$, $\neg\neg(u \le u_{k+1} \vee u \ge u_{k+1})$ holds with no principle, and the bound $d(\sigma(a), f(w(u))) \ge \min(r_1, r_2)$ is a negation, since $\le$ is the negation of $<$; a double negation suffices to prove a negation. Hence γ bounds in the complement of $f(w[u_0, u_{k+2}])$. After n gluings it bounds in the complement of the whole right half. The left half is the right half of f composed with the reflection $(x_0, x_1) \mapsto (-x_0, x_1)$. □

Lemma 23.21 (Gluing the two halves)**.** *Let $f : S^1 \to S^D$ be a native embedding with $H_2(S^D \setminus J_f) = 0$. Then every loop of the complement of f that bounds in $S^D \setminus f(R)$ and bounds in $S^D \setminus f(L)$ bounds in $S^D \setminus f$.*

Proof. Apply Lemma 23.14 with $K_1 = f(R)$, $K_2 = f(L)$ and $K_{12} = J_f$; the junctions lie in both halves. The halves are separated near the junctions: if $a \in R$, $b \in L$ and $d(a, b)$ is small, then $0 \le a_0 \le a_0 - b_0 \le d(a, b)$, so $a_1^2 = 1 - a_0^2$ is near 1, and a is near $(0, 1)$ or near $(0, -1)$; which one is read off by cotransitivity, since $|a_1| > 1/2$ makes a_1 apart from 0. Both halves have finite nets, from a grid in the parameter u and finitely many comparisons. So Lemma 23.13 gives the Lebesgue condition, and Lemma 23.14 gives a 2-chain c with boundary equivalent to the loop, its simplices r_1-apart from $f(R)$ and r_2-apart from $f(L)$. They are $\min(r_1, r_2)$-apart from the whole image of f: for a point x of the circle, $\neg\neg(x_0 \ge 0 \vee x_0 \le 0)$ holds with no principle, and the bound $d(\sigma(a), f(x)) \ge \min(r_1, r_2)$ is a negation, since $\le$ is the negation of $<$; a double negation suffices to prove a negation. So c is a 2-chain of $S^D \setminus f$. □

Lemma 23.22 (Two point complements from the third homology of the sphere)**.** *If $H_3(S^D) = 0$, then $H_2(S^D \setminus \{a, b\}) = 0$ for all points a, b of S^D with $d(a, b) > 0$.*

Proof. This is Mayer–Vietoris one degree up, for the complements of a and of b. Let z be a 2-cycle apart from a and from b. By Lemma 23.12, item 2, $z \sim \partial c_a$ with c_a apart from a and $z \sim \partial c_b$ with c_b apart from b. Then $c_a - c_b$ is a 3-cycle of S^D, so $c_a - c_b \sim \partial e$ by hypothesis. Subdivide e until its simplices are smaller than $d(a, b)/8$; as in the proof of Lemma 23.15, each is then apart from a or from b, and $\mathrm{Sd}^m e = e_a + e_b$. Now $\mathrm{Sd}^m c_a - \partial e_a \sim \mathrm{Sd}^m c_b + \partial e_b$, the left side apart from a and the right side apart from b, so by Lemma 23.9 both equal a chain w apart from both points, with $\partial w \sim \mathrm{Sd}^m \partial c_a \sim \mathrm{Sd}^m z$, using $\partial\partial = 0$ on 4-chains. Finally $z - \mathrm{Sd}^m z \sim \partial T'$ with $T' = \sum_{i<m} T(\mathrm{Sd}^i z)$, since z is a cycle, and T' takes values of z. So $z \sim \partial(w + T')$, a boundary apart from a and b. □

Proposition 23.23 (A linked circle needs a cycle that does not bound)**.** *Let D be a natural number. If $H_2(S^D \setminus \{a,b\}) = 0$ for all points a, b of S^D with $d(a,b) > 0$, then for every native embedding f of the circle into S^D every loop of the complement of f bounds there; so no such embedding is linked. In particular, if $H_3(S^D) = 0$, then D does not detect linking. No omniscience principle and no choice principle is used.*

Proof. Let f be a native embedding and γ a loop of its complement. It is apart from the image of f, hence from $f(R)$ and from $f(L)$, so it bounds in both complements (Lemma 23.20). The junctions are apart: with ω' the inverse modulus of f, $d(f(0,1), f(0,-1)) < \omega'(2)$ would give $d((0,1),(0,-1)) < 2$, but that distance is 2; so $d(f(0,1), f(0,-1)) \geq \omega'(2) > 0$. By hypothesis $H_2(S^D \setminus J_f) = 0$, and Lemma 23.21 shows that γ bounds in $S^D \setminus f$. So every loop of the complement bounds. The last sentence follows with Lemma 23.22. □

23.6 Dimensions zero and one

In the two lowest dimensions there is nothing to link, for two different reasons: the 0-sphere has no room for a circle, and a circle in the circle leaves no room beside itself.

Proposition 23.24 (No circle links in S^0 or S^1)**.** *No map $f : S^1 \to S^0$ is a native embedding. For every native embedding $f : S^1 \to S^1$, no point of S^1 is apart from the image of f. Hence neither $D = 0$ nor $D = 1$ detects linking. No omniscience principle and no choice principle is used.*

Proof. $D = 0$. Let $f : S^1 \to S^0$ be uniformly continuous with an inverse modulus ω'. The arc $u \mapsto z(u) = w(u)^2$, $u \in [-1,0]$, the square of the parametrization of the proof of Lemma 23.20 taken as a complex number, runs along the lower half of the circle from $(-1,0)$ to $(1,0)$, and it is 32-Lipschitz. So $f \circ z$ is a uniformly continuous map from an interval into S^0, hence constant, by the argument of Lemma 23.17: $f(1,0) = f(-1,0)$. Then $d(f(1,0), f(-1,0)) = 0 < \omega'(1)$, so $d((1,0),(-1,0)) < 1$; but that distance is 2.

$D = 1$. Let f be a native embedding of the circle in itself, with moduli ω and ω', and suppose a point p is r-apart from its image; we derive a contradiction. For q on the circle put $C = \langle p, q\rangle$, $S = p_0 q_1 - p_1 q_0$ and $E = 1 - C$. On the image of f, $E \geq r^2/2$, so the stereographic coordinate $\sigma(q) = S/E$ from p is defined there; it is Lipschitz with constant $6/\kappa^2$, $\kappa = r^2/2$, and the rational map that inverts it is 8-Lipschitz: $d(q,q') \leq 8|\sigma(q) - \sigma(q')|$. Put $H(x) = \sigma(f(x)) - \sigma(f(-x))$. Then $H(-x) = -H(x)$, and H is uniformly continuous. Let $\varepsilon = \omega'(1)/16$, and walk along the right half of the circle from $x^{(0)} = (0,-1)$ to $x^{(N)} = (0,1) = -x^{(0)}$ in steps over which H moves by less than ε. At each step cotransitivity gives $|H(x^{(i)})| > \varepsilon$ or $|H(x^{(i)})| < 2\varepsilon$. The second case is impossible: it gives $d(f(x), f(-x)) < 16\varepsilon = \omega'(1)$, hence $d(x,-x) < 1$, while $d(x,-x) = 2\max(|x_0|,|x_1|) \geq 1$ on the circle. So every $|H(x^{(i)})| > \varepsilon$, and $H(x^{(i)})$ has a sign. A step of less than ε cannot pass from above ε to below $-\varepsilon$, so all the signs agree; but $H(x^{(N)}) = -H(x^{(0)})$. Only finitely many comparisons were made. So the complement of f has no points, and a fortiori no loops. □

23.7 The 3-sphere links: a loop that sweeps four quarter turns

In S^3, inside the space of (x_0, x_1, x_2, x_3), take the equatorial circle $e(x, y) = (x, y, 0, 0)$. A loop that runs once around the circle of points $(0, 0, u, v)$ should link it, the way two rings of a chain link. To prove that such a loop bounds no 2-chain of the complement we need an invariant of chains that vanishes on every boundary and not on the loop. Classically it is the integral of the angle form around the origin of the plane of the last two coordinates, the linking cocycle. Here it is the angle swept around that origin, read through four overlapping charts by rational functions, with no arctangent and no decision. It comes as a relation between chains and values on the line, since a function would need data that a simplex does not carry. Figure 23.2 shows the charts and the loop.

Definition 23.25 (Charts and the diamond angle)**.** Let $\rho(x, y) = (y, -x)$ be the clockwise quarter turn of the plane $\mathbb{R}^2_\delta$. For a natural number j, *chart j* is the set of points p whose image $\rho^j(p) = (x', y')$ has $x' > 0$: chart 0 is $x > 0$, chart 1 is $y > 0$, chart 2 is $x < 0$ and chart 3 is $y < 0$. On chart j the *diamond angle* is

$$\theta_j(p) = j + \frac{y'}{x' + |y'|}, \qquad (x', y') = \rho^j(p).$$

The denominator is at least $x' > 0$, so it has an inverse. The angle counts quarter turns, anticlockwise: at $(1, 0)$, $(0, 1)$, $(-1, 0)$ and $(0, -1)$ it takes the values 0, 1, 2 and 3 in the charts that contain them. We write $|p| = \max(|x|, |y|)$ for the sup norm of a point of the plane.

Lemma 23.26 (Charts agree up to whole turns)**.** *On the overlap of charts j and $j + 1$, $\theta_{j+1} = \theta_j$. Chart $j + 4$ is chart j, with $\theta_{j+4} = \theta_j + 4$. Charts j and $j + 2$ do not meet. Hence, if p and q both lie in chart j and in chart k, with $j, k < 4$, then $\theta_j(q) - \theta_j(p) = \theta_k(q) - \theta_k(p)$.*

Proof. Since $\theta_j(p) = j + \theta_0(\rho^j p)$, it suffices to compare charts 0 and 1, where $x > 0$ and $y > 0$: $\theta_0 = y/(x + y)$, and $\theta_1 = 1 + (-x)/(y + x) = y/(x + y)$. Next, ρ^4 is the identity, and $\rho^{j+2}(p) = -\rho^j(p)$, whose first coordinate cannot be positive together with that of $\rho^j(p)$. For the last statement, k is j, $j + 1$ or $j + 3$ modulo 4, and on the overlap, which contains p and q, θ_k differs from θ_j by a constant (0 or ± 4). □

Definition 23.27 (The swept angle of a path)**.** Let $g : [0, 1] \to \mathbb{R}^2_\delta$ be uniformly continuous with $|g(t)| \geq c$ for all t, for some $c > 0$. An *admissible grid* for g is a number N with charts $J(0), \dots, J(N) < 4$ such that g maps the cell $[k/(N + 1), (k + 1)/(N + 1)]$ into chart $J(k)$ for each $k \leq N$. A point v of the line is a *swept angle* of g when, for some admissible grid,

$$v = \sum_{k=0}^{N} \Big(\theta_{J(k)}\big(g(\tfrac{k+1}{N+1})\big) - \theta_{J(k)}\big(g(\tfrac{k}{N+1})\big) \Big).$$

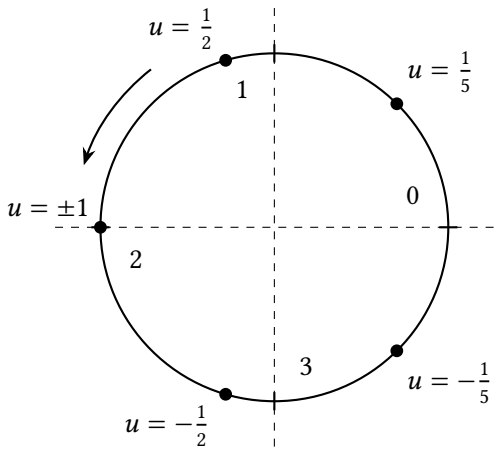

Figure 23.2. The plane of the last two coordinates of S^3. The dashed axes bound the four charts: chart 0 lies right of the vertical axis, chart 1 above the horizontal axis, chart 2 to the left and chart 3 below; the numbers inside the circle are the diamond angles of the four axis points. The loop of Lemma 23.33 runs once around the circle, anticlockwise from $u = -1$ (arrow); the dots mark the ends of the five pieces of Table 23.2.

Lemma 23.28 (A path that avoids the origin sweeps one angle)**.** *Every g as in Definition 23.27 has an admissible grid, and any two swept angles of g, on any two admissible grids, are equal.*

Proof. Let ω be a modulus of g and take N with $1/(N+1) < \omega(c/2)$. At the left end of each cell, $|g| \geq c > c/2$, so by cotransitivity one coordinate exceeds $c/2$ in absolute value, and a second use of cotransitivity gives its sign; that names a chart in which the relevant coordinate exceeds $c/2$. Over the cell, g moves by less than $c/2$, so the coordinate stays positive and the cell lies in the chart. These are finitely many comparisons. For uniqueness, refine both grids to the common grid of $(N+1)(N'+1)$ cells. Inside one coarse cell, the coarse difference is the sum of the fine differences read in the same chart, by telescoping. On each fine cell both readings use charts that contain both end points, so they agree by Lemma 23.26. □

The swept angle is a unique value, but it is a relation between g and v: the grid is computed from the modulus, and g asserts its modulus without handing it over. We never need a map from paths to values.

Lemma 23.29 (The projection stays away from the origin)**.** *Let $\pi(p) = (p_2, p_3)$ for p in S^3. If p is r-apart from the equatorial circle e, then $|\pi(p)| \geq \min(r/2, 1/4)$.*

Proof. Suppose $|p_2|$ and $|p_3|$ are both below $\min(r/2, 1/4)$. Then $s = p_0^2 + p_1^2 = 1 - p_2^2 - p_3^2 > 7/8$ and $1 - s < r/4$. The point $q = (p_0, p_1, 0, 0)/\sqrt{s}$ lies on the equatorial circle, and $|p_i - q_i| \leq (1/\sqrt{s} - 1) \leq (1 - s)/s < 2r/7$ for $i = 0, 1$, while $|p_i - q_i| < r/2$ for $i = 2, 3$. So $d(p, q) < r$, a contradiction. □

Lemma 23.30 (Boundaries sweep no angle). *Let $\tau : \Delta^2 \to \mathbb{R}^2_\delta$ be uniformly continuous with $|\tau| \geq c > 0$, and let v_0, v_1, v_2 be swept angles of its faces $\tau \circ d_0$, $\tau \circ d_1$, $\tau \circ d_2$. Then $v_0 - v_1 + v_2 = 0$.*

Proof. No Stokes theorem is needed; a ladder of shrunken copies of the triangle suffices. The boundary of Δ^2 runs from $(0,0)$ to $(0,1)$ along d_2, to $(1,1)$ along d_0, and back along d_1 reversed. Place M grid points on each edge, spaced $1/M$ apart, and for a level $\lambda = a/M$ scale them by λ towards $(0,0)$. Their images under τ, taken around the boundary, form a closed polygon P_a, read by adding chart differences of consecutive points. Choose M with $2/M$ below the modulus of τ at $c/2$. Then the four points $\tau(\lambda q)$, $\tau(\lambda q')$, $\tau(\lambda' q)$, $\tau(\lambda' q')$ for neighbouring grid points q, q' and neighbouring levels λ, λ' lie within $c/2$ of the first, hence in one chart, chosen as in Lemma 23.28. The reading of P_{a+1} minus that of P_a is a sum, over the small quadrilaterals, of chart differences around each; the rungs between levels are shared by neighbouring quadrilaterals and agree by Lemma 23.26, so the sum telescopes to 0. The polygon P_0 is constant, with reading 0. The polygon P_M is the boundary, and its reading is $v_2 + v_0 - v_1$, by Lemma 23.28 applied to each face. Every distance estimate here is a computation with ratios whose denominators divide M^2. □

Definition 23.31 (The linking value of a chain). For a native 1-simplex σ of $S^3 \setminus e$, the path $\pi \circ \sigma$ satisfies the hypothesis of Definition 23.27, by Lemma 23.29. A 1-chain $(n_1, \sigma_1), \dots, (n_m, \sigma_m)$ of $S^3 \setminus e$ has *linking value* v when $v = \sum_i n_i w_i$ for swept angles w_i of the paths $\pi \circ \sigma_i$.

Lemma 23.32 (The linking value is a cocycle). *Every 1-chain of $S^3 \setminus e$ has a linking value, and only one. Equivalent chains have equal linking values, and the boundary of every 2-chain of $S^3 \setminus e$ has linking value 0.*

Proof. Existence and uniqueness follow term by term from Lemma 23.28, by induction on the length of the chain. An exchange permutes a sum, a merge of two terms with the same simplex uses one swept angle for both, by uniqueness, and a deleted term contributes 0. For a 2-simplex τ of the complement, $\pi \circ \tau$ stays away from the origin by Lemma 23.29, and the faces of τ contribute $v_0 - v_1 + v_2 = 0$ by Lemma 23.30. □

Lemma 23.33 (The loop sweeps four quarter turns). *Put*

$$z(u) = \Big(\frac{(1-u^2)^2 - 4u^2}{(1+u^2)^2},\ \frac{4u(1-u^2)}{(1+u^2)^2} \Big), \qquad \gamma(t) = \big(0, 0, z(2t-1)\big), \quad t \in [0,1].$$

Then γ is a uniformly continuous loop of S^3, $1/2$-apart from the equatorial circle, and $\pi \circ \gamma$ has swept angle 4.

Proof. The point $z(u)$ is the square, as a complex number, of the point $w(u)$ of the proof of Lemma 23.20; so it lies on the circle, runs once around it as u goes from -1 to 1, and $z(-1) = z(1) = (-1, 0)$, which makes γ a loop. Its first two coordinates vanish, so $d(\gamma(t), e(x,y)) \geq |z(2t-1)| \geq 1/2$, since two numbers below $1/2$ in absolute value cannot have squares summing to 1. The map w is 4-Lipschitz, z is 32-Lipschitz, and $u = 2t - 1$ doubles distances, so $\varepsilon \mapsto \varepsilon/64$ is a modulus of γ.

Table 23.2. The angle swept by the loop of Lemma 23.33, piece by piece. The point $z(u)$ is given at the ends of each piece, with its diamond angle in the chart of that piece.

Piece in u	Chart	z at the ends	θ at the ends	Swept
$[-1,-\frac{1}{2}]$	2	$(-1,0)$, $(-\frac{7}{25},-\frac{24}{25})$	$2,\ 2+\frac{24}{31}$	$\frac{24}{31}$
$[-\frac{1}{2},-\frac{1}{5}]$	3	$(-\frac{7}{25},-\frac{24}{25})$, $(\frac{119}{169},-\frac{120}{169})$	$3-\frac{7}{31},\ 3+\frac{119}{239}$	$\frac{7}{31}+\frac{119}{239}$
$[-\frac{1}{5},\frac{1}{5}]$	0	$(\frac{119}{169},\mp\frac{120}{169})$	$-\frac{120}{239},\ \frac{120}{239}$	$\frac{240}{239}$
$[\frac{1}{5},\frac{1}{2}]$	1	$(\frac{119}{169},\frac{120}{169})$, $(-\frac{7}{25},\frac{24}{25})$	$1-\frac{119}{239},\ 1+\frac{7}{31}$	$\frac{119}{239}+\frac{7}{31}$
$[\frac{1}{2},1]$	2	$(-\frac{7}{25},\frac{24}{25})$, $(-1,0)$	$2-\frac{24}{31},\ 2$	$\frac{24}{31}$

Take the grid of 20 cells, so that each cell is an interval of length $1/10$ in u, with charts $2,2,2,2,2,3,3,3,0,0,0,0,1,1,1,2,2,2,2,2$. The charts are constant on the five pieces of Table 23.2, and on each piece the required sign is a polynomial inequality with an explicit positive lower bound. Write $z=(z_0,z_1)$. Then $z_0<0$ where $|u|\geq 1/2$, since there $4u^2-(1-u^2)^2\geq 7/16$; $z_1<0$ for $-1/2\leq u\leq -1/5$ and $z_1>0$ for $1/5\leq u\leq 1/2$, since there $4|u|(1-u^2)\geq 3/5$; and $z_0>0$ where $|u|\leq 1/5$, since there $(1-u^2)^2-4u^2\geq (24/25)^2-4/25>0$. Within a piece the cell differences telescope to the difference of the end values, which Table 23.2 lists. The total is

$$\frac{24}{31}+\Big(\frac{7}{31}+\frac{119}{239}\Big)+\frac{240}{239}+\Big(\frac{119}{239}+\frac{7}{31}\Big)+\frac{24}{31}=\frac{62}{31}+\frac{478}{239}=2+2=4.$$

□

Theorem 23.34 (The equatorial circle of the 3-sphere is linked)**.** *The loop γ of Lemma 23.33 bounds no 2-chain of $S^3\setminus e$. Hence the equatorial circle is a linked native embedding, and $D=3$ detects linking. No omniscience principle and no choice principle is used.*

Conditions and scope.

Base and premises

The native notions of Section 23.1 for $D=3$; the diamond-angle charts of Definition 23.25, which use only rational operations, absolute values and inverses of positive points.

Conclusion

One explicit loop of the complement of the equatorial circle of S^3 bounds no native 2-chain there. The invariant that shows it is a value relation on chains, unique on each chain, kept by equivalence and zero on boundaries.

Identification

Reading the swept angle as the linking number of two closed curves, and the two curves as a kept pair of records, is the physical reading of the theorem, not part of it.

Not claimed

That every native embedding of the circle into S^3 is linked. A linking function from chains to the line.

Proof. The equatorial circle is a native embedding (Remark 23.6), and γ is a loop of its complement (Lemma 23.33). If $(1, \gamma) \sim \partial L$ for a 2-chain L of $S^3 \setminus e$, then by Lemma 23.32 the linking value of $(1, \gamma)$, which is 4 by Lemma 23.33, equals that of ∂L, which is 0. But $4 \neq 0$. □

Read physically, the swept angle of a closed path in the plane normal to the curve's plane is its linking number with the curve, counted in quarter turns, and Lemma 23.30 says that a membrane kept away from the curve sweeps no angle around its own boundary. The loop sweeps four quarter turns, one full turn, so no membrane of the complement fills it.

23.8 Room in four dimensions: pulling a loop off the equatorial circle

The ladder proves that nothing is linked in S^4 without ever moving a loop, and Theorem 23.8 uses only the ladder. It is worth seeing the room directly, for the same equatorial circle; the proposition below does that, and nothing later depends on it. In S^4 the points away from the equatorial circle $e(x, y) = (x, y, 0, 0, 0)$ have three normal coordinates instead of two, and a loop in the normal directions can be slid off a direction it misses. Finding a missed direction without a decision is the interesting step. One tool turns homotopies into chains.

Lemma 23.35 (A homotopy through loops carries bounding)**.** *Let f be a native embedding into S^D and $H : [0,1] \times [0,1] \to S^D$ a uniformly continuous map that is uniformly apart from f, with $H(s,0) = H(s,1)$ for every s. If the loop $H(0,\cdot)$ bounds in $S^D \setminus f$, so does the loop $\gamma = H(1,\cdot)$.*

Proof. Cut the square of pairs (s,t) along its diagonal into two triangles and read H on each as a singular 2-simplex, A and B. Their faces are γ, $H(0,\cdot)$, the diagonal, counted once in each with opposite signs, and the two vertical sides $H(\cdot,0)$ and $H(\cdot,1)$, which are equal. So $\partial(B - A) \sim \gamma - H(0,\cdot)$, and γ bounds whenever $H(0,\cdot)$ does. This is the construction of the opening example. □

Proposition 23.36 (The equatorial circle of S^2 and of S^4 is not linked)**.** *For $D = 2$ and for $D = 4$, every loop of the complement of the equatorial circle in S^D bounds there. The proof uses explicit homotopies and no omniscience principle or choice principle.*

Proof. For $D = 2$ this is the opening example: the sign of the third coordinate is constant along the loop, and the hemisphere homotopy with Lemma 23.35 finishes the proof.

For $D = 4$ let γ be a loop r-apart from the equatorial circle, and write the normal part of a point p as $n(p) = (p_2, p_3, p_4)$. As in Lemma 23.29, $|n(\gamma(t))| \geq \zeta = \min(r/2, 1/4)/2$ for every t. For a vector v of $\mathbb{R}^3_\delta$ with $|v|$ bounded below, let $E(v) = (0, 0, v/|v|)$, a point of the normal 2-sphere; it is at least $1/\sqrt{3}$ from the equatorial circle. Three homotopies, each through loops that stay apart from the equatorial circle, carry γ to a constant loop, and three uses of Lemma 23.35 show that γ bounds.

Retraction. $R(s,p) = \big(sp_0,\ sp_1,\ \sqrt{1 - s^2(p_0^2 + p_1^2)}\, n(p)/|n(p)|\big)$. It lies on S^4, $R(1,p) = p$ because $|n(p)|^2 = 1 - p_0^2 - p_1^2$, and $R(0,p) = E(n(p))$. The normal part of $R(s,p)$ has length $\sqrt{1 - s^2(p_0^2 + p_1^2)} \geq |n(p)|$, so the homotopy stays apart from the equatorial circle.

Straightening. A uniformly continuous loop in the normal 2-sphere may pass through every one of its points; classically, Peano's curves fill whole squares [195]. So no missed direction need exist yet. Take M so large that γ moves by less than $\zeta/4$ over every time step $1/(M+1)$, and let P be the closed polygon through the samples $x_j = n(\gamma(j/(M+1)))$, $j = 0, \dots, M+1$, run at constant speed in t. Then $|P(t) - n(\gamma(t))| < \zeta/2$, so the segment from $n(\gamma(t))$ to $P(t)$ stays at least $\zeta/2$ from 0, and $E(s\,n(\gamma(t)) + (1-s)P(t))$ is a homotopy from $E \circ P$ to $E \circ n \circ \gamma$.

Contraction. The candidates are the points $q_k = (1, k, k^2)$ of the moment curve, for the integers k with $0 \le k \le 2M+2$. All bounds from here on are in the sup norm, in which $|q_k| \le Q = 1 + (2M+2)^2$ and $\zeta \le |x_j| \le 1$, the samples being normal parts of points of S^4; in this norm $|a \times b| \le 2|a||b|$ and $|\det(a,b,c)| \le 6|a||b||c|$. For a candidate q put $K(s,t) = E\big(sP(t) - (1-s)q\big)$: it runs from $E \circ P$ at $s = 1$ to the constant loop $E(-q)$ at $s = 0$, and it is defined as long as $sP(t) - (1-s)q$ stays away from 0, that is, as long as the polygon stays away from the ray through q. Put $e = \zeta/(16(1+2Q))$, and take the cross-product bound $\xi = \zeta e/2$, the chord bound $\eta = \xi e$, the determinant bound $\eta' = \eta e$ and $\mu = \eta' e$, all at most 1. Cotransitivity puts every chord, from x_j to x_{j+1}, into one of two cases: it is *spread*, with $|x_j \times x_{j+1}| > \eta$, or *nearly degenerate*, with $|x_j \times x_{j+1}| < 2\eta$. For each chord and each candidate q it decides again: q is *good* when $|\det(x_j, x_{j+1}, q)| > \eta'$ for a spread chord, or $|x_j \times q| > \xi$ for a nearly degenerate one, and *bad* when these are below $2\eta'$, respectively 2ξ. For a spread chord, $k \mapsto \det(x_j, x_{j+1}, q_k) = q_k \cdot (x_j \times x_{j+1})$ is a quadratic polynomial $f(k) = w_0 + w_1 k + w_2 k^2$ whose coefficients are the coordinates of $x_j \times x_{j+1}$. If $|f(k)| < \beta$ at three integers $k_1 < k_2 < k_3 \le A = 2M+2$, its coefficients are below $4\beta(1+2Q)$. Indeed, the divided difference $\big(f(k_2) - f(k_1)\big)/(k_2 - k_1) = w_1 + w_2(k_1 + k_2)$ is below 2β in absolute value, and so is the one for k_2, k_3; their difference divided by $k_3 - k_1 \ge 2$ is w_2, so $|w_2| < 2\beta$. Then $|w_1| < 2\beta + 2\beta(k_1 + k_2) < 2\beta(1 + 2A)$, and $|w_0| \le |f(k_1)| + |w_1|k_1 + |w_2|k_1^2 < \beta + 2\beta A + 6\beta A^2$; each of these is at most $4\beta(1+2Q) = 4\beta(3 + 2A^2)$. Three bad candidates would give $|x_j \times x_{j+1}| < 8\eta'(1+2Q) \le \eta$, against the spread, so at most two candidates are bad. For a nearly degenerate chord write $x_j = (y_0, y_1, y_2)$; the third coordinate of $x_j \times q_k$ is $ky_0 - y_1$, so if $|x_j \times q_k|$ and $|x_j \times q_{k'}|$ are below β for $k < k'$, then $|y_0|(k' - k) < 2\beta$, so $|y_0| < 2\beta$; the third coordinate then gives $|y_1| < \beta + 2\beta A$, and the second, $y_2 - y_0 k^2$, gives $|y_2| < \beta + 2\beta A^2$, so $|x_j| < 2\beta(1+Q)$; and two bad candidates would give $|x_j| < 4\xi(1+Q) < \zeta$. So at most one candidate is bad. Each of the $M+1$ chords rules out at most two of the $2M+3$ candidates, so some candidate is good for every chord; this count is over finitely many natural numbers.

With that candidate q, $|sP(t) - (1-s)q| \ge \mu$ for all s and t. This bound is a negation, so it suffices to prove it for t in the interval of one chord, which t is up to double negation. There $P(t) = (1-\lambda)x_j + \lambda x_{j+1}$ with $0 \le \lambda \le 1$, and $|P(t)| \ge \zeta/2$ by the straightening step. Suppose that $W = sP(t) - cq$, with $c = 1 - s$, has $|W| < \mu$. Then $s\zeta/2 < \mu + cQ$, that is, $c(\zeta/2 + Q) > \zeta/2 - \mu$. If the chord is spread, $P(t)$ lies in the plane of x_j and x_{j+1}, so $c|\det(x_j, x_{j+1}, q)| = |\det(x_j, x_{j+1}, W)| \le 6|W|$, and $c < 6\mu/\eta' = 6e$. If it is nearly degenerate, $x_j \times W = s\lambda(x_j \times x_{j+1}) - c(x_j \times q)$, so $c\xi < 2|W| + 2\eta < 4\eta$ and $c < 4e$. Either way $\zeta/2 < \mu + 6e(\zeta/2 + Q) \le e(4 + 6Q) \le \zeta/2$, which is absurd. So K is a homotopy through loops apart from the equatorial circle, ending at a constant loop, which bounds (Remark 23.6). □

The proof is a picture of why four dimensions leave room. Two normal coordinates around a circle in S^3 give a circle of directions, and a loop can wind around it; three normal coordinates in S^4 give a 2-sphere of directions, and a loop drawn as finitely many chords misses some direction, which can be found by counting.

23.9 Why three

All the pieces are in place.

Proof of Theorem 23.8. If $D = 3$, the equatorial circle is linked (Theorem 23.34). For $D \neq 3$ we prove a positive statement, stronger than the theorem's: for every native embedding f of the circle into S^D, every loop of the complement of f bounds a native 2-chain of the complement.

If $D = 2$ or $D \geq 4$, then $H_3(S^D) = 0$ (Proposition 23.19), and Lemma 23.22 gives $H_2(S^D \setminus \{a, b\}) = 0$ for all points a, b with $d(a, b) > 0$. The proof of Proposition 23.23 then composes three positive steps: a loop of the complement bounds in the complement of each half (Lemma 23.20); the two junctions of f are apart; and a loop that bounds in the complements of both halves bounds in the complement of f (Lemma 23.21, whose hypothesis is the two-point statement just obtained). If $D = 0$, no map of the circle into S^0 is a native embedding (Proposition 23.24), so there is nothing to check. If $D = 1$, the starting point of a loop of the complement would be a point of S^1 apart from the image of f, which Proposition 23.24 excludes; so the complement has no loop, and again there is nothing to check.

In each case with $D \neq 3$, a loop that bounds no 2-chain of the complement would contradict the positive statement, so no embedding is linked. Every case is a natural number D compared with 0, 1, 2 and 3, which is decided. Every lemma used was proved with no omniscience principle and no choice principle. □

The proof also settles which native spheres have vanishing third homology.

Corollary 23.37 (The third homology of the native spheres)**.** *For every $D \geq 2$, $H_3(S^D) = 0$ if and only if $D \neq 3$. For $D = 2$ and every $D \geq 4$, $H_2(S^D \setminus \{a, b\}) = 0$ for all points with $d(a, b) > 0$; for $D = 3$ this fails. No omniscience principle and no choice principle is used.*

Proof. For $D \neq 3$ this is Proposition 23.19 with Lemma 23.22. If $H_3(S^3) = 0$, or if every two-point complement of S^3 had vanishing H_2, Proposition 23.23 would show that no circle is linked in S^3, against Theorem 23.34. □

The descent (23.1) for $D = 3$ asks for $H_2(S^2) = 0$, and one rung lower for $H_1(S^1) = 0$. The corollary says that it must fail somewhere, and the next theorem says where: the first homology of the circle is $\mathbb{Z}$. Its cycles are read by the same swept angle, now for paths on the circle itself, whose points have $|p| \geq 1/\sqrt{2}$.

Theorem 23.38 (The first homology of the circle is $\mathbb{Z}$, as a relation)**.** *For 1-chains of S^1, say that a chain c has* label $n \in \mathbb{Z}$ *when c is a cycle with swept angle $4n$ (the sum, with coefficients, of the swept angles of its paths). Then every cycle has a label; no chain has two labels; equivalent chains have the same labels; labels add under concatenation; every boundary has label 0; a cycle with label 0 is a boundary; and some cycle has label 1. Moreover the swept angle of every cycle is $4k$ for an integer k, and the cycle is homologous to k copies of one fixed loop. No omniscience principle and no choice principle is used.*

Conditions and scope.

Base and premises

Native 1- and 2-chains of the circle (Definition 23.4 with nothing removed) and the swept angle of Definition 23.27.

Conclusion

The labels have the properties listed, which are those of the classical isomorphism $H_1(S^1) \cong \mathbb{Z}$ restricted to cycles; the label is a relation between cycles and integers, with no omniscience principle and no choice principle.

Not claimed

One integer-valued map on all 1-chains, open paths included; it costs exactly the WLPO function (Theorem 23.40 and Theorem 22.65). The first homology group as a quotient.

Proof. Swept angles of paths on the circle exist and are unique, add along chains, are kept by the moves, and vanish on boundaries, exactly as in Lemmas 23.28, 23.30 and 23.32; the loop z of Lemma 23.33, traced on the circle itself, is a cycle of swept angle 4, hence of label 1. The remaining work is the integrality and the direction "label 0 implies boundary". Subdivide every path of a cycle into pieces that each lie in one chart (Lemma 23.10, item 4). Replace each piece by a *chord*: the path between the same end points that moves linearly in the chart coordinate $y'/(x' + |y'|)$. The straight-line homotopy in that coordinate stays in the chart and fixes the end points, so by Lemma 23.11 the piece and its chord differ by a boundary (constant paths are boundaries). The *fundamental loop* runs by eight chords through the axis points $(1, 0)$, $(0, 1)$, $(-1, 0)$, $(0, -1)$ and the points $(\pm\frac{3}{5}, \pm\frac{4}{5})$ between them; it is a cycle with swept angle 4. For a point x of chart j, the *ray* to x runs from $(1, 0)$ along the fundamental loop to the axis point of chart j, then by one chord to x. A chord from p to q in chart j is homologous to the ray to q minus the ray to p, by a triangle inside the chart. If x lies in charts j and $j + 1$, the two rays to x differ by a boundary, or, across charts 3 and 0, by one fundamental loop: with m_j the point of the fundamental loop between the axis points of charts j and $j + 1$, a triangle in chart j through its axis point, m_j and x, and one in chart $j + 1$ through m_j, its axis point and x, leave the two chords from m_j to x read in charts j and $j + 1$; these coincide, since the overlap is an interval of the chart coordinate on which $\theta_{j+1} - \theta_j$ is constant (Lemma 23.26). Now give every term of the boundary of the cycle the chart of the chord it comes from, so that the sum of the rays to its terms, with their coefficients, is homologous to the cycle, and follow the moves that reduce this boundary to the empty list. An exchange changes nothing; a merge or split of two terms at the same point changes the sum of rays by whole fundamental loops, as their charts are equal or neighbours (charts j and $j + 2$ do not meet); a term with coefficient 0 contributes nothing. By induction, the cycle is homologous to k fundamental loops and its swept angle is $4k$. Its label is k. If the label is 0, then $k = 0$ and the cycle is a boundary. Every step is a finite construction from moduli and grids. □

A label is attached to cycles only. An open path has a swept angle, but an integer for it would need a branch of the angle at its end points, a choice of which whole turn to count from, and nothing in the path supplies one. Whether the label can be extended to one integer-valued function on all chains is the question of Section 23.10, and it has a price.

So the three endings of Table 23.1 explain the theorem. A linked circle in S^D needs a 3-cycle of S^D that does not bound, and the descent derives the vanishing of the third homology of S^D from that of the first homology of S^{D-2}; its steps are implications in one direction. Among the spheres only the circle has cycles that wind: $H_1(S^0) = 0$ because paths in two points are constant, and $H_1(S^m) = 0$ for $m \geq 2$ because S^{m-1} is connected (Proposition 23.19). The sphere S^{D-2} is the circle exactly when $D = 3$, so three is the one dimension the descent cannot settle; there the linked equatorial circle (Theorem 23.34) shows directly that $H_3(S^3)$ does not vanish. Recognition Science reads this as the reason space has three dimensions; with $D = 3$, the count $2^D = 8$ of binary states in Chapter 22 is arithmetic.

23.10 The winding number as data, and its price

Theorem 23.38 gives every cycle of the circle an integer label, as a relation. The classical isomorphism $H_1(S^1) \cong \mathbb{Z}$ is read as more: one homomorphism from chains to integers. Under the reading of maps of Parts VI–VIII (Section 21.1) a map is a rule given as data, and from "each cycle has exactly one label" we do not form a map. So the *data form* of the circle's first homology is a separate statement, and it asks for a value on every chain, open paths included. It is row R2-35d of the table of Chapter 22, and it costs exactly the WLPO function (Theorem 22.65). Table 23.3 sets it among the results of this chapter.

Definition 23.39 (The data form and the principles around it)**.** A *path* is a uniformly continuous map $[0,1] \to S^1$, and 1-chains of S^1 are combinations of paths. Write $ix = (-x_1, x_0)$ for the anticlockwise quarter turn of a point $x = (x_0, x_1)$ of the circle.

1. The *data form* of $H_1(S^1) = \mathbb{Z}$: a map W from 1-chains of S^1 to $\mathbb{Z}$ such that equivalent chains have equal values, W of c followed by c' is $W(c) + W(c')$, $W(\partial L) = 0$ for every 2-chain L, every cycle c with $W(c) = 0$ is a boundary, and some cycle g has $W(g) = 1$.
2. A *quarter-turn colouring*: a map $q : S^1 \to \mathbb{Z}$ with $q(ix) \equiv q(x) + 1 \pmod 4$ for every x.
3. An *antipodal two-colouring*: a map $b : S^1 \to \{0,1\}$ with $b(-x) \neq b(x)$ for every x.
4. The *non-constant unit principle*: a map $F : [0,1] \to \mathbb{Z}$ with $F(0) = 0$ and $F(1) \neq 0$.
5. A *branch of the angle*: a map $\theta : S^1 \to \mathbb{R}_\delta$ such that for every x and every chart $j < 4$ containing x, the diamond angle $\theta_j(x)$ is $\theta(x) + 4m$ for some integer m.
6. *Unique choice of path labels*: every relation between paths and integers that relates each path to exactly one integer contains a map from paths to integers.
7. *Borsuk–Ulam for two-colourings* (BU_2): every map $b : S^1 \to \{0,1\}$ gives some pair of antipodal points the same colour, $b(-x) = b(x)$; its *weak form* says that no map b has $b(-x) \neq b(x)$ for every x.
8. *Continuity on Cantor space*: for every map d from binary sequences to $\{0,1\}$ and every binary sequence α there is n such that $d(\beta) = d(\alpha)$ for every β that agrees with α below n.

The WLPO function is that of Definition 21.1: one map from binary sequences to $\{0,1\}$ that answers "is the sequence identically 0?".

Table 23.3. The native statements of this chapter and their prices. "Free" means proved with no omniscience principle and no choice principle.

Statement	Price	Result
A circle can be linked in S^D exactly when $D = 3$	free	Theorem 23.8
The equatorial circle of S^3 is linked	free	Theorem 23.34
$H_3(S^D) = 0$ exactly when $D \neq 3$, for $D \geq 2$	free	Corollary 23.37
$H_1(S^m) = 0$ for $m \geq 2$; $H_2(S^m) = 0$ for $m = 1$, $m \geq 3$	free	Proposition 23.19
Cycles of S^D apart from a point bound	free	Lemma 23.12
Loops apart from an arc bound in its complement	free	Lemma 23.20
No circle in S^0; no room beside a circle in S^1	free	Proposition 23.24
The equatorial circle of S^2 and of S^4 is not linked, by explicit homotopies	free	Proposition 23.36
$H_1(S^1) = \mathbb{Z}$ as a relation	free	Theorem 23.38
$H_1(S^1) = \mathbb{Z}$ as a function on all chains	the WLPO function; refuted by BU_2	Theorems 23.40, 22.65
The WLPO function	refuted by continuity on Cantor space	Theorem 23.40

Theorem 23.40 (The price of the winding number as data)**.** *On* $\mathbb{R}_\delta$*:*

1. *the data form implies a quarter-turn colouring, a quarter-turn colouring implies an antipodal two-colouring, and an antipodal two-colouring implies the non-constant unit principle;*
2. *the WLPO function gives a branch of the angle; a branch of the angle with unique choice of path labels gives the data form; so the WLPO function with unique choice of path labels gives the data form, and the WLPO function alone gives the non-constant unit principle;*
3. BU_2 *refutes the antipodal two-colouring, hence the quarter-turn colouring and the data form; the nonexistence of an antipodal two-colouring is exactly the weak form of* BU_2*; and continuity on Cantor space refutes the WLPO function.*

Every implication is proved with no omniscience principle and no choice principle.

Conditions and scope.

Base and premises

The line and the native circle; the reading of maps of Section 21.1. Each part is an implication between the named statements.

Conclusion

The data form lies between the quarter-turn colouring, which it implies, and the WLPO function with unique choice of path labels, which imply it. Both ends are refuted by principles that hold in Brouwer's intuitionistic mathematics. Theorem 22.65 closes the bracket: each of the four data forms is exactly the WLPO function, and unique choice of path labels is not needed.

Not claimed

Within this theorem, the converses of parts 1 and 2; they are Theorem 22.65. That BU_2 or continuity on Cantor space is consistent with the base: that is the standard fact about Brouwerian models cited below, not a model built here.

Proof. Part 1. Let W be the data form. Then $W(\varnothing) = 0$, since $W(\varnothing) = W(\varnothing) + W(\varnothing)$, and $W(-c) = -W(c)$, since $-c$ followed by c is equivalent to the empty list. The *quarter chord* at x is the path $s \mapsto ((1-s)x + six)/\sqrt{(1-s)^2 + s^2}$, defined because $(1-s)^2 + s^2 \geq 1/2$; it sweeps exactly one quarter turn. To see this, read it on the halves $s \leq \frac{1}{2}$ and $s \geq \frac{1}{2}$. With x in chart j and $\rho^j(x) = (\alpha, \gamma)$, $\alpha > 0$, the chart coordinates of the chord are proportional to $((1-s)\alpha - s\gamma, (1-s)\gamma + s\alpha)$, and cotransitivity gives $\gamma < 0$, when the whole chord lies in chart j, or $\gamma > -\alpha$ and then $\gamma > 0$, when it lies in chart $j+1$, or $\gamma < \alpha$, when the halves lie in charts j and $j+1$. In each case the readings add up to $\theta_{j+1}(ix) - \theta_j(x) = 1$, as $\rho^{j+1}(ix) = (\alpha, \gamma)$ and $\theta_{j+1} = \theta_j$ on the overlap. The quarter chords at x, ix, $-x$, $-ix$ in turn form a cycle of label 1. Let g be the cycle with $W(g) = 1$, and let k_0 be its label (Theorem 23.38). For a cycle c of label n, the cycle $k_0 c - ng$ has label 0, so it is a boundary and W vanishes on it: $k_0 W(c) = n$. Put $G(x) = W(\text{quarter chord at } x)$. The cycle of four quarter chords gives

$$k_0\big(G(x) + G(ix) + G(-x) + G(-ix)\big) = 1,$$

so $k_0 = \pm 1$. Put $q(x) = k_0\big(3G(x) + 2G(ix) + G(-x)\big)$. With a, b, c, d the values of G at $x, ix, -x, -ix$,

$$q(ix) - q(x) - 1 = k_0(3b + 2c + d - 3a - 2b - c) - 1 = k_0(a + b + c + d) - 1 - 4k_0 a = -4k_0 a,$$

a multiple of 4. So q is a quarter-turn colouring. Applying it twice, $q(-x) \equiv q(x) + 2 \pmod 4$, so $b(x) = 1$ when $q(x)$ is 0 or 1 modulo 4, and $b(x) = 0$ otherwise, is an antipodal two-colouring; residues of integers are decided. Finally, let w parametrize the right half of the circle from $(0, -1)$ to $(0, 1)$ as in Lemma 23.20, and put $F(s) = 0$ if $b(w(2s-1)) = b(0, -1)$ and $F(s) = 1$ otherwise; equality of bits is decided. Then $F(0) = 0$, and $F(1) = 1$ because $(0, 1) = -(0, -1)$.

Part 2. With the WLPO function every comparison of a point with a ratio by $\leq$, in either order, is decided as data: $x \leq a$ says that a binary sequence computed from the stages of x is identically 0, and $a \leq x$ is $-x \leq -a$. At a point x of the circle, decide first whether $|x_0| \geq 1/4$. If so, decide whether $x_0 \leq 0$: then x lies in chart 2 or in chart 0, because $|x_0| \geq 1/4$ makes x_0 apart from 0. If not, then $x_1^2 = 1 - x_0^2 \geq 15/16$, so $|x_1| > 1/4$, and deciding whether $x_1 \leq 0$ places x in chart 3 or in chart 1. Let $\theta(x)$ be the diamond angle in the chart so picked. By Lemma 23.26, in any other chart containing x the angle differs by 0 or ± 4: θ is a branch of the angle. Only comparisons with $\leq$ were decided, so the LPO function is not needed.

Now let θ be a branch. For a path γ with swept angle w, read on an admissible grid, replace each chart reading by θ: each changes by a multiple of 4, and the θ readings telescope. So $w + \theta(\gamma(0)) - \theta(\gamma(1)) = 4n$ for exactly one integer n. This relation between paths and integers relates each path to one integer, and unique choice of path labels turns it into a map $n(\gamma)$. Put $W(c) = \sum_i n_i\, n(\gamma_i)$ for $c = (n_1, \gamma_1), \ldots, (n_m, \gamma_m)$. It respects the moves and adds. On a cycle the end-point terms cancel, because θ is a map and the 0-chain of end points is equivalent to the empty list; so $4W(c)$ is the swept angle of c and $W(c)$ is its label. Theorem 23.38 then gives

the remaining properties: boundaries have label 0, a cycle of label 0 is a boundary, and some cycle has label 1. The WLPO function also gives the non-constant unit principle directly: the map $F(s) = 0$ if $s \leq 1/2$ and $F(s) = 1$ otherwise is defined by one comparison of s with $1/2$.

Part 3. An antipodal two-colouring is a map b that BU_2 says cannot exist, and the negation of "some b has $b(-x) \neq b(x)$ for every x" is, by logic alone, "no b has it". Let d be a WLPO function, so $d(\bar{0}) = 1$ for the sequence $\bar{0}$ of zeros. Continuity at $\bar{0}$ gives n with $d(\beta) = 1$ for every β that agrees with $\bar{0}$ below n. The sequence β with a single 1, at place n, is such a sequence, yet it is not identically 0, so $d(\beta) = 0$. This contradiction refutes the WLPO function. □

Both separating principles hold in Brouwer's intuitionistic mathematics, where every map from Cantor space to $\{0, 1\}$ is continuous, and every map from the connected circle to $\{0, 1\}$ is constant [4], [40]; there, by part 3, neither the data form nor the WLPO function exists. Both principles fail classically: the colouring $b(x) = 1$ exactly when $x_1 > 0$, or $x_1 = 0$ and $x_0 > 0$, is antipodal, and excluded middle with unique choice gives a WLPO function. The classical Borsuk–Ulam theorem says that every continuous map from the circle to the line takes equal values at two antipodal points [192]; BU_2 is its form for two-valued maps, made a principle by dropping the continuity hypothesis.

So the free relation of Theorem 23.38 is all that the proof of Theorem 23.8 needs, and the function costs more. Read physically: one integer label on all records of motion around a circle, read as a single function, fixes at every point a phase in $\mathbb{Z}/4$ that advances by one under a quarter turn, a discontinuous field of quarter phases; a world whose two-valued readings of the circle obey BU_2 cannot carry it.

Questions to work through

1. (Lemma 23.17.) Show that a native embedding of the circle into S^0 cannot exist, using only Lemma 23.17 and the inverse modulus, and explain why no decision of the sign of a point is needed to show that two points of S^0 closer than 1 are equal.

2. (Lemma 23.12.) Verify $|2tx + kp|^2 = Q^2$ from the definitions of A, Q and k. For $D = 1$, $p = (1, 0)$ and $x = (0, 1)$, compute $H(\frac{1}{2}, x)$, check that it lies on the circle, and check that it is farther from p than x is.

3. (Lemma 23.26, Theorem 23.38.) The fundamental loop runs through $(1, 0)$, $(\frac{3}{5}, \frac{4}{5})$, $(0, 1)$, $(-\frac{3}{5}, \frac{4}{5})$, $(-1, 0)$, $(-\frac{3}{5}, -\frac{4}{5})$, $(0, -1)$, $(\frac{3}{5}, -\frac{4}{5})$ and back. Compute the diamond angle swept by each of its eight chords and show that the total is 4.

4. (Lemma 23.16.) Show that the slide of Lemma 23.16 does not reach the equator from points near a pole, and explain why the proof never needs it to: which property of the cycle z makes $H(1, \cdot)$ land on the equator at every value of z?

5. (Theorem 23.40, part 1.) Given a quarter-turn colouring q, show that $b(x) = 1$ exactly when $q(x)$ is 0 or 1 modulo 4 is an antipodal two-colouring, and that the identity $q(ix) - q(x) - 1 = -4k_0 G(x)$ holds for the colouring built from W.

6. (Theorem 23.40, part 3.) Prove that continuity on Cantor space refutes the WLPO function. Then show classically that both BU_2 and continuity on Cantor space are false.

Chapter 24

Ledgers, rates and the light cone

An account kept by double entry changes in one way only: a post adds one unit to its debit side or one unit to its credit side. After some posts the account's record is a pair of counts (D, C). What does one account's history of debits and credits already contain?

More than bookkeeping suggests. Take the eight posts

$$d\,c\,d\,d\,c\,d\,c\,d,$$

where d is a debit and c a credit. After each post write down the record (D, C), the number of posts $t = D + C$, the balance $x = D - C$ and the product DC:

post	d	c	d	d	c	d	c	d
(D, C)	$(1,0)$	$(1,1)$	$(2,1)$	$(3,1)$	$(3,2)$	$(4,2)$	$(4,3)$	$(5,3)$
t	1	2	3	4	5	6	7	8
x	1	0	1	2	1	2	1	2
DC	0	1	2	3	6	8	12	15

Every post raises t by one and moves x by one, up for a debit and down for a credit. In the plane of x and t each post is a step at speed one, and the record never leaves the cone $|x| \le t$. The product DC is a quarter of $t^2 - x^2$: at the end, $(64 - 4)/4 = 15 = 5 \cdot 3$.

The cost $J(r) = \frac{1}{2}(r + r^{-1}) - 1 = (r-1)^2/(2r)$ of Chapter 21 reads this motion. The final ratio $D/C = 5/3$ costs $J(5/3) = 2^2/(2 \cdot 5 \cdot 3) = 2/15$. With the velocity $\beta = x/t = 1/4$ and $\gamma = (1 - \beta^2)^{-1/2} = 4/\sqrt{15}$, that is exactly $2(\gamma\beta)^2$. The square root of the ratio costs $J(\sqrt{5/3}) = 8/(2\sqrt{15}) - 1 = \gamma - 1$, the excess of the Lorentz factor over one.

Now split the history after four posts into two legs, *dcdd* with counts $(3,1)$ and *cdcd* with counts $(2,2)$. The number $\tau = 2\sqrt{DC}$ is $2\sqrt{3}$ for the first leg, 4 for the second and $2\sqrt{15}$ for the whole history. The whole exceeds the sum of its parts, $2\sqrt{15} \approx 7.746 > 2\sqrt{3} + 4 \approx 7.464$, as the proper time of the stay-at-home twin exceeds that of the traveller, and the excess is again a value of J:

$$(2\sqrt{15})^2 - (2\sqrt{3} + 4)^2 = 32 - 16\sqrt{3} = 2 \cdot 2\sqrt{3} \cdot 4 \cdot J\big(\sqrt{3/1}\big).$$

The integer core of this identity needs no square roots. With $s_1 = 3 \cdot 1$, $s_2 = 2 \cdot 2$ and $s = 5 \cdot 3$, $(s - s_1 - s_2)^2 - 4s_1 s_2 = 64 - 48 = 16 = (3 \cdot 2 - 2 \cdot 1)^2$. Figure 24.1 draws the history.

This chapter proves that these coincidences are laws, and finds where they stop. One account's records fill exactly the future light cone of the interval $DC = (t^2 - x^2)/4$, and DC is the only quadratic form, up to a factor, that vanishes on the two directions a single post can take (Section 24.1). J of the ratio is twice the squared proper velocity, and J of its square root is $\gamma - 1$ (Section 24.2). The number $\tau = 2\sqrt{DC}$ is superadditive over the legs of a history, and

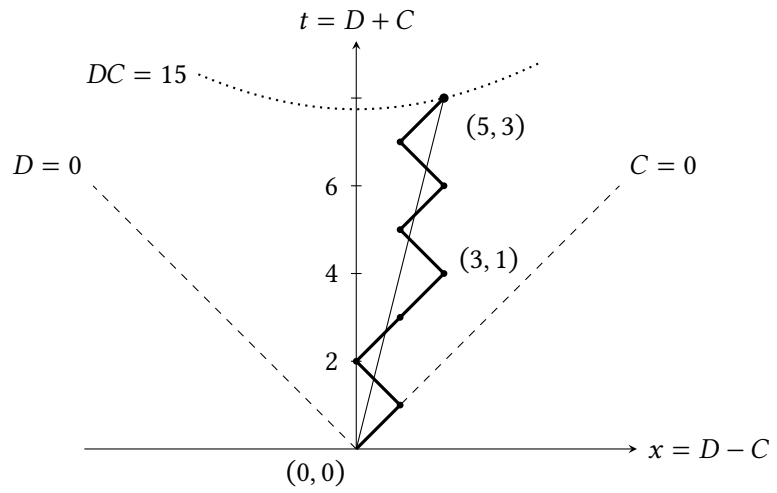

Figure 24.1. The history *dcddcdcd* in the plane of balance x and post count t (thick). A debit steps up and to the right, a credit up and to the left, so every post runs along the light cone (dashed). The thin chord is the inertial history with the same end record $(5, 3)$; the dotted hyperbola is $t^2 - x^2 = 60$, on which $DC = 15$.

the deficit is J of the relative ratio, so a history has the greatest τ for its end record exactly when it does not change ratio (Section 24.3). The posting word of the recognition hierarchy, the history above continued, approaches the inertial line of velocity $\varphi^{-3} = \sqrt{5} - 2$, bending at every step by the least amount an integer history can bend, and its time dilation is exactly $2\varphi^{-3/2} \approx 0.9717$ (Section 24.4).

None of this survives to more accounts. Several accounts posted one unit at a time reach exactly a taxicab cone, which is the cone of a quadratic form only in one space dimension (Section 24.5). The cone of one time and three space dimensions appears instead as the record cone of a single binary distinction carried coherently, by 2×2 Hermitian matrices whose diagonal is the ledger's debit and credit and whose coherent changes of determinant one are exactly the proper orthochronous Lorentz group (Section 24.6). Such a distinction can sit in any finite complex register, single posts are light-like under weak premises, and among coherent carriers only the complex one lets record counts multiply (Section 24.7). A history's comparison cost against its own frame is its proper-time deficit, so the least comparison cost is the greatest proper time and is attained exactly by inertial histories; counting shows that, over a split into two legs of fixed proportions, most posting orders have a first leg posting at nearly the rate of the whole (Section 24.8). The clock of Recognition Science has an exact resolution and a band in which it recognizes itself, and a change of a register's configuration has an action floor of sharp sine form (Section 24.9). We price the questions one can ask about an unending balance history: solvency forever, closing, waiting, alarms and deadlines (Section 24.10). Finally we climb from posting toward a clock, complex amplitudes and the square law, conserved charges and a space of cells, proving what posting forces and naming the premise at each step where it stops deciding (Section 24.11).

Three kinds of statement occur, and Table 24.1 sorts them. Statements about counts are statements about $\mathbb{N}$, $\mathbb{Z}$ and the golden integers $\mathbb{Z}[\varphi]$ of Definition 21.24, and we prove them by integer arithmetic. Those that the table marks free we claim with no omniscience principle and no choice principle. Those it marks *integer arithmetic* are proved in the same way, but

Table 24.1. Where the results of this chapter live.

Results	Objects	Logic
Reachability, interval, forms vanishing on the rays, common futures; twin identity in integers; Fibonacci counts and golden identities; Cassini and the kink identity; reach of separate accounts	$\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Z}[\varphi]$	free
Cone inequality, light rays, diamond count, the frame; forms reversed by a join; the kink bound; taxicab reach; record counts; binomial word counts	$\mathbb{N}$, $\mathbb{Z}$	integer arithmetic, claimed classically
J and velocity; proper time; limits of the recognition word; dilation; quadratic cones; Hermitian records and $\mathrm{SO}^{+}(1,3)$; carriers; comparison cost; counting bounds; clocks and the action floor	classical $\mathbb{R}$ and $\mathbb{C}$	classical
Prices of solvency, closing, waiting, alarms, revision, deadlines	binary sequences, balances in $\mathbb{Z}_{\delta}$	choice-free; each price named
Refutable and confirmable: solvency and closing; computable deadlines (Kleene's tree)	recorders, programs	classical
One-bit flip of a post; symmetries and symmetric charges of three accounts	$\{0,1\}^3$, $\mathbb{Z}^d$	free
Uniform item times, finest changes and joint ticks; conservation under writing rules and transfer laws; gluings, transport and linked traces	patterns, ledgers, $\mathbb{Z}^D$	classical
Tick registers, the square law, contextual reads	classical $\mathbb{R}^8$ and $\mathbb{C}$	classical

we claim them only in classical mathematics: the label says how they are proved, not what they cost, and we make no claim about their constructive strength. The scope note of each result says which of its parts are free. Statements about square roots, limits, real quadratic forms and complex matrices are proved in classical mathematics over the classical real and complex numbers, and each says so; we do not claim them on $\mathbb{R}_{\delta}$. The prices of Section 24.10, the equivalences of questions about balance histories, alarms and recorders with principles on binary sequences, are proved with no choice principle; the refutable and confirmable classification of solvency and closing, and the statements there about computable runs, are proved classically. Readings of counts as time, position or spacetime are identifications. We name each one where it enters, and no theorem assumes one unless its statement says so.

24.1 One account fills a light cone

We first fix the objects of the opening.

Definition 24.1 (Accounts, posts and cone coordinates)**.** A *side* is a debit d or a credit c. A *posting word* is a finite string w of sides; $D(w)$ and $C(w)$ are its numbers of debits and of credits, so that its length is $|w| = D(w) + C(w)$. The *record* of an account is a pair $s = (D, C)$ of natural numbers. Posting w to s gives $s \cdot w = (D + D(w),\ C + C(w))$, and a record s' is *reachable* from s when $s' = s \cdot w$ for some posting word w. The *cone coordinates* of s are the integers

$$t(s) = D + C, \qquad x(s) = D - C,$$

the number of posts since the empty record and the balance. The *proper time* of a posting word is the number $\tau(w) = 2\sqrt{D(w)\,C(w)}$. A *ledger of d accounts* gives each account k a debit count D_k and a credit count C_k; a post at account k on a side adds one to that count of account k and changes no other count.

So each account of a ledger carries its own record, posted by its own words. The name "proper time" is a name for a function of two counts. Reading it as the time shown by a clock carried along the history is an identification, and so is reading t and x as time and position; we keep both apart from what is proved.

Theorem 24.2 (The light cone of one account)**.** *Let $s = (D, C)$ and $s' = (D', C')$ be records of one account, and put $\Delta t = t(s') - t(s)$ and $\Delta x = x(s') - x(s)$.*

(a) s' is reachable from s if and only if $D \le D'$ and $C \le C'$.

(b) Equivalently, s' is reachable from s if and only if $|\Delta x| \le \Delta t$.

(c) For integers a and b: $a \ge 0$ and $b \ge 0$ if and only if $4ab \ge 0$ and $a + b \ge 0$; and $(a+b)^2 - (a-b)^2 = 4ab$. Hence the reachable displacements are exactly those with $\Delta t \ge 0$ and $\Delta t^2 - \Delta x^2 \ge 0$, and $\Delta t^2 - \Delta x^2 = 4(D' - D)(C' - C)$.

(d) A posting word w has $|D(w) - C(w)| = D(w) + C(w)$ if and only if all its letters are debits or all are credits.

(e) For integers α, β, γ, the form $q(a, b) = \alpha a^2 + \beta ab + \gamma b^2$ vanishes on both axes, $q(n, 0) = q(0, n) = 0$ for every integer n, if and only if $q(a, b) = \beta ab$ for all integers a, b.

(f) A record s is reachable from both $s_1 = (D_1, C_1)$ and $s_2 = (D_2, C_2)$ if and only if it is reachable from $(\max(D_1, D_2), \max(C_1, C_2))$.

(g) If s' is reachable from s, the records r with $s \le r \le s'$ in the componentwise order number exactly

$$\frac{\Delta t^2 - \Delta x^2}{4} + \Delta t + 1.$$

Conditions and scope.

Base and premises

Natural numbers and integers; posting as in Definition 24.1. Every clause is proved below by integer arithmetic; clauses (a), (c), (e) and (f) with no omniscience principle and no choice principle, while (b), (d) and (g) are claimed in classical mathematics.

Conclusion

Posting fills exactly the future cone $\{\Delta t \geq |\Delta x|\}$; its light rays are the one-sided words; up to a factor, $DC = (t^2 - x^2)/4$ is the only integer quadratic form vanishing on both rays; common futures are futures of the componentwise maximum; a causal diamond holds $(\tau/2)^2 + \Delta t + 1$ records, τ its proper time.

Identification

That t is elapsed time and x position on the account's worldline, counted from the empty record, is an identification; the theorem does not supply it. So is the reading that a comparison of two records is a record in the future of both, which by (f) places it in the future of their componentwise maximum.

Not claimed

Any relation between different accounts: each account has its own plane.

Proof. (a) If $s' = s \cdot w$, then $D' = D + D(w) \geq D$ and $C' = C + C(w) \geq C$. Conversely, if $D \leq D'$ and $C \leq C'$, the word of $D' - D$ debits followed by $C' - C$ credits takes s to s'.

(b) Put $a = D' - D$ and $b = C' - C$, so that $\Delta t = a + b$ and $\Delta x = a - b$. The inequality $|a - b| \leq a + b$ says $-(a + b) \leq a - b \leq a + b$, that is, $b \geq 0$ and $a \geq 0$. By (a) this is reachability.

(c) If $a, b \geq 0$, then $4ab \geq 0$ and $a + b \geq 0$. Conversely, let $4ab \geq 0$ and $a + b \geq 0$. If $a < 0$, then $b > 0$ would give $ab < 0$, and $b \leq 0$ would give $a + b < 0$; so $a \geq 0$, and likewise $b \geq 0$. The identity is expansion. With $a = D' - D$ and $b = C' - C$ it gives $\Delta t^2 - \Delta x^2 = 4ab$, and the first part with (a) gives the description of reachable displacements.

(d) Write $D = D(w)$ and $C = C(w)$, both at least 0. The equation $|D - C| = D + C$ says $D - C = D + C$ or $C - D = D + C$, that is, $C = 0$ or $D = 0$. A word has no credit exactly when all its letters are debits, and no debit exactly when all are credits.

(e) Evaluating at $(1, 0)$ gives $\alpha = 0$, and at $(0, 1)$ gives $\gamma = 0$; then $q(a, b) = \beta ab$. Conversely βab vanishes when $a = 0$ or $b = 0$.

(f) By (a), reachability from s_1 and from s_2 says $D_1 \leq D$, $D_2 \leq D$, $C_1 \leq C$ and $C_2 \leq C$, which is $\max(D_1, D_2) \leq D$ and $\max(C_1, C_2) \leq C$; by (a) again this is reachability from the maximum.

(g) The records between s and s' are the pairs (i, j) with $D \leq i \leq D'$ and $C \leq j \leq C'$. There are $(a + 1)(b + 1) = ab + (a + b) + 1$ of them, and $4ab = \Delta t^2 - \Delta x^2$ by (c). □

The interval is thus not chosen. Among integer quadratic forms in the displacement $(D' - D, C' - C)$, those that vanish on the two kinds of single post are the multiples of $(D' - D)(C' - C)$, a quarter of $\Delta t^2 - \Delta x^2$. The integer records also fix a frame: no rescaling of debit against credit maps the record order to itself.

Proposition 24.3 (Counts single out a frame)**.** *Let f be a bijection of $\mathbb{N}\times\mathbb{N}$ such that $p\le q$ if and only if $f(p)\le f(q)$, in the componentwise order. Then f is the identity or the exchange $(D,C)\mapsto(C,D)$.*

Proof. An order bijection keeps every notion defined from the order alone. The least element $(0,0)$ is kept. Call p a *ray point* when any two records below p are comparable. The ray points are exactly the records with $D=0$ or $C=0$: below $(a,0)$ lie only the records $(i,0)$, which are comparable, while below (a,b) with $a,b\ge 1$ lie $(1,0)$ and $(0,1)$, which are not. Say that q *covers* p when $p<q$ and nothing lies strictly between; q covers (a,b) exactly when $q=(a+1,b)$ or $q=(a,b+1)$. The two records covering $(0,0)$ are $(1,0)$ and $(0,1)$, and f permutes them. Composing with the exchange if necessary, we may assume $f(1,0)=(1,0)$, and then $f(0,1)=(0,1)$.

Suppose $f(a,0)=(a,0)$ with $a\ge 1$. Then $f(a+1,0)$ covers $(a,0)$ and is a ray point, so it is $(a+1,0)$ or $(a,1)$; the second is not a ray point because $a\ge 1$. By induction f fixes every $(a,0)$, and in the same way every $(0,b)$. Finally, for $a,b\ge 1$ the record (a,b) is the least upper bound of $(a-1,b)$ and $(a,b-1)$, and an order bijection keeps least upper bounds; by induction on $a+b$, $f(a,b)=(a,b)$. Every comparison used is a comparison of natural numbers. □

A Lorentz boost of the plane would stretch D by a factor k and shrink C by $1/k$. On integer records no such map with $k\neq 1$ preserves the order, so the counts carry a preferred frame: the one in which they are counts. Boosts act on ratios of counts, which is where J enters.

24.2 The cost of a ratio reads the motion

A record (D,C) with $D,C\ge 1$ has the ratio $r=D/C$ and the velocity $\beta=x/t=(D-C)/(D+C)$. The two are tied by the map

$$v(r)=\frac{r-1}{r+1},\qquad r>0,$$

for $v(D/C)=(D-C)/(D+C)$. Write $\gamma=(1-\beta^2)^{-1/2}$ for the Lorentz factor and $\tau=2\sqrt{DC}$ for the proper time of any word with these counts.

Theorem 24.4 (J reads velocity and the Lorentz factor)**.**

(a) For natural numbers $D,C\ge 1$,

$$J\Big(\frac{D}{C}\Big)=\frac{2(D-C)^2}{(D+C)^2-(D-C)^2}=\frac{2x^2}{t^2-x^2}=2\gamma^2\beta^2.$$

(b) For natural numbers $D,C\ge 1$,

$$J\Big(\sqrt{D/C}\Big)=\frac{D+C}{2\sqrt{DC}}-1=\frac{t}{\tau}-1=\gamma-1.$$

(c) For every real $r>0$: $|v(r)|<1$, $J(r)=2v(r)^2/(1-v(r)^2)$, and $J(r)\ge\frac14$ if and only if $|v(r)|\ge\frac13$.

(d) For all real $r_1, r_2 > 0$,

$$v(r_1 r_2) = \frac{v(r_1) + v(r_2)}{1 + v(r_1)v(r_2)}.$$

(e) For every posting word w with $t = D(w) + C(w) > 0$ and $x = D(w) - C(w)$, $\tau(w) = t\sqrt{1 - (x/t)^2}$.

Conditions and scope.

Base and premises

The classical real numbers, for the square roots and the real ratio r. Proved in classical mathematics.

Conclusion

The cost of a record's ratio is twice its squared proper velocity $\gamma\beta$; the cost of the square root of the ratio, the Doppler factor, is $\gamma - 1$; the threshold $J \geq \frac{1}{4}$ is the speed $|\beta| \geq \frac{1}{3}$, a ratio outside $(\frac{1}{2}, 2)$; velocities of multiplied ratios add relativistically; proper time is time dilated by $\sqrt{1 - \beta^2}$.

Identification

Velocity, Lorentz factor and Doppler factor are names for functions of the counts. Their physical reading rests on the reading of t and x as time and position.

Not claimed

That any ledger operation multiplies record ratios: (d) is a property of the map v. Nor any statement on $\mathbb{R}_\delta$.

Proof. For $a, b > 0$,

$$J\Big(\frac{a}{b}\Big) = \frac{a^2 + b^2}{2ab} - 1 = \frac{(a-b)^2}{2ab}.$$

(a) Take $a = D$ and $b = C$. Since $(D + C)^2 - (D - C)^2 = 4DC$, the middle expression equals $2(D - C)^2/(4DC) = (D - C)^2/(2DC) = J(D/C)$. Dividing numerator and denominator of $2x^2/(t^2 - x^2)$ by t^2 gives $2\beta^2/(1 - \beta^2) = 2\gamma^2\beta^2$.

(b) Take $a = \sqrt{D}$ and $b = \sqrt{C}$: $J(\sqrt{D}/\sqrt{C}) = (D + C)/(2\sqrt{DC}) - 1$. This is $t/\tau - 1$, and $t/\tau = t/\sqrt{t^2 - x^2} = (1 - \beta^2)^{-1/2} = \gamma$.

(c) For $r > 0$, $|r - 1| < r + 1$, so $|v(r)| < 1$. Next $1 - v(r)^2 = 4r/(r + 1)^2$, so $2v(r)^2/(1 - v(r)^2) = 2(r - 1)^2/(4r) = (r - 1)^2/(2r) = J(r)$. Since $1 - v^2 > 0$, $2v^2/(1 - v^2) \geq \frac{1}{4}$ says $8v^2 \geq 1 - v^2$, that is, $v^2 \geq \frac{1}{9}$.

(d) With $v_i = v(r_i)$,

$$v_1 + v_2 = \frac{2(r_1 r_2 - 1)}{(r_1 + 1)(r_2 + 1)}, \qquad 1 + v_1 v_2 = \frac{2(r_1 r_2 + 1)}{(r_1 + 1)(r_2 + 1)},$$

and the quotient is $(r_1 r_2 - 1)/(r_1 r_2 + 1) = v(r_1 r_2)$.

(e) $2\sqrt{DC} = \sqrt{(D + C)^2 - (D - C)^2} = \sqrt{t^2 - x^2} = t\sqrt{1 - (x/t)^2}$. □

In rapidities the theorem is a statement about the hyperbolic cosine. With $\eta = \frac{1}{2}\ln r$ one has $v(r) = \tanh\eta$, $J(r) = \cosh 2\eta - 1$ and $J(\sqrt{r}) = \cosh\eta - 1 = \gamma - 1$; multiplying ratios adds rapidities, which is (d). The Doppler factor $\sqrt{D/C}$ is Bondi's k [138], and the velocity addition law is that of special relativity [147]. Part (c) translates the threshold $J \geq \frac{1}{4}$ that Chapter 21 attaches to a certain change into a speed: a third of the speed of a single post.

24.3 Proper time is superadditive, and the deficit is J

A *history* of an account is a finite list of legs $w_1, \dots, w_n$, posting words posted one after another; the whole history is the word $w_1 w_2 \cdots w_n$, whose counts are the sums of the legs' counts. It is *inertial* when all legs post in the same proportion, $D(w_i)C(w_j) = D(w_j)C(w_i)$ for all i and j. The opening split the history *dcddcdcd* into the legs *dcdd* and *cdcd* and found the whole longer in proper time than its parts. That is general, and the deficit has an exact form.

Theorem 24.5 (The twin paradox is J). *Let w_1, w_2 be posting words with counts (D_1, C_1) and (D_2, C_2), and write $s_i = D_i C_i$ and $s = (D_1 + D_2)(C_1 + C_2)$.*

(a) In integers, $(s - s_1 - s_2)^2 - 4 s_1 s_2 = (D_1 C_2 - D_2 C_1)^2$, and $s_1 + s_2 \leq s$.

(b) $\tau(w_1) + \tau(w_2) \leq \tau(w_1 w_2)$, with equality if and only if $D_1 C_2 = D_2 C_1$.

(c) For every finite list of words $w_1, \dots, w_n$, $\sum_i \tau(w_i) \leq \tau(w_1 \cdots w_n)$, with equality if and only if $D(w_i)C(w_j) = D(w_j)C(w_i)$ for all i and j.

(d) If $D_1, C_1, D_2, C_2 \geq 1$ and $r_i = D_i/C_i$, then

$$\tau(w_1 w_2)^2 - \big(\tau(w_1) + \tau(w_2)\big)^2 = 2\,\tau(w_1)\,\tau(w_2)\,J\big(\sqrt{r_1/r_2}\big).$$

(e) A word of $2n$ posts has $\tau \leq 2n$, with equality if and only if it has n debits and n credits. In particular a window of eight posts has $\tau \leq 8$, with equality exactly for four debits and four credits.

Proposition 24.6 (The deficit of many legs). *Let $w_1, \dots, w_n$ be posting words with $D(w_i)$, $C(w_i) \geq 1$, and write $\tau_i = \tau(w_i)$ and $r_i = D(w_i)/C(w_i)$. Then*

$$\tau(w_1 \cdots w_n)^2 - \Big(\sum_i \tau_i\Big)^2 = \sum_{i<j} 2\,\tau_i\,\tau_j\,J\big(\sqrt{r_i/r_j}\big).$$

Conditions and scope.

Base and premises

Part (a) is an identity of integers, proved with no omniscience principle and no choice principle. Parts (b) to (e) and the proposition involve square roots and are proved in classical mathematics over the real numbers.

Conclusion

Proper time $2\sqrt{DC}$ is superadditive over legs; the inertial history has the greatest proper time for its end record and is the only history that attains it; the squared deficit of two legs is $2\tau_1\tau_2$ times the cost J of their relative Doppler factor, and the deficit of many legs is the sum of these pair costs.

Identification

That the physical proper time of a posting history is $2\sqrt{DC}$ is an identification, and so is the reading of one eight-tick cycle of Recognition Science as eight posts at one account; under the latter, (e) says a cycle has proper time at most 8, reached exactly by the balanced cycle.

Proof. For legs $i \neq j$ put $p_{ij} = D(w_i)C(w_j)$. The whole history has counts $\sum_i D(w_i)$ and $\sum_j C(w_j)$, so

$$\frac{1}{4}\tau(w_1 \cdots w_n)^2 = \sum_{i,j} D(w_i)C(w_j) = \sum_i s_i + \sum_{i<j}(p_{ij} + p_{ji}),$$

with $s_i = D(w_i)C(w_i)$. Also $\frac{1}{4}\tau_i^2 = s_i$ and $\frac{1}{4}\tau_i\tau_j = \sqrt{s_i s_j} = \sqrt{p_{ij}}\sqrt{p_{ji}}$. Hence

$$\tau(w_1 \cdots w_n)^2 - \Big(\sum_i \tau_i\Big)^2 = 4\sum_{i<j}\big(\sqrt{p_{ij}} - \sqrt{p_{ji}}\big)^2. \tag{24.1}$$

(a) For two legs, $s - s_1 - s_2 = p_{12} + p_{21}$ and $4s_1s_2 = 4p_{12}p_{21}$, so $(s-s_1-s_2)^2 - 4s_1s_2 = (p_{12}-p_{21})^2$, and $s = s_1 + s_2 + p_{12} + p_{21} \geq s_1 + s_2$. Only integer arithmetic is used.

(b) and (c). The right side of (24.1) is at least 0, so $(\sum_i \tau_i)^2 \leq \tau(w_1 \cdots w_n)^2$, and both sides are square roots of nonnegative numbers, so $\sum_i \tau_i \leq \tau(w_1 \cdots w_n)$. Equality holds exactly when every term $(\sqrt{p_{ij}} - \sqrt{p_{ji}})^2$ vanishes, that is, when $p_{ij} = p_{ji}$ for all $i < j$. Part (b) is the case $n = 2$.

(d) and the proposition. When all counts are at least 1, p_{ij} and p_{ji} are positive and $p_{ij}/p_{ji} = r_i/r_j$. By the formula for $J(a/b)$ in the proof of Theorem 24.4,

$$J\big(\sqrt{r_i/r_j}\big) = J\Big(\frac{\sqrt{p_{ij}}}{\sqrt{p_{ji}}}\Big) = \frac{(\sqrt{p_{ij}} - \sqrt{p_{ji}})^2}{2\sqrt{p_{ij}p_{ji}}},$$

and $2\tau_i\tau_j = 8\sqrt{p_{ij}p_{ji}}$. So each term of (24.1) is $2\tau_i\tau_j J(\sqrt{r_i/r_j})$. Part (d) is the case $n = 2$.

(e) If $D + C = 2n$, then $4DC = (D+C)^2 - (D-C)^2 \leq 4n^2$, with equality exactly when $D = C$; so $\tau = 2\sqrt{DC} \leq 2n$, with equality exactly when $D = C = n$. □

The theorem says that "no cost between the legs" and "inertial" are the same condition. A change of posting ratio between two legs costs $J(\sqrt{r_1/r_2})$, and that cost, times $2\tau_1\tau_2$, is exactly the squared proper time the history gives up. In special relativity the same statement is the reverse triangle inequality for timelike vectors [147]; here it is an identity among counts, and its integer core (a) holds with nothing beyond arithmetic.

24.4 The recognition worldline

The history of the opening was not chosen at random. It is the fourth recognition word.

Definition 24.7 (The recognition words)**.** Let σ be the substitution of posting words that replaces each debit by dc and each credit by d, so that $\sigma(uv) = \sigma(u)\sigma(v)$. The *recognition words* are $w_0 = d$ and $w_{k+1} = \sigma(w_k)$:

$$w_1 = dc, \quad w_2 = dcd, \quad w_3 = dcddc, \quad w_4 = dcddcdcd, \ \ldots$$

The Fibonacci numbers are $F(0) = 0$, $F(1) = 1$ and $F(k+2) = F(k+1) + F(k)$. In the golden integers $\mathbb{Z}[\varphi]$ of Definition 21.24, whose elements are $a + b\varphi$ with integers a, b and $\varphi^2 = \varphi + 1$, we write $\psi = 1 - \varphi$ and $N(a + b\varphi) = a^2 + ab - b^2$.

In Recognition Science the substitution is one recognition join acting on an account's posting history. On census coordinates a join sends (a, b) to $(b, a + b)$, which is multiplication by φ in $\mathbb{Z}[\varphi]$: $\varphi(a+b\varphi) = b+(a+b)\varphi$. The recognition words are the Fibonacci words of combinatorics on words.

Theorem 24.8 (The recognition worldline)**.**

(a) w_k *has* $F(k+1)$ *debits and* $F(k)$ *credits.*

(b) In $\mathbb{Z}[\varphi]$, $F(k+1) - \varphi F(k) = \psi^k$ *and* $F(k+2) = \varphi^2 F(k) + \psi^k$. *Hence* $s_k = D(w_k)C(w_k)$ *satisfies* $s_{k+1} = \varphi^2 s_k + F(k+1)\psi^k$.

(c) $\tau(w_{k+2})/\tau(w_{k+1}) \to \varphi$ *as* $k \to \infty$.

(d) The velocity $(D(w_k) - C(w_k))/(D(w_k) + C(w_k))$ *tends to* $\sqrt{5} - 2 = \varphi^{-3}$.

(e) $J(\varphi) = (\sqrt{5} - 2)/2 = \varphi^{-3}/2$, *and with* $\beta = \sqrt{5} - 2$, $J(\varphi) = 2\beta^2/(1 - \beta^2)$.

(f) For integers λ, μ, ν *let* $q(a, b) = \lambda a^2 + \mu ab + \nu b^2$. *Then* $q(b, a + b) = -q(a, b)$ *for all integers* a, b *if and only if* $\mu = \lambda$ *and* $\nu = -\lambda$, *that is,* $q = \lambda N$; *and* $q(b, a + b) = q(a, b)$ *for all* a, b *if and only if* $\lambda = \mu = \nu = 0$.

(g) For real $C > 0$ *and* D: $C^2 + CD - D^2 = 0$ *and* $D > 0$ *if and only if* $D = \varphi C$.

Conditions and scope.

Base and premises

Parts (a) and (b) are statements about natural numbers and $\mathbb{Z}[\varphi]$, proved with no omniscience principle and no choice principle; part (f) is a statement about integer forms, proved by integer arithmetic and claimed in classical mathematics. Parts (c), (d), (e) and (g) are proved in classical mathematics over the real numbers.

Conclusion

The recognition words post Fibonacci counts; their squared half proper time grows by exactly φ^2 up to the alternating correction $F(k+1)\psi^k$; each recognition dilates proper time by φ in the limit; the velocity tends to φ^{-3}, at which $J(\varphi)$ is twice the squared proper velocity; the norm of $\mathbb{Z}[\varphi]$ is, up to a factor, the only integer form a join reverses, no nonzero form is preserved by a join, and the norm's null ray is the ratio φ.

Identification

Reading the words as the worldline of a recognizing account carries the identifications of Section 24.1.

Proof. (a) If a word has counts (D, C), its image under σ has $D + C$ debits, one for each letter, and D credits, one for each debit. Starting from $(1, 0) = (F(1), F(0))$, the counts $(F(k+1), F(k))$ go to $(F(k+2), F(k+1))$.

(b) In $\mathbb{Z}[\varphi]$, $\varphi\psi = \varphi - \varphi^2 = -1$. For $k = 0$, $F(1) - \varphi F(0) = 1 = \psi^0$. If $F(k+1) - \varphi F(k) = \psi^k$, then

$$F(k+2) - \varphi F(k+1) = (1-\varphi)F(k+1) + F(k) = \psi F(k+1) - \varphi\psi F(k)$$
$$= \psi\big(F(k+1) - \varphi F(k)\big) = \psi^{k+1}.$$

Then $F(k+2) = F(k+1) + F(k) = (\varphi+1)F(k) + \psi^k = \varphi^2 F(k) + \psi^k$, and multiplying by $F(k+1)$ gives $s_{k+1} = F(k+2)F(k+1) = \varphi^2 s_k + F(k+1)\psi^k$. Each step is a computation with pairs of integers.

(c) and (d). Over the reals $F(k+1)/F(k) \to \varphi$ (Binet's formula, or (b) with $|\psi| < 1$). Then

$$\frac{\tau(w_{k+2})}{\tau(w_{k+1})} = \sqrt{\frac{F(k+3)}{F(k+2)} \cdot \frac{F(k+2)}{F(k+1)}} \to \varphi,$$

and with $\rho_k = F(k)/F(k+1) \to \varphi^{-1}$ the velocity is $(1-\rho_k)/(1+\rho_k) \to (1-\varphi^{-1})/(1+\varphi^{-1})$. Since $\varphi^{-1} = (\sqrt{5}-1)/2$, this is $(3-\sqrt{5})/(1+\sqrt{5}) = \sqrt{5}-2$, as $(\sqrt{5}-2)(1+\sqrt{5}) = 3-\sqrt{5}$. Finally $\varphi^3 = 2\varphi + 1 = 2 + \sqrt{5}$ and $(2+\sqrt{5})(\sqrt{5}-2) = 1$.

(e) $J(\varphi) = \frac{1}{2}(\varphi + \varphi^{-1}) - 1 = \frac{1}{2}\sqrt{5} - 1$. With $\beta = \sqrt{5}-2$, $\beta^2 = 9 - 4\sqrt{5}$ and $1 - \beta^2 = 4\sqrt{5} - 8 = 4\beta$, so $2\beta^2/(1-\beta^2) = \beta/2 = J(\varphi)$.

(f) Suppose $q(b, a+b) = -q(a, b)$ for all a, b. At $(a, b) = (1, 0)$ this reads $\nu = -\lambda$; at $(0, 1)$ it reads $\lambda + \mu + \nu = -\nu$, so $\mu = -\lambda - 2\nu = \lambda$. Conversely, $N(b, a+b) = b^2 + b(a+b) - (a+b)^2 = -(a^2 + ab - b^2)$. Suppose instead $q(b, a+b) = q(a, b)$ for all a, b. Then $(1, 0)$ gives $\nu = \lambda$, $(0, 1)$ gives $\lambda + \mu + \nu = \nu$, so $\mu = -\lambda$, and $(1, 1)$ gives $\lambda + 2\mu + 4\nu = \lambda + \mu + \nu$, so $\mu + 3\nu = 0$, whence $2\lambda = 0$ and all three vanish.

(g) $C^2 + CD - D^2 = -(D - \varphi C)(D - \psi C)$, and $\psi C < 0 < D$ excludes the second factor. □

In the worked history w_4 the velocity was already $1/4$; the limit is $\varphi^{-3} \approx 0.2361$. The words never become inertial, and they bend toward the line of velocity φ^{-3} by the least amount an integer history can bend.

Proposition 24.9 (Each recognition bends by the least integer kink)**.**

(a) (Cassini) $F(k+2)F(k) - F(k+1)^2 = (-1)^{k+1}$ *for every* k.

(b) $w_{k+2} = w_{k+1}w_k$, *and with* $s_k = D(w_k)C(w_k)$,

$$(s_{k+2} - s_{k+1} - s_k)^2 - 4s_{k+1}s_k = 1.$$

(c) *If posting words u, v have $D(u)C(v) \neq D(v)C(u)$, then $(D(u)C(v) - D(v)C(u))^2 \geq 1$.*

(d) *$\tau(w_{k+1}) + \tau(w_k) < \tau(w_{k+2})$ for every k.*

Parts (a) and (b) are proved with no omniscience principle and no choice principle; part (c) is proved by integer arithmetic and claimed in classical mathematics; part (d) uses real square roots and is proved classically.

Proof. (a) For $k = 0$, $F(2)F(0) - F(1)^2 = -1$. The step: $F(k+3)F(k+1) - F(k+2)^2 = (F(k+2)+F(k+1))F(k+1) - F(k+2)(F(k+1)+F(k)) = F(k+1)^2 - F(k+2)F(k)$, the negative of the previous value.

(b) $w_2 = dcd = w_1 w_0$, and if $w_{k+2} = w_{k+1}w_k$ then applying σ gives $w_{k+3} = w_{k+2}w_{k+1}$. By Theorem 24.5(a) with the legs w_{k+1} and w_k, the left side is the square of $D(w_{k+1})C(w_k) - D(w_k)C(w_{k+1}) = F(k+2)F(k) - F(k+1)^2$, which is ± 1 by (a).

(c) A nonzero integer has square at least 1.

(d) By Theorem 24.5(b), equality would force the cross term of (b) to vanish, and it is ± 1. □

By Theorem 24.5(a), the quantity in (b) is the squared cross term of the two legs, and by (c) no two legs of different ratio have a smaller one. So each recognition is the closest an integer history can come to an inertial step without being one.

Along the recognition worldline the velocity tends to $\beta = \varphi^{-3}$, and the dilation of proper time at that velocity has an exact golden form. The value is $2\varphi^{-3/2} = 2/\varphi^{3/2}$, about 0.9717.

Theorem 24.10 (The recognition dilation). *Let $\beta = \sqrt{5} - 2$ and $\gamma = (1 - \beta^2)^{-1/2}$.*

(a) *In $\mathbb{Z}[\varphi]$ the element $b = 2\varphi - 3$ satisfies $b\varphi^3 = 1$, $b^2 + 4b = 1$ and $1 + b = \varphi(1 - b)$; over the reals $b = \beta$.*

(b) *$\beta = \varphi^{-3}$; $1 - \beta^2 = 4\beta$; the time dilation is $\sqrt{1 - \beta^2} = 2\sqrt{\beta} = 2\varphi^{-3/2} \approx 0.97174$; and $\gamma = \varphi^{3/2}/2 \approx 1.02909$.*

(c) *The Doppler factor is $\sqrt{(1+\beta)/(1-\beta)} = \sqrt{\varphi}$, with rapidity $\frac{1}{2}\ln\varphi$ and $\cosh(\frac{1}{2}\ln\varphi) = \gamma$; $J(\sqrt{\varphi}) = \gamma - 1 \approx 0.02909$; and $1 - \beta^2 = 8J(\varphi)$.*

(d) *The proper time per post of the recognition words tends to the dilation:*

$$\tau(w_k)/(D(w_k) + C(w_k)) \to 2\sqrt{\beta}.$$

Conditions and scope.

Base and premises

Part (a) is a computation in $\mathbb{Z}[\varphi]$ with no omniscience principle and no choice principle. Parts (b) to (d) are proved in classical mathematics over the real numbers.

Conclusion

At the recognition velocity φ^{-3} the squared dilation is $4\varphi^{-3} = 8J(\varphi)$, the dilation is $2\varphi^{-3/2}$, and the Lorentz excess $\gamma - 1$ is the cost of the Doppler factor $\sqrt{\varphi}$.

Not claimed

Any physical link between this dilation and other quantities of Recognition Science: the theorem is a set of equalities between numbers.

Proof. (a) In $\mathbb{Z}[\varphi]$, $\varphi^2 = \varphi + 1$ and $\varphi^3 = 2\varphi + 1$. Then $(2\varphi - 3)(2\varphi + 1) = 4\varphi^2 - 4\varphi - 3 = 1$; $(2\varphi - 3)^2 + 4(2\varphi - 3) = (4\varphi^2 - 12\varphi + 9) + (8\varphi - 12) = 4(\varphi + 1) - 4\varphi - 3 = 1$; and $1 + b = 2\varphi - 2$, while $\varphi(1 - b) = 4\varphi - 2\varphi^2 = 2\varphi - 2$. Over the reals $2\varphi - 3 = \sqrt{5} - 2$.

(b) $\beta = \varphi^{-3}$ by (a). As in the proof of Theorem 24.8(e), $1 - \beta^2 = 4\beta$, so $\sqrt{1 - \beta^2} = 2\sqrt{\beta} = 2\varphi^{-3/2}$ and $\gamma = 1/(2\varphi^{-3/2}) = \varphi^{3/2}/2$. Numerically $\sqrt{\beta} = 0.48587$ and $\varphi^{3/2} = 2.05817$.

(c) By (a), $(1+\beta)/(1-\beta) = \varphi$. Next $\cosh(\frac{1}{2}\ln\varphi) = \frac{1}{2}(\sqrt{\varphi} + 1/\sqrt{\varphi})$, whose square is $\frac{1}{4}(\varphi + 2 + \varphi^{-1}) = \frac{1}{4}(2 + \sqrt{5}) = \varphi^3/4$; so it is $\varphi^{3/2}/2 = \gamma$, and $J(\sqrt{\varphi}) = \frac{1}{2}(\sqrt{\varphi} + 1/\sqrt{\varphi}) - 1 = \gamma - 1$. Finally $8J(\varphi) = 4(\sqrt{5} - 2) = 4\beta = 1 - \beta^2$ by Theorem 24.8(e).

(d) $\tau(w)/(D + C) = 2\sqrt{DC}/(D + C) = \sqrt{1 - v^2}$ with $v = (D - C)/(D + C)$, which tends to β by Theorem 24.8(d); the map $v \mapsto \sqrt{1 - v^2}$ is continuous. □

24.5 Many accounts reach only the taxicab cone

One account gives a light cone in one space dimension. The obvious way to get more space dimensions is to take more accounts: let the total number of posts be time and the balances of the accounts be the coordinates of position. This fails, and it fails for a reason that can be stated exactly.

Definition 24.11 (Ledgers of several accounts)**.** A ledger state of d accounts is a list $r = (r_1, \dots, r_d)$ of records $r_i = (D_i, C_i)$. A *single post* changes one account's record by posting one side to it; r' is *reachable* from r when finitely many single posts lead from r to r'. The *total post count* is $T(r) = \sum_i (D_i + C_i)$ and the *potentials* are $x_i = D_i - C_i$. The *taxicab cone*, or ℓ^1 cone, in $\mathbb{R}^{1+d}$ is $\{(t, x) : \sum_i |x_i| \le t\}$. A set $K \subseteq \mathbb{R}^{1+n}$ is a *quadratic cone* when $K = \{p : p_0 \ge 0 \text{ and } p^{\mathsf{T}} M p \ge 0\}$ for some real $(1 + n) \times (1 + n)$ matrix M.

Theorem 24.12 (Separate accounts give the taxicab cone)**.** *Let $d \ge 1$.*

(a) A ledger state r' is reachable from r if and only if every count of every account in r' is at least the corresponding count in r.

(b) From the empty ledger there is a reachable state with total post count T and potentials $x \in \mathbb{Z}^d$ if and only if $\sum_i |x_i| \le T$ and $T - \sum_i x_i$ is even.

(c) The state with total post count $2T$ and potentials $2x$ is reachable from the empty ledger if and only if $\sum_i |x_i| \le T$, that is, if and only if (T, x) lies in the taxicab cone.

(d) The taxicab cone in $\mathbb{R}^{1+d}$ is a quadratic cone if and only if $d \le 1$. (This part holds for $d = 0$ as well.)

Conditions and scope.

Base and premises

Part (a) is a statement about natural numbers, proved with no omniscience principle and no choice principle; parts (b) and (c) are statements about integers, proved by integer arithmetic and claimed in classical mathematics. Part (d) is about real quadratic forms and is proved in classical mathematics.

Conclusion

Posting d separate accounts one unit at a time reaches, after coarse graining by two, exactly the taxicab cone, and that cone is the future cone of a quadratic form only when $d \leq 1$.

Identification

Reading the total post count as time and the potentials as position. Under that reading, posting of separate accounts is Lorentzian only in one space dimension.

Not claimed

Other posting laws: steps of other sizes, links between accounts, or other ways of comparing accounts. For any finite set of steps the coarse-grained cone would be a polytope; we do not prove this.

Proof. (a) A single post raises one count, so counts never decrease along a sequence of posts. Conversely, if every count of r' is at least that of r, raise the counts one account at a time, one post at a time.

(b) For each account, $|x_i| \leq D_i + C_i$ and $D_i + C_i \equiv x_i \pmod 2$. Summing over the accounts gives $\sum_i |x_i| \leq T$ and $T \equiv \sum_i x_i$. Conversely, put $D_i = \max(x_i, 0)$ and $C_i = \max(-x_i, 0)$, so that $D_i + C_i = |x_i|$ and $D_i - C_i = x_i$. The remaining $T - \sum_i |x_i|$ posts number an even amount, since $|x_i| \equiv x_i \pmod 2$; post them to account 1 as debit–credit pairs, which leaves its potential unchanged. By (a) the result is reachable from the empty ledger.

(c) For the doubled point the parity condition holds automatically, and $\sum_i |2x_i| \leq 2T$ exactly when $\sum_i |x_i| \leq T$.

(d) For $d = 0$ the cone is $\{t \geq 0\}$, the cone of $M = 0$. For $d = 1$, $|x| \leq t$ holds exactly when $t \geq 0$ and $t^2 - x^2 \geq 0$.

Let $d \geq 2$, and suppose the taxicab cone equals $\{p_0 \geq 0,\ p^{\mathsf{T}} M p \geq 0\}$. Restricting to points whose coordinates after the first two space coordinates vanish, we obtain a real quadratic form $Q(t, a, b) = q_1 t^2 + q_2 a^2 + q_3 b^2 + q_4 ta + q_5 tb + q_6 ab$ with

$$|a| + |b| \leq t \iff \big(t \geq 0 \text{ and } Q(t, a, b) \geq 0\big) \qquad \text{for all real } t, a, b.$$

First a boundary lemma: if p lies in the cone and, for every $\varepsilon > 0$, $p + \varepsilon v$ lies outside it with nonnegative time coordinate, then $Q(p) = 0$. Indeed $Q(p + \varepsilon v) < 0$ for every $\varepsilon > 0$, and $Q(p + \varepsilon v) = Q(p) + \varepsilon L + \varepsilon^2 M'$ for numbers L, M', so letting $\varepsilon \to 0$ gives $Q(p) \leq 0$; and $Q(p) \geq 0$ because p is in the cone.

Apply the lemma at $p = (1, 1, 0)$ with $v = (0, 1, 0)$: $q_1 + q_2 + q_4 = 0$. At $p = (1, 0, 1)$ with $v = (0, 0, 1)$: $q_1 + q_3 + q_5 = 0$. At $p = (2, 1, 1)$ with $v = (0, 1, 0)$: $4q_1 + q_2 + q_3 + 2q_4 + 2q_5 + q_6 = 0$. Twice the first plus twice the second minus the third gives $q_2 + q_3 - q_6 = 0$, which says

$Q(0,1,-1)=0$. So the point $(0,1,-1)$ has $t\geq 0$ and $Q\geq 0$, yet $|1|+|-1|=2>0=t$: it is not in the cone. This contradiction proves the claim. □

The parity condition in (b) is the reason for coarse graining by two: a single account can reach $x=1$ only at odd times. The quadratic no-go in (d) does not depend on the parity at all. The taxicab cone is a pyramid with flat faces, and a quadratic form whose cone it were would have to vanish at three of its boundary points; that already forces the form to vanish at $(0,1,-1)$, outside the cone.

24.6 The record cone of one coherent binary distinction

The cone of one time and three space dimensions comes from a different place: from a single binary distinction whose two values are carried coherently. The ledger reappears as the diagonal of its record.

Definition 24.13 (Coherent records and coherent changes)**.** The Pauli matrices are

$$\sigma_1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0&-i\\i&0\end{pmatrix},\quad \sigma_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix}.$$

For $t\in\mathbb{R}$ and $x=(x_1,x_2,x_3)\in\mathbb{R}^3$ put

$$R(t,x)=\tfrac{1}{2}\big(t\,1+x_1\sigma_1+x_2\sigma_2+x_3\sigma_3\big)=\frac{1}{2}\begin{pmatrix}t+x_3&x_1-ix_2\\x_1+ix_2&t-x_3\end{pmatrix}.$$

The *coordinates* of a complex 2×2 matrix ρ are $t=\mathrm{Re}(\rho_{00}+\rho_{11})$, $x_1=2\,\mathrm{Re}\,\rho_{01}$, $x_2=-2\,\mathrm{Im}\,\rho_{01}$ and $x_3=\mathrm{Re}(\rho_{00}-\rho_{11})$. The Minkowski form is $Q(t,x)=t^2-|x|^2$ and the future cone is $K=\{(t,x)\,:\,t\geq 0,\ Q(t,x)\geq 0\}$. A *coherent record* is a Hermitian 2×2 complex matrix ρ with $v^\dagger\rho v\geq 0$ for every $v\in\mathbb{C}^2$. A *coherent change* is a map $\rho\mapsto A\rho A^\dagger$ with A a complex 2×2 matrix; its action on coordinates, $p\mapsto$ the coordinates of $AR(p)A^\dagger$, is a real linear map of $\mathbb{R}^4$, whose matrix we write Λ_A.

A coherent record is an unnormalized state of a two-level system, the smallest system that carries a binary distinction coherently. Its two diagonal entries are the weights of the two values; its off-diagonal entry is the coherence between them.

Theorem 24.14 (The record cone of a coherent binary distinction)**.** *For all real t and $x\in\mathbb{R}^3$:*

(a) $R(t,x)$ is Hermitian and has coordinates (t,x); every Hermitian 2×2 complex matrix is R of its coordinates. So coherent records have four real parameters, one plus three.

(b) $\det R(t,x)=(t^2-|x|^2)/4$.

(c) $R(t,x)$ is a coherent record if and only if $t\geq 0$ and $|x|^2\leq t^2$, that is, if and only if $(t,x)\in K$.

(d) $R(D+C,0,0,D-C)=\mathrm{diag}(D,C)$, with determinant DC: the records of one account are the diagonal slice, and the determinant restricts to the interval of Theorem 24.2.

(e) If $\det A=1$ and ρ is a coherent record, then $A\rho A^\dagger$ is a coherent record with the same determinant.

(f) For $k > 0$ the matrix $B_k = \operatorname{diag}(\sqrt{k}, 1/\sqrt{k})$ has determinant 1, and $B_k R(t,x) B_k^\dagger = R(t', x_1, x_2, x_3')$ with

$$t' = \tfrac{1}{2}\big(k(t+x_3) + (t-x_3)/k\big), \qquad x_3' = \tfrac{1}{2}\big(k(t+x_3) - (t-x_3)/k\big);$$

on the diagonal it sends (D, C) to $(kD, C/k)$.

(g) If A is unitary with $\det A = 1$, then $AR(t,x)A^\dagger$ has time coordinate t and spatial length $|x|$.

(h) All entries of $R(t,x)$ are real if and only if $x_2 = 0$.

Conditions and scope.

Base and premises

Complex 2×2 matrices over the classical real and complex numbers. Proved in classical mathematics.

Conclusion

The coherent records of one binary distinction form exactly the future light cone of one time and three space dimensions, with the determinant as a quarter of the interval; the ledger is the diagonal slice; the Doppler rescaling of one account, which is no symmetry of integer counts (Proposition 24.3), is a determinant-one change of records; unitary changes are rotations; real amplitudes leave one space dimension out.

Identification

That the record of an account is the diagonal of a coherent record, and that physical spacetime is this cone, are identifications. The theorem does not supply them.

Proof. (a) The formula is Hermitian because the Pauli matrices are, and reading the coordinates off it returns (t, x). If ρ is Hermitian, ρ_{00} and ρ_{11} are real and $\rho_{10} = \overline{\rho_{01}}$, so ρ is R of its coordinates.

(b) $\det R = \frac{1}{4}\big((t+x_3)(t-x_3) - (x_1 - ix_2)(x_1 + ix_2)\big) = \frac{1}{4}(t^2 - x_3^2 - x_1^2 - x_2^2)$.

(c) A Hermitian matrix $\begin{pmatrix} a & \bar{z} \\ z & b \end{pmatrix}$ has $v^\dagger \rho v = a|v_0|^2 + 2\,\mathrm{Re}(\bar{z}\bar{v}_0 v_1) + b|v_1|^2$. It is positive semidefinite exactly when $a \geq 0$, $b \geq 0$ and $|z|^2 \leq ab$. If these hold, $v^\dagger \rho v \geq a|v_0|^2 - 2\sqrt{ab}|v_0||v_1| + b|v_1|^2 = (\sqrt{a}|v_0| - \sqrt{b}|v_1|)^2 \geq 0$. Conversely, the basis vectors give $a, b \geq 0$; the vector $v = (-\bar{z}, a)$ gives $a(ab - |z|^2) \geq 0$, which settles $a > 0$; and if $a = 0$, the vectors $(-s\bar{z}, 1)$ give $b - 2s|z|^2 \geq 0$ for every $s > 0$, so $z = 0$. For $R(t,x)$, $a = (t + x_3)/2$, $b = (t - x_3)/2$ and $|z|^2 = (x_1^2 + x_2^2)/4$, so $ab - |z|^2 = (t^2 - |x|^2)/4$, and $a, b \geq 0$ says $t \geq |x_3|$. The three conditions together say $t \geq 0$ and $|x|^2 \leq t^2$.

(d) Substitute: $t + x_3 = 2D$ and $t - x_3 = 2C$.

(e) $A\rho A^\dagger$ is Hermitian, $v^\dagger A\rho A^\dagger v = (A^\dagger v)^\dagger \rho (A^\dagger v) \geq 0$, and $\det(A\rho A^\dagger) = |\det A|^2 \det \rho = \det \rho$.

(f) $\det B_k = 1$. Conjugation by B_k multiplies the upper diagonal entry by k, the lower by $1/k$, and the off-diagonal entries by $\sqrt{k} \cdot (1/\sqrt{k}) = 1$. Reading coordinates gives the formulas, and on the diagonal $D = (t + x_3)/2$ and $C = (t - x_3)/2$ go to kD and C/k.

(g) The time coordinate is the trace, and $\operatorname{tr}(ARA^\dagger) = \operatorname{tr}(RA^\dagger A) = \operatorname{tr} R$. By (b) and $\det(ARA^\dagger) = |\det A|^2 \det R$ the determinant is also kept, so $t^2 - |x'|^2 = t^2 - |x|^2$.

(h) The imaginary parts of the off-diagonal entries are $\mp x_2/2$. □

Which linear maps of $\mathbb{R}^4$ come from coherent changes of determinant one? Exactly the proper orthochronous Lorentz transformations: the maps of determinant 1 that keep the Minkowski form and the future cone. And an invertible linear map that merely keeps the future cone, in both directions, keeps the Minkowski form up to a positive factor.

Theorem 24.15 (The Lorentz group of a coherent binary distinction)**.**

(i) Let Λ be an invertible real 4×4 matrix with $p \in K$ if and only if $\Lambda p \in K$, for every p. Then there is a real $c > 0$ with $Q(\Lambda p) = cQ(p)$ for every p.

(ii) A real 4×4 matrix Λ satisfies $Q(\Lambda p) = Q(p)$ for all p, maps K into K, and has $\det\Lambda = 1$, if and only if $\Lambda = \Lambda_A$ for some complex 2×2 matrix A with $\det A = 1$.

Proof. (i) Since $p \in -K$ exactly when $-p \in K$, the map Λ also keeps $-K$, hence the double cone $K \cup (-K) = \{Q \geq 0\}$: $Q(p) \geq 0$ if and only if $Q(\Lambda p) \geq 0$. Next, Λ maps null vectors to null vectors. Let $Q(p) = 0$; then $Q(\Lambda p) \geq 0$. If $p = 0$ there is nothing to show. If $p = (t, x) \neq 0$, then $t \neq 0$, and $p_\varepsilon = ((1-\varepsilon)t, x)$ has $Q(p_\varepsilon) < 0$ for $0 < \varepsilon < 1$, hence $Q(\Lambda p_\varepsilon) < 0$; letting $\varepsilon \to 0$ gives $Q(\Lambda p) \leq 0$. So $Q(\Lambda p) = 0$.

Write $Q(\Lambda p) = \sum_{j,k} N_{jk} p_j p_k$ with N symmetric. The null vectors $(1, \pm e_i)$ give $N_{00} \pm 2N_{0i} + N_{ii} = 0$, so $N_{0i} = 0$ and $N_{ii} = -N_{00}$. For $i \neq j$ the null vector $(5, 3e_i + 4e_j)$, null because $25 = 9+16$, gives $25N_{00} + 9N_{ii} + 16N_{jj} + 24N_{ij} = 24N_{ij} = 0$. Hence $Q(\Lambda p) = N_{00} Q(p)$. Finally $N_{00} = Q(\Lambda e_0) \geq 0$ because $e_0 \in K$, and $N_{00} \neq 0$ because Λ is onto: some p has $\Lambda p = e_0$, and then $N_{00} Q(p) = 1$.

(ii) First let $\det A = 1$. Since $\det(A\rho A^\dagger) = |\det A|^2 \det\rho$ for every ρ (proof of Theorem 24.14(e)), part (b) shows that Λ_A keeps $Q = 4\det$, and (c) with (e) shows that it maps K into K. Keeping Q means $\Lambda_A^{\mathsf{T}} \eta \Lambda_A = \eta$ for $\eta = \operatorname{diag}(1,-1,-1,-1)$, so $\det\Lambda_A = \pm 1$. To see the sign, note that $A \mapsto \Lambda_A$ is multiplicative, $\Lambda_{AB} = \Lambda_A \Lambda_B$, and that $\Lambda_A = \Lambda_{-A}$. Replacing A by $-A$ if necessary we may assume $\operatorname{tr} A \neq -2$. Choose a complex s with $s^2 = \operatorname{tr} A + 2$ and put $B = (A+1)/s$. By the Cayley–Hamilton theorem $A^2 = (\operatorname{tr} A)A - 1$, so

$$B^2 = \frac{A^2 + 2A + 1}{\operatorname{tr} A + 2} = \frac{(\operatorname{tr} A)A - 1 + 2A + 1}{\operatorname{tr} A + 2} = A.$$

Hence $\det\Lambda_A = (\det\Lambda_B)^2 \geq 0$, and so $\det\Lambda_A = 1$.

Conversely, let Λ keep Q and K and have determinant 1, and put $u = \Lambda e_0$. Then $Q(u) = 1$ and $u \in K$, so $u_0 \geq 1$. The matrix $P = 2R(u)$ is Hermitian with $\det P = Q(u) = 1$ and $\operatorname{tr} P = 2u_0$, so $P^2 = 2u_0 P - 1$. Put $B = (P+1)/\sqrt{2u_0 + 2}$. Then $B^2 = (P^2 + 2P + 1)/(2u_0 + 2) = P$, and $\det B = (\det P + \operatorname{tr} P + 1)/(2u_0 + 2) = 1$, using $\det(P+1) = \det P + \operatorname{tr} P + 1$ for 2×2 matrices. Since B is Hermitian, $BR(e_0)B^\dagger = \frac{1}{2}B^2 = \frac{1}{2}P = R(u)$: the change B carries e_0 to u. The matrix $\Lambda' = \Lambda_{B^{-1}}\Lambda$ keeps Q, fixes e_0 and has determinant 1 by the first part. Keeping the bilinear form of Q and fixing e_0, it keeps the time coordinate and maps the space $\{t = 0\}$ to itself, where $Q = -|x|^2$; so $\Lambda' = \operatorname{diag}(1, S)$ with S a real orthogonal 3×3 matrix of determinant 1.

Such an S is a rotation about an axis. Indeed $\det(S-1)=\det(S-SS^{\mathsf T})=\det S\det(1-S^{\mathsf T})=\det(1-S)=-\det(S-1)$, so S fixes a unit vector n; it maps the plane orthogonal to n to itself with determinant 1, so it turns that plane by an angle θ, and

$$Sx=\cos\theta\,x+(1-\cos\theta)(n\cdot x)\,n+\sin\theta\,(n\times x)$$

for a suitable orientation of n (Rodrigues' formula). Put $U=\cos\frac{\theta}{2}\,1-i\sin\frac{\theta}{2}\,(n\cdot\sigma)$, which is unitary with $\det U=1$. The Pauli identity $(a\cdot\sigma)(b\cdot\sigma)=(a\cdot b)\,1+i(a\times b)\cdot\sigma$ gives $(n\cdot\sigma)(x\cdot\sigma)-(x\cdot\sigma)(n\cdot\sigma)=2i(n\times x)\cdot\sigma$ and $(n\cdot\sigma)(x\cdot\sigma)(n\cdot\sigma)=2(n\cdot x)(n\cdot\sigma)-x\cdot\sigma$, and expanding,

$$U(x\cdot\sigma)U^{\dagger}=\big(\cos\theta\,x+(1-\cos\theta)(n\cdot x)n+\sin\theta\,n\times x\big)\cdot\sigma=(Sx)\cdot\sigma.$$

With $UU^{\dagger}=1$ this says $\Lambda_U=\operatorname{diag}(1,S)=\Lambda'$. Hence $\Lambda=\Lambda_B\Lambda_U=\Lambda_{BU}$ with $\det(BU)=1$. □

Part (i) is a linear form of Zeeman's theorem that causality implies the Lorentz group [150], and part (ii) is the classical spinor description of $\mathrm{SO}^{+}(1,3)$ by $\mathrm{SL}(2,\mathbb{C})$ [145]; A and $-A$ give the same change. The proof needs no angles beyond the rotation angle of S, and it shows how the boost part arises: as the positive square root of the record $2R(u)$.

Why two values carried by complex amplitudes, and not by real ones or by quaternions? Count the real parameters of a record of a distinction with n values. The n diagonal weights are real; each of the $n(n-1)/2$ coherences between two values has k real components, where $k=0$ for a classical carrier, 1 for real amplitudes, 2 for complex, 4 for quaternionic and 8 for octonionic ones.

Definition 24.16 (Record counts)**.** For natural numbers k and n put $P_k(n)=n+k\,n(n-1)/2$. Record counts *multiply* for k when $P_k(nm)=P_k(n)P_k(m)$ for all n and m.

Multiplication of record counts says that a record of a composite of two systems is fixed by the parameters of the parts and their products, the condition known as local tomography [142, 149].

Theorem 24.17 (Record counts multiply only for two carriers)**.** *Record counts multiply for k if and only if $k=0$ or $k=2$. In particular, among $k\in\{1,2,4,8\}$ only $k=2$ multiplies. If $k>0$ and record counts multiply for k, a binary distinction has $P_k(2)=4=1+3$ real parameters; the classical carrier has $P_0(2)=2=1+1$.*

Proof. $P_k(2)=2+k$ and $P_k(4)=4+6k$, so multiplication at $n=m=2$ requires $(2+k)^2=4+6k$, that is, $k^2=2k$, that is, $k\in\{0,2\}$. Conversely $P_0(n)=n$ and $P_2(n)=n+n(n-1)=n^2$ are multiplicative. The rest is arithmetic. Everything is a computation with natural numbers. □

Conditions and scope.

Base and premises

Theorem 24.15 is proved in classical mathematics over the real and complex numbers; Theorem 24.17 is proved by natural-number arithmetic.

Conclusion

The coherent changes of determinant one of one binary distinction act on its record cone as exactly $\mathrm{SO}^+(1,3)$ (A and $-A$ giving the same map), and an invertible linear map that keeps the record cone in both directions keeps the Minkowski form up to a positive factor. Among carriers of a binary distinction, the classical one gives $1+1$ parameters and the only coherent one whose record counts multiply gives $1+3$.

Identification

That the physical carrier's records multiply, that the carrier is coherent ($k>0$), and that physical spacetime is the record cone, are identifications. The whole causal order of postings is not a record-cone order in any chart (Theorem 24.84), so the last identification is not one of the posting order itself. "Three is selected" means exactly what the theorem says: $k \in \{0,2\}$ are the only multiplicative carriers, and $k=2$ gives $1+3$.

Not claimed

That the dimension of the record cone equals the parameter count for carriers other than the complex one; the cone is computed above for $k=2$ only.

This route to three space dimensions is independent of the linking route of Chapter 23. The two agree in the number: the space of the complex record cone has dimension $P_2(2)-1=3$, the dimension in which that chapter finds linking. The agreement is a match of numbers, not an identification of the two spaces.

24.7 Where the distinction is carried

Recognition Science's least costly change of a ledger is a single post, and the binary datum of a post is its side. This section asks where that datum can be held so that its records form the cone of Section 24.6, and how much of the cone a post of definite side actually uses.

Definition 24.18 (Registers, compressions and run records)**.** A *register* is a finite set $\mathscr{R}$ of basis states; its states are complex matrices indexed by $\mathscr{R}\times\mathscr{R}$. For two distinct basis states $e(0), e(1)$, the *compression* of a matrix ρ on $\mathscr{R}$ is the 2×2 matrix $(\rho_{e(i)e(j)})_{i,j\in\{0,1\}}$. For $v\in\mathbb{C}^2$ the *pure record* of v is $vv^\dagger$. The *side vector* of a debit is $(1,0)$ and of a credit $(0,1)$, and the *run record* of a posting word is the sum, over its posts, of the pure records of their side vectors. A change $L\to L'$ of a ledger of d accounts is *monotone* when no count decreases, and Recognition Science charges it the *step cost*

$$\sum_k G(D'_k-D_k)+\sum_k G(C'_k-C_k), \qquad G(u)=\cosh u-1,$$

the logarithmic form of J (Chapter 21) applied to each change of count.

Theorem 24.19 (The carrier of the record cone)**.**

(a) Let $d \geq 1$. If a monotone change $L \to L' \neq L$ has step cost at most that of every monotone change $L \to L'' \neq L$, then L' arises from L by a single post at one account. The debit post and the credit post at one account give different ledgers.

(b) For every register and distinct basis states $e(0), e(1)$, the compression of every positive semidefinite matrix is a coherent record, and every coherent record is the compression of a positive semidefinite matrix.

(c) For $v \in \mathbb{C}^2$, $vv^\dagger$ is a coherent record whose coordinates are null, $Q = 0$, with time coordinate $|v_0|^2 + |v_1|^2$. Conversely, every coherent record of determinant 0 is $vv^\dagger$ for some v.

(d) Every coherent record is $vv^\dagger + ww^\dagger$ for some $v, w \in \mathbb{C}^2$.

(e) The pure record of a debit has coordinates $(1, 0, 0, 1)$ and that of a credit $(1, 0, 0, -1)$. The run record of a word w is $\mathrm{diag}(D(w), C(w))$; its coordinates have $x_1 = x_2 = 0$.

(f) The Hermitian $n \times n$ complex matrices form a real vector space of dimension $n^2 = P_2(n)$, and $(nm)^2 = n^2 m^2$. The real symmetric $n \times n$ matrices form one of dimension $n(n+1)/2 = P_1(n)$, and $P_1(4) = 10 \neq 9 = P_1(2)^2$.

Conditions and scope.

Base and premises

The classical real and complex numbers. Proved in classical mathematics.

Conclusion

A post's side, held on two basis states of any finite complex register, has exactly the record cone of Theorem 24.14; its pure records are exactly the null records, every record is the sum of two of them, and classical posts are the two null rays of the account's plane. Complex record counts multiply and real ones do not.

Identification

That a physical run's record is its run record, with the two sides stored on two basis states, and that a post can carry a coherent amplitude, which is needed for the directions x_1 and x_2, are identifications. Recognition Science's native register is complex by definition; the theorem counts its records and does not derive that it is complex.

Proof. (a) For an integer change $u \geq 0$, $G(0) = 0$, $G(1) > 0$, and $G(u) > G(1)$ for $u \geq 2$, since cosh increases on $[0, \infty)$. A monotone change $L \to L'' \neq L$ raises some count, so its step cost is at least $G(1)$, and a single post at any account costs exactly $G(1)$. So the least change L' costs at most $G(1)$. If it raised two counts, or one count by two or more, it would cost more. Hence it raises exactly one count by exactly one. A debit post raises a debit count and a credit post does not.

(b) Let ρ be positive semidefinite on $\mathscr{R}$. For $v \in \mathbb{C}^2$ let $\tilde{v}$ be the vector on $\mathscr{R}$ with $\tilde{v}_{e(i)} = v_i$ and zeros elsewhere; then $v^\dagger(\text{compression})v = \tilde{v}^\dagger \rho \tilde{v} \geq 0$, and the compression is Hermitian. Conversely a coherent record M is the compression of the matrix equal to M on the block $\{e(0), e(1)\}$ and zero elsewhere, which is positive semidefinite.

(c) $vv^\dagger$ is Hermitian with $u^\dagger vv^\dagger u = |v^\dagger u|^2 \geq 0$, its determinant is $|v_0|^2|v_1|^2 - |v_0 v_1|^2 = 0$, so $Q = 4\det = 0$, and its trace is $|v_0|^2 + |v_1|^2$. Conversely let $M = \begin{pmatrix} a & \bar{z} \\ z & b \end{pmatrix}$ be a coherent record with $ab = |z|^2$. If $a > 0$, take $v = (\sqrt{a}, z/\sqrt{a})$; then $vv^\dagger$ has entries a, $\bar{z}$, z and $|z|^2/a = b$. If $a = 0$, then $|z|^2 \leq ab = 0$, and $v = (0, \sqrt{b})$ serves.

(d) In the notation of (c), $|z|^2 \leq ab$. If $a = 0$, then $z = 0$ and $M = ww^\dagger$ with $w = (0, \sqrt{b})$ and $v = 0$. If $a > 0$, take $v = (\sqrt{a}, z/\sqrt{a})$ and $w = (0, \sqrt{b - |z|^2/a})$.

(e) $\mathrm{diag}(1,0) = R(1,0,0,1)$ and $\mathrm{diag}(0,1) = R(1,0,0,-1)$; summing over the posts gives $\mathrm{diag}(D, C)$, whose off-diagonal entries vanish.

(f) A Hermitian matrix is fixed by its n real diagonal entries and its $n(n-1)/2$ complex entries above the diagonal, $n + n(n-1) = n^2$ real numbers; a real symmetric one by $n + n(n-1)/2$ real numbers. The rest is arithmetic. □

Part (c) is the flagpole picture of a null vector as a spinor, and (d) is Penrose's zig-zag: a timelike record is two null ones [145]. Classical runs stay in the plane $x_1 = x_2 = 0$, the plane of Section 24.1. Two questions remain: why the two sides should be stored on two basis states, and whether a post can point anywhere else in the cone. The first can be answered from weaker premises, in two ways.

Theorem 24.20 (An exact debit readout makes every post light-like)**.** *Let ρ assign to every posting word w a complex 2×2 matrix $\rho(w)$, with ρ of the empty word 0, $\rho(ww') = \rho(w) + \rho(w')$, and each single post's matrix $\rho(d)$, $\rho(c)$ a coherent record of trace 1.*

(a) Suppose some E with E and $1 - E$ coherent records reads the debit count exactly: $\mathrm{tr}(E\rho(w)) = D(w)$ *for every w. Then there is a unit vector $a \in \mathbb{R}^3$ with*

$$\rho(w) = R\big(D(w) + C(w),\ (D(w) - C(w))\, a\big) \qquad \text{for every } w.$$

In particular every single post's record is null with time coordinate 1.

(b) Suppose instead that $\rho(w)_{00} = D(w)$ for every w. Then $\rho(w)$ is the run record $\mathrm{diag}(D(w), C(w))$ *for every w.*

Proof. Additivity gives $\rho(w) = D(w)P_d + C(w)P_c$ with $P_d = \rho(d)$ and $P_c = \rho(c)$. Both are Hermitian of trace 1, so $P_d = R(1, a)$ and $P_c = R(1, b)$ with $|a|, |b| \leq 1$ by Theorem 24.14(c).

(a) Write $E = R(e_0, \varepsilon)$. Since $\mathrm{tr}\,\sigma_i = 0$ and $\mathrm{tr}(\sigma_i\sigma_j) = 2\delta_{ij}$, one has $\mathrm{tr}(R(t,x)R(s,y)) = \frac{1}{2}(ts + x\cdot y)$. Exact readout of one debit and of one credit gives $e_0 + \varepsilon\cdot a = 2$ and $e_0 + \varepsilon\cdot b = 0$. Positivity of E and $1 - E = R(2 - e_0, -\varepsilon)$ gives $|\varepsilon| \leq e_0$ and $|\varepsilon| \leq 2 - e_0$. By the Cauchy–Schwarz inequality,

$$2 - e_0 = \varepsilon\cdot a \leq |\varepsilon| \leq e_0, \qquad e_0 = -\varepsilon\cdot b \leq |\varepsilon| \leq 2 - e_0.$$

So $e_0 = 1$ and $|\varepsilon| = 1$, and both chains are equalities: $\varepsilon\cdot a = 1 = |\varepsilon||a|$ with $|a| \leq 1$ forces $a = \varepsilon$, and likewise $b = -\varepsilon$. Hence $\rho(w) = D\,R(1,a) + C\,R(1,-a) = R(D + C, (D - C)a)$, and a single post has $Q = 1 - |a|^2 = 0$.

(b) The upper diagonal entries give $(1 + a_3)/2 = 1$ and $(1 + b_3)/2 = 0$. With $|a|, |b| \leq 1$ this forces $a = (0,0,1)$ and $b = (0,0,-1)$, so $P_d = \mathrm{diag}(1,0)$, $P_c = \mathrm{diag}(0,1)$ and $\rho(w) = \mathrm{diag}(D, C)$. □

The second way starts from how a ledger is written into a register. Fix a bound $N \geq 1$, and let a *ledger code* be a ledger of d accounts with every count in $\{0, \dots, N\}$. A post at account k on a side raises that count by one modulo $N+1$. In the *census encoding*, a register with a reference part $\mathscr{R}_0$ and a code part whose basis states are the codes holds, after the ledger with code y, the state $\rho_y \otimes |y\rangle\langle y|$ with $\operatorname{tr} \rho_y = 1$. The *side record* of a post at account k from code y is the state after the post, with the reference traced out, compressed to the two possible outcome codes: first the code after a debit post, then the code after a credit post.

Proposition 24.21 (Census encoding stores the side on two basis states)**.** *In the census encoding:*

(a) if the posted count is less than N, the side record of a post is $\operatorname{diag}(1,0)$ *for a debit and* $\operatorname{diag}(0,1)$ *for a credit, so it lies on the axis* $x_1 = x_2 = 0$*;*

(b) the two outcome codes of a post are distinct basis states;

(c) for a posting word w *with* $D(w), C(w) \leq N$*, posted at one account from the empty code, the side records of its posts add up to the run record* $\operatorname{diag}(D(w), C(w))$*.*

Proof. (b) A debit post changes the debit count of account k and a credit post does not; since $N \geq 1$, raising a count by one modulo $N+1$ changes it. (a) After the post the state is $\rho_{y'} \otimes |y'\rangle\langle y'|$, where y' is the outcome code of the posted side. Tracing out the reference leaves $(\operatorname{tr} \rho_{y'})|y'\rangle\langle y'| = |y'\rangle\langle y'|$, and its compression to the two outcome codes, which are distinct by (b), has a single entry 1, in the place of the posted side. (c) Along the word no count exceeds N, so each post has a posted count below N, and (a) applies post by post; the sum of the side records is the run record. □

So the storage of sides on two basis states follows either from an exact readout of the debit count or from the census encoding of the ledger. Both routes also show the limit of posting. A post of definite side lands on the axis of the account's plane. A coherent post, one whose side record is a pure record off that axis, would be a superposition of two posted ledgers, and posting does not produce one. Such posts can be prepared, however, in any register.

Theorem 24.22 (Coherent posts can be prepared)**.**

(a) In every register with distinct basis states $e(0), e(1)$*, for every unit vector* $v \in \mathbb{C}^2$ *there is a unitary* U *of the register such that the compression of* $U|e(0)\rangle\langle e(0)|U^\dagger$ *is* $vv^\dagger$*.*

(b) For every unit $v \in \mathbb{C}^2$ *some unitary* A *with* $\det A = 1$ *has* $A \operatorname{diag}(1,0) A^\dagger = vv^\dagger$*; and for every nonzero coherent record* M *of determinant* 0 *some* A *with* $\det A = 1$ *has* $A \operatorname{diag}(1,0) A^\dagger = M$*.*

(c) A change A *keeps the debit post on the axis, that is, the coordinates* x_1, x_2 *of* $A \operatorname{diag}(1,0) A^\dagger$ *vanish, if and only if* $A_{00} = 0$ *or* $A_{10} = 0$*.*

(d) Every set of possible post records that contains the debit post $\operatorname{diag}(1,0)$ *and is closed under* $\rho \mapsto A \rho A^\dagger$ *for unitary* A *with* $\det A = 1$ *contains every pure record of trace* 1*.*

Conditions and scope.

Base and premises

Theorems 24.20 and 24.22 and Proposition 24.21 are proved in classical mathematics over the complex numbers. The readout route assumes additive records, coherent posts of trace 1 and an exact debit readout; the encoding route assumes the census encoding and stays within the count bound.

Conclusion

The storage of a post's side on two basis states follows from either set of premises. Single posts are light-like: classical posts are the two null rays, and under an exact readout every single post is null, along whatever axis. Every pure record of a side superposition can be prepared by a unitary of any register, and invariance of the possible post records under rotations would force all of them.

Identification

The directions x_1, x_2 of the record cone still rest on a premise that is not derived: either that nature prepares posts in side superpositions, or that the set of possible post records is invariant under rotations of the frame. Neither follows from posting; by (d) the second, with the debit post, makes every side superposition a possible post record.

Proof. (a) Let $u = \begin{pmatrix} v_0 & -\bar{v}_1 \\ v_1 & \bar{v}_0 \end{pmatrix}$, a unitary of determinant $|v_0|^2 + |v_1|^2 = 1$ with first column v. Let V embed $\mathbb{C}^2$ into the register along e, so $V^\dagger V = 1$, and put $U = 1 + V(u-1)V^\dagger$. Then $U^\dagger U = 1 + V\big((u-1) + (u^\dagger - 1) + (u^\dagger - 1)(u-1)\big)V^\dagger = 1 + V(u^\dagger u - 1)V^\dagger = 1$, and $V^\dagger U V = u$. The compression of $U|e(0)\rangle\langle e(0)|U^\dagger$ is $(V^\dagger U V|0\rangle)(V^\dagger U V|0\rangle)^\dagger = (u|0\rangle)(u|0\rangle)^\dagger = vv^\dagger$.

(b) The matrix u of (a) has $u\,\mathrm{diag}(1,0)u^\dagger = vv^\dagger$. For a nonzero null record, $M = vv^\dagger$ with $v \neq 0$ by Theorem 24.19(c); take $A = u\,\mathrm{diag}(|v|, 1/|v|)$ with u built from $v/|v|$.

(c) $A\,\mathrm{diag}(1,0)A^\dagger = cc^\dagger$ with $c = (A_{00}, A_{10})$, whose off-diagonal entry is $A_{00}\overline{A_{10}}$; it vanishes exactly when one factor does.

(d) Apply the unitaries u of (a) to the debit post. □

24.8 Least comparison cost is greatest proper time

Section 24.3 found that the inertial history has the greatest proper time for its end record. Does a least-cost principle select it? It depends on which cost. Charged leg by leg, Recognition Science's step cost prefers the opposite: its cheapest histories have no proper time at all. Charged against the frame of the whole history, the comparison cost is exactly the proper-time deficit, and its least value selects exactly the inertial histories.

Definition 24.23 (Step cost and comparison cost of a history)**.** Let $(w_1, \dots, w_n)$ be a history with whole word $W = w_1 \cdots w_n$. Its *step cost* charges each leg as one step of a single account, $\sum_i \big(G(D(w_i)) + G(C(w_i))\big)$, with $G(u) = \cosh u - 1$ as in Definition 24.18. When $D(W), C(W) \geq 1$, the *comparison cost* of a leg w against W is

$$c_W(w) = \frac{\left(\sqrt{D(w)C(W)} - \sqrt{C(w)D(W)}\right)^2}{\sqrt{D(W)C(W)}},$$

and the comparison cost of the history is $\sum_i c_W(w_i)$.

Theorem 24.24 (The step cost is not proper time)**.**

(a) On a ledger of one account, the step cost of a change is $G(D' - D) + G(C' - C)$. On a ledger of any number of accounts, a run of n single posts at one account, each charged as one step, costs $nG(1)$ whatever the order of its sides.

(b) For natural numbers with $a + b = a' + b'$: $G(a) + G(b) \le G(a') + G(b')$ if and only if $a'b' \le ab$.

(c) For every history, splitting it into single posts never raises its step cost, and the split has total proper time 0.

(d) The statement "between histories with the same end record, the lower step cost belongs to the greater total proper time" is false. For every word W with $D(W), C(W) \ge 1$, the split of W into single posts has the least step cost among all histories with the end record of W, and total proper time 0, while $\tau(W) > 0$.

Proof. (a) The first statement is the definition of the step cost for one account. A single post changes one count by 1 and the other by 0, and $G(0) = 0$, so each post costs $G(1)$.

(b) $\cosh a + \cosh b = 2\cosh\frac{a+b}{2}\cosh\frac{a-b}{2}$. With $a + b$ fixed this increases with $|a - b|$, and $(a - b)^2 = (a + b)^2 - 4ab$ decreases as ab increases.

(c) G is superadditive on $[0, \infty)$: $G(a) + G(b) \le G(a + b)$ is $\cosh a + \cosh b - 1 \le \cosh a \cosh b + \sinh a \sinh b$, that is, $0 \le (\cosh a - 1)(\cosh b - 1) + \sinh a \sinh b$, true for $a, b \ge 0$. By induction $mG(1) \le G(m)$, so a leg with counts (D, C) costs at least $(D + C)G(1)$, the cost of its $D + C$ single posts. A single post is one-sided, so its proper time is 0.

(d) By (c), every history with the end record of W costs at least $(D(W) + C(W))G(1)$, which is the cost of the split of W into single posts; that split has total proper time $0 < 2\sqrt{D(W)C(W)}$. A concrete instance: the legs dd and dc cost $G(2) + 2G(1) \approx 3.848$ and have total proper time $0 + 2 = 2$, while the single leg $dddc$ costs $G(3) + G(1) \approx 9.611$ and has proper time $2\sqrt{3} \approx 3.464$. The cheaper history has the smaller proper time. □

The step cost prefers the null zigzag: a history that never posts both sides in one step. Proper time measures the opposite, how much the two sides are mixed. The comparison cost repairs this by charging each leg against the frame of the whole.

Theorem 24.25 (The comparison cost is the proper-time deficit)**.** *Let $(w_1, \dots, w_n)$ be a history whose whole word W has $D(W), C(W) \ge 1$.*

(a) $\tau(W) - \sum_i \tau(w_i) = \sum_i c_W(w_i)$.

(b) For every leg w, $c_W(w) \ge 0$, with equality if and only if $D(w)C(W) = D(W)C(w)$. If $D(w), C(w) \ge 1$, then

$$c_W(w) = \tau(w)\, J\Big(\sqrt{\frac{D(w)/C(w)}{D(W)/C(W)}}\Big).$$

(c) For two histories with the same end record, the comparison cost of the first is at most that of the second if and only if the total proper time of the second is at most that of the first. The one-leg history (W) has comparison cost 0.

(d) A history has the least comparison cost among all histories with its end record if and only if every leg is parallel to the whole: $D(w_i)C(W) = D(W)C(w_i)$ for every i.

Conditions and scope.

Base and premises

Real square roots and cosh; both theorems are proved in classical mathematics.

Conclusion

"Least cost equals greatest proper time" is false for the step cost, which is minimized by a null zigzag, and true for the comparison cost against the history's own frame, which equals the proper-time deficit exactly. Least comparison cost means inertial.

Identification

That physical histories are those of least comparison cost is an identification; by (d) it says exactly that physical histories are inertial. The comparison cost refers to the frame of the whole history, so it is not a cost charged step by step.

Proof. Write $D = D(W)$, $C = C(W)$, $D_i = D(w_i)$ and $C_i = C(w_i)$, so that $\sum_i D_i = D$ and $\sum_i C_i = C$.

(a) Expanding the square, $c_W(w_i) = (D_i C + C_i D - 2\sqrt{D_i C_i DC})/\sqrt{DC}$. Summing over i gives $2DC/\sqrt{DC} - 2\sum_i \sqrt{D_i C_i} = \tau(W) - \sum_i \tau(w_i)$.

(b) $c_W(w)$ is a square divided by a positive number, and it vanishes exactly when $D(w)C = C(w)D$. If $D(w), C(w) \geq 1$, put $p = D(w)C$ and $q = C(w)D$. Then p/q is the ratio inside the square root, and, as in the proof of Theorem 24.5, $J(\sqrt{p/q}) = (\sqrt{p} - \sqrt{q})^2/(2\sqrt{pq})$. Since $\sqrt{pq} = \sqrt{D(w)C(w)}\sqrt{DC}$, we get $\tau(w)J(\sqrt{p/q}) = (\sqrt{p} - \sqrt{q})^2/\sqrt{DC} = c_W(w)$.

(c) By (a), each comparison cost is $\tau(W)$ minus the total proper time, and $\tau(W)$ is the same for both histories. The one-leg history has $c_W(W) = 0$.

(d) Every history with this end record has comparison cost at least 0, by (b), and the one-leg history attains 0. So a history is least exactly when its cost is 0, that is, by (b), when every leg is parallel to W. □

By Theorem 24.5(b) a leg parallel to the whole has the same ratio as the whole, so (d) says that least comparison cost means inertial. The identity (a) is the posting form of the special-relativistic formula for proper time as a sum of dilated pieces. It is linear in the deficit, where Theorem 24.5(d) was quadratic.

Why would a history be inertial? Counting gives a partial answer. Most posting orders with a given end record are nearly inertial over any split into two legs of fixed proportions.

Theorem 24.26 (Most posting orders are nearly inertial). *Let $n = n_1 + n_2$ and $0 \le D \le n$, and write $\binom{m}{a}$ for binomial coefficients, zero when $a < 0$ or $a > m$.*

(a) There are $\binom{n}{a}$ posting words of length n with a debits.

(b) Among the words of length n with D debits, those whose first n_1 posts contain a debits number $\binom{n_1}{a}\binom{n_2}{D-a}$, and $\sum_a \binom{n_1}{a}\binom{n_2}{D-a} = \binom{n}{D}$.

(c) $n\sum_a a\binom{n_1}{a}\binom{n_2}{D-a} = n_1 D\binom{n}{D}$: on average the first leg posts debits at the rate of the whole.

(d) $(n-1)\sum_a (an - n_1 D)^2 \binom{n_1}{a}\binom{n_2}{D-a} = n_1 n_2 D(n-D)\binom{n}{D}$.

(e) Let $\varepsilon > 0$, $n_1 \ge 1$ and $n \ge 2$. Among the words of length n with D debits, the share of those whose first leg's debit fraction a/n_1 differs from D/n by at least ε is at most

$$\frac{n_2}{4\varepsilon^2 n_1 (n-1)}.$$

If $n_1 = p_1 m$ and $n_2 = p_2 m$ with fixed $p_1, p_2 \ge 1$, this share tends to 0 as $m \to \infty$, for every choice of $D \le n$.

(f) If a weighting of posting words gives equal weight to words of the same length and debit count, then the weighted share of any set of words with D debits equals its counted share.

Conditions and scope.

Base and premises

Parts (a) to (d) are identities of natural numbers and integers, proved below with binomial identities. Parts (e) and (f) are proved over the real numbers in classical mathematics.

Conclusion

Over a split into two legs of fixed proportions, the share of posting orders whose first leg deviates from the whole's rate by ε tends to 0.

Identification

That all posting orders with the same length and debit count are equally weighted is an identification.

Not claimed

Approximate inertia of histories with more than two legs, or a derivation of the inertial reading: counting supports it and does not derive it.

Proof. (a) A word is fixed by the set of positions of its debits. (b) Choose the a debit positions among the first n_1 places and the other $D-a$ among the last n_2; summing over a counts every word once.

(c) and (d). Write $S = \binom{n}{D}$ and $\Sigma_f = \sum_a f(a)\binom{n_1}{a}\binom{n_2}{D-a}$. From $a\binom{n_1}{a} = n_1\binom{n_1-1}{a-1}$ and $a(a-1)\binom{n_1}{a} = n_1(n_1-1)\binom{n_1-2}{a-2}$, with (b) applied to $n-1$ and $n-2$ places, and from $n\binom{n-1}{D-1} = D\binom{n}{D}$ and $n(n-1)\binom{n-2}{D-2} = D(D-1)\binom{n}{D}$:

$$n\,\Sigma_a = n_1 D S, \qquad n(n-1)\,\Sigma_{a(a-1)} = n_1(n_1-1)D(D-1)S.$$

The first is (c). For (d), expand $(an - n_1 D)^2 = n^2 a(a-1) + n^2 a - 2nn_1 Da + n_1^2 D^2$ and multiply by $n - 1$:

$$(n-1)\Sigma_{(an-n_1D)^2} = S\big(nn_1(n_1-1)D(D-1) + (n-1)nn_1 D - 2(n-1)n_1^2 D^2 + (n-1)n_1^2 D^2\big).$$

The bracket equals $n_1 D\big(n^2 - nn_1 - nD + n_1 D\big) = n_1 D(n-n_1)(n-D)$, and $n - n_1 = n_2$.

(e) The first leg's fraction deviates by at least ε exactly when $|an - n_1 D| \geq \varepsilon n_1 n$. On those words $(an - n_1 D)^2 \geq (\varepsilon n_1 n)^2$, so by (d) (Chebyshev's argument) the number of deviating words is at most $n_1 n_2 D(n-D)S/((n-1)\varepsilon^2 n_1^2 n^2)$. Divide by S and use $D(n-D) \leq n^2/4$. With $n_1 = p_1 m$ and $n_2 = p_2 m$ the bound is $p_2/(4\varepsilon^2 p_1(n-1))$, which tends to 0 and does not depend on D.

(f) All words with D debits have the same length and debit count, hence the same weight. □

The mean and variance in (c) and (d) are those of the hypergeometric distribution [140]. The theorem concerns the rate of the first leg; it says nothing about how often the first leg is exactly parallel to the whole.

24.9 Clocks: resolution, self-recognition and the action floor

A ledger counts posts; a clock counts turns. Recognition Science's clock has eight modes, and mode k turns $k/8$ of a turn per tick. Records of the clock are phases, and a phase does not show how many whole turns it has made. So two questions arise. How finely do phase records identify the energies that drive the clock? And what does it cost, in drive, to change a register's configuration with certainty? The answers are exact, and the first one has a twist: what limits resolution is not what a record reads but when it is taken.

Definition 24.27 (Clock generators and records)**.** Fix $\hbar > 0$ and a tick $\tau_0 > 0$. A *generator* is a list $E = (E_0, \dots, E_7)$ of real mode energies. The *record* of mode k at time t is the phase $e^{-iE_k t/\hbar}$. Two generators have the *same tick map* when their records agree on every mode at every whole tick $n\tau_0$, $n \in \mathbb{Z}$. The *source generator* is $E_k^{\mathrm{src}} = \pi\hbar k/(4\tau_0)$, under which mode k turns by $-k/8$ of a turn per tick. The *extra turns* of E against E' on mode k are $x_k = (E_k - E'_k)\tau_0/(2\pi\hbar)$; the energy $2\pi\hbar/\tau_0$ of one extra turn per tick is the *branch quantum.* A set T of real numbers *identifies* E' when every generator whose records agree with those of E' on every mode at every time $s\tau_0$, $s \in T$, equals E'. The *native coefficient field* is $\mathbb{Q}(i, \sqrt{2}) = \mathbb{Q}(\zeta_8)$, $\zeta_8 = e^{2\pi i/8} = (1+i)/\sqrt{2}$.

Lemma 24.28 (The record law)**.** *The records of E and E' on mode k agree at time $s\tau_0$ if and only if $x_k s \in \mathbb{Z}$.*

Proof. $e^{-iE_k s\tau_0/\hbar} = e^{-iE'_k s\tau_0/\hbar}$ exactly when $(E_k - E'_k)s\tau_0/\hbar \in 2\pi\mathbb{Z}$, that is, when $x_k s \in \mathbb{Z}$. □

Theorem 24.29 (The resolution of the clock)**.**

(a) Let $M \geq 1$. If $0 \leq E_k\tau_0/\hbar < 2\pi M$ for every k and the records of E agree with those of E^{src} on every mode at time τ_0/M, then $E = E^{\mathrm{src}}$. This identification is not robust: for every $\varepsilon > 0$ some $E \neq E^{\mathrm{src}}$ in the same window has records at τ_0/M within ε of the source's on every mode.

(b) The window is sharp. For $M \geq 1$, the generator $E^{(M)}$ with M extra turns per tick on mode 1 and the source energies on the other modes differs from E^{src}, has the same tick map (hence the same cost of the one-tick map), nonnegative energies and $E_0^{(M)} = 0$, has $E_1^{(M)}\tau_0/\hbar = \pi/4 + 2\pi M$, and agrees with E^{src} on every mode at every time $j\tau_0/M$, $j \in \mathbb{Z}$.

(c) No finite set of rational times identifies the source: for every finite set S of rationals some $E \neq E^{\mathrm{src}}$ with the same tick map, nonnegative energies and $E_0 = 0$ agrees with E^{src} on every mode at every time $q\tau_0$, $q \in S$. Yet every $E \neq E^{\mathrm{src}}$ disagrees with E^{src} on some mode at some rational time $q\tau_0$. And if s is irrational, the set $\{1, s\}$ identifies E^{src}.

(d) The records of E^{src} at whole ticks lie in $\mathbb{Q}(i, \sqrt{2})$ and repeat with period 8 ticks. For rational q, the record of mode 1 at time $q\tau_0$ lies in $\mathbb{Q}(i, \sqrt{2})$ if and only if q is an integer.

Proof. (a) By the record law with $s = 1/M$, each $(E_k - E_k^{\mathrm{src}})\tau_0/\hbar$ lies in $2\pi M\mathbb{Z}$. Both $E_k\tau_0/\hbar$ and $E_k^{\mathrm{src}}\tau_0/\hbar = \pi k/4$ lie in $[0, 2\pi M)$, so their difference lies in $(-2\pi M, 2\pi M) \cap 2\pi M\mathbb{Z} = \{0\}$. For the instability, let $0 < \delta \leq \min(\pi, \varepsilon M/2)$ and change only mode 0, to $E_0\tau_0/\hbar = 2\pi M - \delta$. Its record at τ_0/M is $e^{i\delta/M}$, within $\delta/M < \varepsilon$ of the source's record 1.

(b) The extra turns are $x_1 = M$ and $x_k = 0$ otherwise. At $s = j/M$ the record law holds, since $Mj/M = j$; whole ticks are the case $M \mid j$. The cost of the one-tick map is a function of the tick map. The remaining statements are read off the definition.

(c) Let L be the product of the denominators of the elements of S, and give E exactly L extra turns on mode 1: then $Lq \in \mathbb{Z}$ for every $q \in S$, and E has the same tick map, nonnegative energies and $E_0 = 0$. If $E \neq E^{\mathrm{src}}$, some $x_k \neq 0$. If $x_k \notin \mathbb{Z}$, the time τ_0 already disagrees; otherwise $q = 1/(|x_k| + 1)$ gives $x_k q \in (-1, 1) \setminus \{0\}$, not an integer. Finally, agreement at τ_0 gives $x_k \in \mathbb{Z}$, and agreement at $s\tau_0$ gives $x_k s \in \mathbb{Z}$; if $x_k \neq 0$, then $s = x_k s/x_k$ would be rational.

(d) The record of mode k at $n\tau_0$ is $e^{-i\pi kn/4} = \zeta_8^{-kn}$, which lies in $\mathbb{Q}(\zeta_8)$ and depends on n only modulo 8. For rational r, $e^{2\pi ir} \in \mathbb{Q}(\zeta_8)$ exactly when $8r \in \mathbb{Z}$: if $r = a/b$ in lowest terms, $e^{2\pi ir}$ is a primitive bth root of unity, and if it lies in $\mathbb{Q}(\zeta_8)$ then $\mathbb{Q}(\zeta_{\mathrm{lcm}(b,8)}) = \mathbb{Q}(\zeta_b, \zeta_8) = \mathbb{Q}(\zeta_8)$ has degree 4 over $\mathbb{Q}$; the cyclotomic field $\mathbb{Q}(\zeta_m)$ has degree $\phi(m)$ [148], and among multiples of 8 only $m = 8$ has $\phi(m) = 4$, so $b \mid 8$. The converse is $e^{2\pi ir} = \zeta_8^{8r}$. The record of mode 1 at $q\tau_0$ is $e^{2\pi i(-q/8)}$, and $8 \cdot (-q/8) = -q$. □

Conditions and scope.

Base and premises

Real generators and complex phases; the theorem and Proposition 24.30 are proved in classical mathematics.

Conclusion

One record per mode at τ_0/M identifies the source within a band of M turns per tick, and no better; finitely many rational sample times never identify it, while each wrong generator is caught at some rational time; the tick and one irrational time identify it with no band. Records can be exact native numbers below the tick: the continuum enters through when a record is taken, not through what it reads.

Not claimed

Robustness of (a) to noise in the records, which fails.

Which sets of times identify the source? Exactly those that generate a dense group.

Proposition 24.30 (Identifying times generate a dense group)**.**

(a) A set T of reals identifies E^{src} if and only if the additive subgroup of $\mathbb{R}$ generated by T is dense.

(b) For a finite set S of rationals, with L the least common multiple of their denominators: the records of E and E' on mode k agree at τ_0 and at every $q\tau_0$, $q \in S$, if and only if x_k is an integer multiple of L.

(c) If T identifies E^{src} and the mode-1 source record at $s\tau_0$ lies in $\mathbb{Q}(i, \sqrt{2})$ for every $s \in T$, then T contains an irrational number. The Pythagorean time *$s_P = -4\arccos(3/5)/\pi$ is irrational, $\{1, s_P\}$ identifies E^{src}, and every source record at $s_P\tau_0$ lies in $\mathbb{Q}(i)$: on mode k it is $\big((3+4i)/5\big)^k$.*

Proof. (a) For a real $x \neq 0$, the times s with $xs \in \mathbb{Z}$ form the group $x^{-1}\mathbb{Z}$, which has no element in $(0, 1/|x|)$. By the record law, the records of E and E^{src} on mode k agree on all of T exactly when $x_k s \in \mathbb{Z}$ for all s in the group generated by T. If that group is dense, it meets $(0, 1/|x_k|)$ when $x_k \neq 0$, so every x_k vanishes. If it is not dense, it is $a\mathbb{Z}$ for some $a \geq 0$, since every additive subgroup of $\mathbb{R}$ is dense or cyclic; a generator with $1/a$ extra turns per tick on mode 1 (any nonzero number of extra turns if $a = 0$) agrees on T and is not the source.

(b) Agreement at τ_0 is $x_k \in \mathbb{Z}$. For $q = u/v$ in lowest terms, $x_k u/v \in \mathbb{Z}$ means $v \mid x_k u$, that is, $v \mid x_k$. All denominators divide x_k exactly when L does.

(c) By the proof of Theorem 24.29(d), a rational s with native mode-1 record is an integer. If every element of T were rational, T would generate a subgroup of $\mathbb{Z}$, which is not dense, and T would not identify the source by (a). Next, mode k at $s_P\tau_0$ has record $e^{ik\arccos(3/5)} = (3/5 + 4i/5)^k$. The number $z = (3+4i)/5$ is not a root of unity: it satisfies $z^2 - \frac{6}{5}z + 1 = 0$, and as it is not real this is its minimal polynomial, which does not have integer coefficients, so z is not an algebraic integer. Hence $\arccos(3/5)/\pi$ is irrational, since $\arccos(3/5)/\pi = u/v$ would give $z^{2v} = 1$; so s_P is irrational, and $\{1, s_P\}$ identifies the source by Theorem 24.29(c). □

A clock can also recognize itself. Mode k of the source returns to phase 1 for the first time at $8\tau_0/k$. Records taken at the tick and at these seven first returns identify the generator up to a fixed band.

Theorem 24.31 (The self-recognition band is 105)**.**

(i) For $k = 1, \dots, 7$, the record of source mode k is 1 at time $8\tau_0/k$ and differs from 1 at every time t with $0 < t < 8\tau_0/k$.

(ii) A generator E agrees with E^{src} on every mode at the eight times $q\tau_0$ with

$$q \in \{1,\ 8,\ 4,\ \tfrac{8}{3},\ 2,\ \tfrac{8}{5},\ \tfrac{4}{3},\ \tfrac{8}{7}\}$$

if and only if, mode by mode, E differs from E^{src} by an integer multiple of $105 = 3 \cdot 5 \cdot 7$ branch quanta.

(iii) These eight times generate the group $\frac{1}{105}\mathbb{Z}$, since $1 + \frac{8}{3} + \frac{8}{7} - 3 \cdot \frac{8}{5} = \frac{1}{105}$; agreement at all of them is equivalent to agreement at the single time $\tau_0/105$ on every mode.

Proof. (i) $e^{-i\pi kt/(4\tau_0)} = 1$ exactly when $kt/(8\tau_0) \in \mathbb{Z}$, and the least positive such t is $8\tau_0/k$.

(ii) By the record law the condition is $x_j q \in \mathbb{Z}$ for each listed q. The tick gives $x_j \in \mathbb{Z}$; then $\frac{8}{3}x_j \in \mathbb{Z}$ gives $3 \mid x_j$, $\frac{8}{5}x_j$ gives $5 \mid x_j$ and $\frac{8}{7}x_j$ gives $7 \mid x_j$, so $105 \mid x_j$. Conversely $105q$ is an integer for each listed q: the values are $105, 840, 420, 280, 210, 168, 140, 120$.

(iii) $(105+280+120-504)/105 = 1/105$, and every listed time is a multiple of $1/105$. Agreement at $\tau_0/105$ says $x_j/105 \in \mathbb{Z}$, which is (ii). □

By Proposition 24.30(a) the clock's own returns never single out its source: the generator with 105 extra turns per tick on mode 1 passes all of them. Reading a comparison against mode k as stopping at that mode's first return is an identification; the band itself needs none.

The second question concerns registers rather than clocks: what a single change of configuration costs. Recognition Science executes register operations by words of tokens, each driven for a duration ε while the register's own holding Hamiltonian acts. Section 21.7 met the same question for comparisons, on registers of binary channels (Definition 21.35); here the channels have eight states, the paid token is the same, and the object is the register itself.

Definition 24.32 (Tokens, words and paid words)**.** Let a register be given, with its configurations as basis and the operator norm $\|\cdot\|$. A *token* t carries a skew-Hermitian *generator* G_t; a *word* is a finite list of tokens, and its *drive* is $\sum_t \|G_t\|$, in units of $\hbar$. Given a self-adjoint *holding* H and $\hbar, \varepsilon > 0$, the *paid token* is $e^{-i\|G_t\|} \exp(G_t - i\varepsilon H/\hbar)$, the token driven for time ε with the holding on, and the *paid word* W is the product of its paid tokens; with $H = 0$ it is the *ideal word*, up to a phase. In Recognition Science's native alphabet, given in full in Definition 30.19, the register consists of eight-state channels; a *braid token* on a channel has generator θB for a real angle θ and one of the 21 triad generators B of that definition, fixed nonzero real antisymmetric matrices on that channel, and an *entangling token* on an ordered pair (k, l) of distinct channels has generator $\frac{\pi}{4} i S_k F_l$, where S_k multiplies each configuration by the sign $(-1)^b$, b the number of bits 1 in the state of channel k, and F_l flips the low bit of the state of channel l. Recognition Science's *native register* is a register with this alphabet and the holding of Section A.8, equation (A.13): it has $20 + 2N + 4a + 4b$ channels for parameters $N, a, b \geq 0$ and $m, \beta \in \mathbb{Z}$, and its holding is built there from a positive interior holding $H_{\mathrm{old}}(N, m)$ that the construction takes as supplied.

The operator $S_k F_l$ is self-adjoint with square 1, so the entangling token's ideal action is $\exp(\frac{\pi}{4} i S_k F_l) = (1 + i S_k F_l)/\sqrt{2}$, the ideal entangler. The cost of certainty rests on one geometric fact: overlap angles add.

Lemma 24.33 (Overlap angles add)**.** *Let p, q, r be unit vectors with $|\langle p, q\rangle| \geq \cos\alpha$ and $|\langle q, r\rangle| \geq \cos\beta$, where $\alpha, \beta \in [0, \pi/2]$. Then $|\langle p, r\rangle| \geq \cos(\alpha + \beta)$.*

Proof. Multiplying p and r by unit phases, we may assume $a = \langle q, p\rangle$ and $b = \langle q, r\rangle$ are real and nonnegative. Write $p = aq + p'$ and $r = bq + r'$ with p', r' orthogonal to q, so $\|p'\| = \sqrt{1 - a^2}$ and $\|r'\| = \sqrt{1 - b^2}$. Then $|\langle p, r\rangle| = |ab + \langle p', r'\rangle| \geq ab - \sqrt{1 - a^2}\sqrt{1 - b^2} = \cos(\alpha' + \beta')$ with $a = \cos\alpha'$, $b = \cos\beta'$ and $\alpha', \beta' \in [0, \pi/2]$. Since $a \geq \cos\alpha$ and $b \geq \cos\beta$, $\alpha' \leq \alpha$ and $\beta' \leq \beta$, and cos decreases on $[0, \pi]$. □

Theorem 24.34 (The action floor of a native step)**.** *Let a register, a self-adjoint holding H, $\hbar, \varepsilon > 0$ and a word w of n tokens be given, with paid word W, and put $\theta = \mathrm{drive}(w) + n\varepsilon\|H\|/\hbar$.*

(a) For distinct configurations $x \neq y$, $|\langle y, Wx\rangle| \leq \sin\big(\min(\pi/2, \theta)\big)$.

(b) Hence a word that moves x to $y \neq x$ with probability $|\langle y, Wx\rangle|^2 \geq 1 - 2\delta$, $0 \leq \delta \leq \frac{1}{2}$, pays drive

$$\hbar\,\mathrm{drive}(w) \geq \hbar \arcsin\sqrt{1 - 2\delta} - n\varepsilon\|H\|,$$

and a certain move, $|\langle y, Wx\rangle| = 1$, pays at least $\hbar\pi/2 - n\varepsilon\|H\|$.

(c) The bound is attained. For distinct channels k, l, the word of two entangling tokens on (k, l) has drive exactly $\pi/2$ and ideal word iS_kF_l, and with zero holding its paid word moves every configuration x to the configuration x' with the low bit of channel l flipped, with $|\langle x', Wx\rangle| = 1 = \sin(\pi/2)$.

(d) On Recognition Science's native register, under its holding H, the same word moves x to x' with $|\langle x', Wx\rangle| \geq 1 - 2\varepsilon\|H\|/\hbar$.

Conditions and scope.

Base and premises

Complex matrices over the classical numbers; proved in classical mathematics. Parts (a) and (b) hold for every register, holding and word; their proof uses only that the token generators are skew-Hermitian. Part (c) holds on every register of at least two channels with the native alphabet; its proof uses the entangling generator itself.

Conclusion

The amplitude of any change of configuration is bounded by the sine of the drive plus the holding drift, so a change with certainty pays at least a quarter turn, $\hbar\pi/2$, less the drift; the doubled entangler attains the bound.

Identification

For a comparison clocked against a reference cycle whose action $A_0 = 2\pi\hbar$ uses the register's $\hbar$, the floor reads $A_0/4$ less the drift; that reading is an identification.

Not claimed

That the native register attains the quarter turn exactly under its holding: (d) gives the amplitude $1 - 2\varepsilon\|H\|/\hbar$, not 1.

Proof. (a) Each paid token is, up to a phase, e^{Y_t} with $Y_t = G_t - i\varepsilon H/\hbar$ skew-Hermitian and $\|Y_t\| \le \|G_t\| + \varepsilon\|H\|/\hbar =: \theta_t$. First, for skew-Hermitian Y with $\|Y\| \le \pi/2$ and unit v, $|\langle v, e^Y v\rangle| \ge \cos\|Y\|$: in an orthonormal eigenbasis of Y, with eigenvalues $i\lambda_j$ and $|\lambda_j| \le \|Y\|$, the real part of $\langle v, e^Y v\rangle$ is $\sum_j |v_j|^2 \cos\lambda_j \ge \cos\|Y\|$. So $|\langle v, P_t v\rangle| \ge \cos(\min(\pi/2, \theta_t))$ for every unit v, the bound being trivial when $\theta_t \ge \pi/2$. Next, if unitaries U_1, U_2 satisfy $|\langle v, U_i v\rangle| \ge \cos\Theta_i$ for all unit v, with $\Theta_i \in [0, \pi/2]$, then Lemma 24.33 with $p = v$, $q = U_1 v$ and $r = U_2 U_1 v$ gives $|\langle v, U_2 U_1 v\rangle| \ge \cos(\Theta_1 + \Theta_2)$, and the bound $\cos(\pi/2) = 0$ is trivial. By induction over the tokens, $|\langle v, Wv\rangle| \ge \cos\Theta$ with $\Theta = \min(\pi/2, \theta)$. Finally W is unitary and $x \perp y$, so $|\langle x, Wx\rangle|^2 + |\langle y, Wx\rangle|^2 \le \|Wx\|^2 = 1$, and $|\langle y, Wx\rangle|^2 \le 1 - \cos^2\Theta = \sin^2\Theta$.

(b) If $\theta \ge \pi/2$ the claims hold because arcsin $\le \pi/2$. Otherwise (a) gives $\sqrt{1 - 2\delta} \le \sin\theta$, so $\arcsin\sqrt{1 - 2\delta} \le \theta$; multiply by $\hbar$. Certainty is $\delta = 0$.

(c) Write $S = S_k F_l$. As S is self-adjoint with $S^2 = 1$, $\exp(\frac{\pi}{4} iS) = \cos\frac{\pi}{4} + i\sin\frac{\pi}{4} S$, and the square is $\exp(\frac{\pi}{2} iS) = iS$. Each generator has norm $\pi/4$, so the drive is $\pi/2$. With $H = 0$ the paid word is $e^{-i\pi/2} \cdot iS = S$, and $Sx = \pm x'$.

(d) For skew-Hermitian A and B, Duhamel's formula $e^{A+B} - e^A = \int_0^1 e^{s(A+B)} B e^{(1-s)A}\, ds$ gives $\|e^{A+B} - e^A\| \le \|B\|$. So each paid token is within $\varepsilon\|H\|/\hbar$ of its zero-holding version, the two-token word is within $2\varepsilon\|H\|/\hbar$ of the word of (c), and the amplitude drops by at most that much. □

The theorem has the form of a quantum speed limit, in the line of Mandelstam and Tamm [103] and Margolus and Levitin [104], stated for drive rather than energy: a quarter turn of drive buys one certain change. Part (a) is the step bound of Lemma 21.36(2), proved there for binary channels with the Fubini–Study distance and here for every register by adding overlap angles, and the word of (c) is the one that attains the threshold of Corollary 21.38(2). Whether the native register can make a certain change at all under its holding is a different question, and it is open. We can say exactly what it reduces to.

Definition 24.35 (Phased words, density, exactness and entangler reach)**.** Fix a register, a holding H and $\hbar, \varepsilon > 0$. A *phased paid word* is cW with $|c| = 1$ and W a paid word. The setting is *dense* when every unitary of the register is an operator-norm limit of phased paid words, and *exact* when every unitary is a phased paid word. It has *entangler reach* when every ideal entangler $(1 + iS_k F_l)/\sqrt{2}$ is a limit of phased paid words.

Proposition 24.36 (Certain flips reduce to reaching the entangler)**.** *Consider a register of at least two channels with Recognition Science's native alphabet, a self-adjoint holding H and $\hbar, \varepsilon > 0$.*

(a) If the setting is dense, it is exact.

(b) Every ideal braid rotation $\exp(\alpha B)$ *is a limit of phased paid words.*

(c) *Suppose the ideal native alphabet is universal on the register: the closed group generated by the ideal braid rotations and the ideal entanglers contains every unitary of determinant* 1. *Then entangler reach, density and exactness are equivalent.*

(d) *Under the universality of (c) on every native register, if entangler reach holds at every setting of the native register under its holding, then at every setting some paid native word moves some configuration to a different one with amplitude of modulus exactly* 1.

(e) *Adding a real multiple of the identity to H does not change entangler reach, and $(\hbar, \varepsilon)$ enter paid words only through $\varepsilon/\hbar$. In Recognition Science's native register with parameters (N, a, b, m), the exterior flux β enters the holding only as such a multiple, the energy $c(\beta)$ of one exterior edge. So entangler reach at $(N, a, b, m, \beta, \hbar, \varepsilon)$ is equivalent to entangler reach at $(N, a, b, m, 0, 1, \varepsilon/\hbar)$.*

Proof. Let $\mathscr{P}$ be the set of phased paid words. It is closed under products, and so is its closure $\overline{\mathscr{P}}$, a closed set of unitaries that is closed under products contains the inverse of each element g, because the powers of g have a convergent subsequence g^{m_j} in the compact unitary group, and then $g^{m_{j+1}-m_j-1} \to g^{-1}$.

(a) Fix a braid token and write $T(\theta) = \exp(\theta B + D)$ with $D = -i\varepsilon H/\hbar$; each $T(\theta)$ is in $\mathscr{P}$. Some θ_0 has a derivative $T'(\theta_0)T(\theta_0)^{-1}$ that is not a multiple of the identity: otherwise $T(\theta)T(0)^{-1}$ would be scalar for all θ, the differences of eigenvalues of the normal matrix $\theta B + D$ would stay in a countable set, and their spread $\sum_{j,k} |\lambda_j - \lambda_k|^2 = 2d\|\theta B + D\|_F^2 - 2|\operatorname{tr}(\theta B + D)|^2$ would be constant, whereas it is a quadratic polynomial in θ with leading coefficient $2d\|B\|_F^2 > 0$. Consider words $F(\theta_1, \dots, \theta_m) = U_m T(\theta_m) \cdots U_1 T(\theta_1)$ with fixed $U_i \in \mathscr{P}$. At $\theta_i = \theta_0$ their partial derivatives are conjugates of that non-scalar direction by the partial products. The unitary conjugates of a non-scalar skew-Hermitian matrix span all traceless skew-Hermitian matrices, and $\mathscr{P}$ is dense, so the U_i can be chosen one at a time until these directions, together with the phase direction, span the tangent space of the unitary group. By the inverse function theorem the map $(c, \theta_1, \dots, \theta_m) \mapsto cF(\theta)$ covers a neighbourhood O of $g_0 = c_0 F(\theta_0, \dots, \theta_0)$, so $O \subseteq \mathscr{P}$. For any unitary V, density gives $A \in \mathscr{P}$ so close to $V g_0^{-1}$ that $A^{-1}V \in O$; then $V = A \cdot A^{-1}V \in \mathscr{P}$.

(b) Put $B_\Theta = B + D/\Theta$ for $\Theta > 0$, so $T(\Theta) = \exp(\Theta B_\Theta)$ and $\exp((\Theta + \alpha)B_\Theta) = \exp(\alpha B_\Theta)T(\Theta)$. By Duhamel's bound, $T(\Theta + \alpha)$ is within $|\alpha|\|D\|/\Theta$ of $\exp((\Theta + \alpha)B_\Theta)$, and $\exp(\alpha B_\Theta)$ is within the same of $\exp(\alpha B)$. Hence $\|T(\Theta + \alpha)T(\Theta)^{-1} - \exp(\alpha B)\| \le 2|\alpha|\|D\|/\Theta \to 0$, and $T(\Theta)^{-1} \in \overline{\mathscr{P}}$ by the remark on inverses.

(c) Exactness gives density, and density gives entangler reach. Conversely, with entangler reach and (b), $\overline{\mathscr{P}}$ contains the ideal braid rotations and entanglers; it is a closed group, so by universality it contains every unitary of determinant 1, and with phases every unitary. So the setting is dense, and exact by (a).

(d) At each setting the setting is exact by (c). The permutation matrix that exchanges two distinct configurations x and y is unitary, so it is cW for a paid word W, and $|\langle y, Wx\rangle| = 1$.

(e) Adding $\lambda 1$ to H multiplies each paid token by the phase $e^{-i\varepsilon\lambda/\hbar}$, which phased words absorb; and the exponent $G_t - i(\varepsilon/\hbar)H$ involves $\hbar$ and ε only through their ratio. In the native register, β occurs in the placed holding (A.11) only in the term $c(\beta)I$, and (A.13) carries that term to $c(\beta)$ times the identity of the whole register; so passing from β to 0 adds the real multiple $c(0) - c(\beta)$ of the identity. □

Conditions and scope.

Base and premises

Classical analysis of the unitary group: the inverse function theorem, compactness, and the irreducibility of the conjugation action on traceless skew-Hermitian matrices. Parts (c) and (d) also assume the universality of the ideal native alphabet, as stated. That universality holds on every register of at least two channels with Recognition Science's native alphabet, by Theorem A.6: the braid rotations about the 21 triads are the rotations $\exp(tC_{ab7}/\sqrt{3})$, t real, which supply all the local cyclic rotations of that theorem, and the ideal entanglers include its couplings $(I + iS \otimes F)/\sqrt{2}$ and $(I + iF \otimes S)/\sqrt{2}$ on adjacent channels. So the only open premise of (d) is entangler reach. Part (e) reads off equations (A.11) and (A.13) that β enters the native holding only as the multiple $c(\beta)$ of the identity.

Conclusion

Exact certainty on a register is exactly as hard as approximate universality, and approximate universality reduces to one gate type, the entangler; the class of settings where it holds depends only on (N, a, b, m) and the dimensionless duration $\varepsilon/\hbar$.

Not claimed

Entangler reach itself. It is the open statement below.

Open problem (entangler reach on the native register). Let $N, a, b \geq 0$ and $m \in \mathbb{Z}$, let $H_{\mathrm{old}}(N, m)$ be a positive interior holding supplied as in Section A.8, and let H be the native holding (A.13) built from it at $\beta = 0$. For every $\varepsilon/\hbar > 0$: is every ideal entangler $(1 + iS_kF_l)/\sqrt{2}$ of the register an operator-norm limit of phased paid native words, each token driven for the duration $\varepsilon/\hbar$ under H with $\hbar = 1$? The question is asked for each such $H_{\mathrm{old}}(N, m)$. Neither a proof nor a refutation is known. The question is whether the drift of the native holding can be refocused in the limit.

24.10 What one balance history can be asked

Section 17.7 asked what finite records of a repeatedly examined system can confirm, refute or settle, and what deciding a question about it costs. An account under posting is such a system, and its own histories supply every binary world. Let the posts go on without end, and ask about the balance: will the account stay solvent forever? Will it ever close at zero? Each question has an exact price, and so do the detectors and deadlines one might build to answer it. Here *deciding* a question means proving, for every history, that it holds or fails; a map that returns the answer would be the corresponding data form (Section 21.1), which we do not use. Every price in this section, that is every equivalence with a principle, is proved with no choice principle; Theorem 24.39(i), Theorem 24.43(b) and the last statement of Theorem 24.43(d) reason classically, as they say. The principles are those of Definition 7.8, with Markov's principle in its binary form $\mathrm{MP}_{\mathrm{bin}}$.

Definition 24.37 (Balance histories and their questions)**.** A *balance history* is a map h from the natural numbers to sides, $h(n)$ being the side of post n. Its *balance* $b_h(n)$ is the number of debits minus the number of credits among the first n posts, an integer of $\mathbb{Z}_\delta$; so $b_h(0) = 0$ and $b_h(n+1) = b_h(n) \pm 1$, with $+$ for a debit. The history is *solvent forever*, $S(h)$, when $b_h(n) \geq 0$ for every n; it *closes*, $Z(h)$, when $b_h(n) = 0$ for some $n > 0$; it is *overdrawn*, $O(h)$, when $b_h(n) < 0$ for some n. Its *transfer partner* $\bar{h}$ posts the opposite side at every step. Examining a history n times yields its first n posts. A question Q about histories is *decided* when $Q(h)$ or $\neg Q(h)$ holds for every h.

The balance $b_h(n)$ is the cone coordinate x of the account's record after n posts (Definition 24.1). The prices come from one lemma about questions of the two simplest logical shapes.

Lemma 24.38 (Prices of one-quantifier questions)**.** *Let worlds be examined as in Section 17.7, and let $P(w, n)$ be decidable for every world w and number n.*

(a) If $Q(w) \Leftrightarrow \forall n\, P(w, n)$ and the zero test reduces to Q (Definition 17.14), then deciding Q is equivalent to WLPO, and the statement

$$\forall w, w'\ \big(\neg(\neg Q(w) \wedge \neg Q(w')) \to Q(w) \vee Q(w')\big)$$

is equivalent to LLPO.

(b) If $Q(w) \Leftrightarrow \exists n\, P(w, n)$ and the event test reduces to Q, then deciding Q is equivalent to LPO, and $\forall w(\neg\neg Q(w) \to Q(w))$ is equivalent to $\mathrm{MP}_{\mathrm{bin}}$.

None of the four equivalences uses a choice principle.

Proof. For a world w let $\alpha_w(n) = 1$ when $P(w, n)$ fails, in case (a), or holds, in case (b), and 0 otherwise; α_w is a binary sequence.

(a) WLPO at α_w gives $\alpha_w \equiv 0$, hence $Q(w)$, or $\neg(\alpha_w \equiv 0)$, hence $\neg Q(w)$. Conversely, if Φ reduces the zero test to Q, deciding $Q(\Phi(\alpha))$ decides $\alpha \equiv 0$.

For LLPO, let w, w' satisfy $\neg(\neg Q(w) \wedge \neg Q(w'))$. Interleave the failures of w at even places and of w' at odd places, and keep only the first: $\beta(2n) = 1$ when $P(w, n)$ fails and no earlier place of the interleaving records a failure, and likewise $\beta(2n+1)$ for w'. Then β has at most one entry 1. Suppose LLPO gives $\beta(2k) = 0$ for all k. If $P(w, n)$ failed, the first recorded failure would come at or before place $2n$, at an odd place, so w' would fail somewhere too, and $\neg Q(w) \wedge \neg Q(w')$ would hold, which is excluded; as $P(w, n)$ is decidable, it holds. So $Q(w)$; the odd case gives $Q(w')$. Conversely, given α with at most one entry 1, let $\alpha_e(k) = \alpha(2k)$ and $\alpha_o(k) = \alpha(2k+1)$, and apply the statement to $w = \Phi(\alpha_e)$ and $w' = \Phi(\alpha_o)$. Its hypothesis holds: suppose $\neg(\alpha_e \equiv 0)$ and $\neg(\alpha_o \equiv 0)$. If some $\alpha(2k) = 1$, every odd entry is 0, against $\neg(\alpha_o \equiv 0)$; so every $\alpha(2k)$ is 0, against $\neg(\alpha_e \equiv 0)$. Its conclusion is $\alpha_e \equiv 0$ or $\alpha_o \equiv 0$, which is LLPO at α.

(b) LPO at α_w gives $\alpha_w \equiv 0$, hence $\neg Q(w)$, or an n with $P(w, n)$, hence $Q(w)$. Conversely, deciding $Q(\Phi(\alpha))$ decides $\exists n\, \alpha(n) = 1$, and the negative case gives $\alpha \equiv 0$ because each entry is 0 or 1. If $\neg\neg Q(w)$, then $\neg(\alpha_w \equiv 0)$, and $\mathrm{MP}_{\mathrm{bin}}$ gives an n with $P(w, n)$. Conversely, if $\neg(\alpha \equiv 0)$, then $\neg\neg Q(\Phi(\alpha))$, so $Q(\Phi(\alpha))$, which gives an n with $\alpha(n) = 1$. □

Theorem 24.39 (The prices of one balance history)**.** *For balance histories of one account:*

(a) deciding solvency forever is equivalent to WLPO;

(b) deciding closing is equivalent to LPO;

(c) "every history that cannot fail to close closes", $\forall h\,(\neg\neg Z(h) \to Z(h))$, is equivalent to $\mathrm{MP}_{\mathrm{bin}}$;

(d) naming a solvent history of two that are not both insolvent, $\forall h, h'\,(\neg(\neg S(h) \wedge \neg S(h')) \to S(h) \vee S(h'))$, is equivalent to LLPO;

(e) deciding overdraft is equivalent to LPO, and $\forall h\,(\neg\neg O(h) \to O(h))$ to $\mathrm{MP}_{\mathrm{bin}}$;

(f) deciding closing is equivalent to deciding solvency together with (c);

(g) $b_h(n) + b_{\bar{h}}(n) = 0$ for every h and n, so this conservation is decided with no principle, while deciding "h is solvent forever and its transfer pair conserves" is equivalent to WLPO;

(h) for every N, "$b_h(n) \geq 0$ for all $n \leq N$" and "$b_h(n) = 0$ for some $0 < n \leq N$" are decided with no principle;

(i) solvency forever is refutable and not confirmable, and closing is confirmable and not refutable.

Parts (a) to (h) use no choice principle. Part (i) reasons classically about recorders, as Section 17.7 does.

Conditions and scope.

Base and premises
Unending posting histories of one account and integer balances; the omniscience principles on binary sequences.

Conclusion
Each classical price is a question about one balance history: solvency forever is WLPO, closing is LPO, waiting for a closing that cannot fail is $\mathrm{MP}_{\mathrm{bin}}$, naming a solvent account of two is LLPO. Closing costs solvency plus waiting, the ledger form of LPO = WLPO+$\mathrm{MP}_{\mathrm{bin}}$; a conserved total costs nothing, and so does every question with a horizon.

Identification
That the nth examination of an account yields its nth post is the examination model, a reading of what observing an account means.

Not claimed
Which history nature posts. The coding histories in the proof are devices showing that the ledger's own histories contain every binary world.

Proof. Solvency is $\forall n\,(b_h(n) \geq 0)$, closing is $\exists n\,(n > 0 \wedge b_h(n) = 0)$ and overdraft is $\exists n\,(b_h(n) < 0)$, each with a decidable test, since $b_h(n)$ is computed from the first n posts. Two coding histories give the reductions. The *solvency coder* of a binary sequence α posts $d\,c$ for each entry $\alpha(n) = 0$ and $c\,d$ for each entry $\alpha(n) = 1$. Its balance is 0 after every pair, +1 inside a pair

for 0, and -1 inside a pair for 1; so it is solvent forever exactly when $\alpha \equiv 0$, and overdrawn exactly when some $\alpha(n) = 1$. The *closing coder* posts one debit and then the solvency coder of α; its balance is 1 after every pair, 2 inside a pair for 0 and 0 inside a pair for 1, so it closes exactly when some $\alpha(n) = 1$. Each post of either coder depends on one entry of α, so both maps have finite information.

Parts (a) and (d) are Lemma 24.38(a) with the solvency coder; (b), (c) and (e) are Lemma 24.38(b) with the closing and solvency coders. For (f), (a)–(c) reduce it to LPO $\Leftrightarrow$ WLPO $\wedge$ $\mathrm{MP}_{\mathrm{bin}}$: LPO gives both principles, and conversely WLPO decides $\alpha \equiv 0$ or $\neg(\alpha \equiv 0)$, and in the second case $\mathrm{MP}_{\mathrm{bin}}$ finds a 1 (Proposition 7.35). For (g), $b_{\bar{h}} = -b_h$ by induction on n; so conservation holds outright, and the conjunction says the same as solvency, priced by (a). For (h), a bounded quantifier over a decidable test is decided by inspecting finitely many cases. For (i), solvency is Π_1 and closing is Σ_1 in the sense of Definition 17.12, and the coders reduce the zero test to solvency and the event test to closing; apply Theorems 17.13 and 17.15. □

A record of an overdraft refutes solvency, and no record confirms it; a record of a closing confirms closing, and no record refutes it. The prices say more: they are what it costs to know the answer for every history at once.

Detectors that revise their verdict have exact prices too. We use the guessing rules of Definition 17.19, writing 1 for *yes* and 0 for *no*.

Definition 24.40 (Sound rules and alarms)**.** The *verdict stream* of a guessing rule g on a world w is $\sigma(n) = g(w{\restriction}n)$. The stream *changes* at $n+1$ when $\sigma(n+1) \neq \sigma(n)$, and it *settles* on b when $\sigma(n) = b$ for all large n. The rule is *sound* for a question Q when, on every world, verdicts that settle on 1 imply $Q(w)$ and verdicts that settle on 0 imply $\neg Q(w)$. A stream is an *alarm from* b when $\sigma(0) = b$ and it changes at most once. A *refuting alarm* is a rule whose stream is an alarm from 1 on every world, a *confirming alarm* one whose stream is an alarm from 0 on every world.

An alarm latches: once it has left its starting value it never returns, for a return would be a second change. A refuting alarm trips to refute; a confirming alarm trips to confirm.

Theorem 24.41 (The alarm table)**.** *The following equivalences and implications hold for all sets of worlds, examinations, guessing rules and questions, with no choice principle.*

(a) Every question with a sound refuting alarm is decided if and only if WLPO holds.

(b) Every question with a sound confirming alarm is decided if and only if LPO holds.

(c) Every question with a sound rule whose verdict stream, on each world, changes at most some number of times (a bound depending on the world and not given as data) is decided if and only if LPO holds.

(d) In particular, if g is sound for Q and each world's verdict stream has a bound on its changes, then LPO decides Q on every world.

(e) The statement "LPO decides every question that some guessing rule decides in the limit" is equivalent to the statement that LPO implies $\neg\neg P \to P$ for every proposition P.

(f) Further: $\neg\neg Q \to Q$ for every question with a sound confirming alarm, and the trip of every alarm from 0 that is not silent forever, are each equivalent to $\mathrm{MP}_{\mathrm{bin}}$; whether an alarm from b stays at b forever, for every alarm from b, is equivalent to WLPO, for either b; $Q(w) \vee R(w)$ on every world, for sound refuting alarms of Q and of R that never both trip on one world, is equivalent to LLPO; that every alarm from b settles, for either b, and that every stream with a bound on its changes settles, are each equivalent to LPO; and with a bound B on the changes fixed in advance for all worlds, sound rules decide their questions with no principle when $B = 0$, while for every $B \geq 1$ this is equivalent to LPO.

Conditions and scope.

Base and premises

Arbitrary worlds, examinations, guessing rules and questions; implications between decisions and principles, proved without excluded middle and without choice.

Conclusion

WLPO, LPO and LLPO are each exactly the cost of reading an end-of-time property of latching detectors: one alarm's silence, its trip or final verdict, which of two never-both-tripping alarms is silent. $\mathrm{MP}_{\mathrm{bin}}$ is not a reading but a wait. A refuting alarm costs WLPO, a confirming one LPO, and no question with a sound detector that revises finitely often costs more than LPO.

Not claimed

The ceiling (e) as a theorem: it holds exactly when LPO gives double-negation elimination for every proposition, a statement far beyond the binary sequences that LPO speaks about. The proved ceiling is (d).

Proof. Take W to be the binary runs, each read by itself, for the directions that yield a principle.

(a) Given WLPO and a sound refuting alarm on w, apply WLPO to $n \mapsto 1 - \sigma(n)$. If $\sigma \equiv 1$, the verdicts settle on 1 and $Q(w)$. Otherwise suppose $Q(w)$: any n with $\sigma(n) = 0$ would latch the stream at 0, settling it on 0 and refuting $Q(w)$; so $\sigma \equiv 1$, a contradiction, and $\neg Q(w)$. Conversely, for $Q(\alpha) \Leftrightarrow \alpha \equiv 0$ the rule "1 while no entry 1 has been seen" is a sound refuting alarm, and deciding Q is WLPO.

(b) Given LPO, apply it to σ: an n with $\sigma(n) = 1$ latches the stream at 1 and gives $Q(w)$; $\sigma \equiv 0$ settles on 0 and gives $\neg Q(w)$. Conversely "1 once an entry 1 has been seen" is a sound confirming alarm for $\exists n\, \alpha(n) = 1$.

(c) and (d). An alarm has at most one change, so (c) contains (b) and gives LPO. Given LPO and a bound on the changes of σ, prove, by induction on r, that if σ changes at most r times after place k then $Q(w)$ or $\neg Q(w)$. Apply LPO to $j \mapsto [\sigma(k + j) \neq \sigma(k)]$. If it is identically 0, the verdicts settle on $\sigma(k)$ and soundness decides $Q(w)$. Otherwise σ changes between k and some $k + j$, so it changes at most $r - 1$ times after $k + j$, and the induction hypothesis applies; for $r = 0$ the first case is the only one. The bound need not be given as data: the goal is a disjunction, so its existence suffices.

(e) Suppose the ceiling, and let LPO hold and $\neg\neg P$. Take one world and the question $Q = P$, with the rule that always says 1. It decides Q in the limit: if P, it settles on 1, and $\neg P$ is

impossible. So $P \vee \neg P$, and with $\neg\neg P$ this gives P. Conversely, if LPO yields double-negation elimination, apply it to $\neg\neg(Q(w) \vee \neg Q(w))$, which holds outright.

(f) For a sound confirming alarm with $\neg\neg Q(w)$, its stream cannot be identically 0, which would settle on 0; $\mathrm{MP}_{\mathrm{bin}}$ finds a trip, which latches and gives $Q(w)$. Waiting for a trip is $\mathrm{MP}_{\mathrm{bin}}$ applied to the stream. Conversely the stream "some entry 1 seen before place n" of a binary sequence α is an alarm from 0, silent forever exactly when $\alpha \equiv 0$; it yields $\mathrm{MP}_{\mathrm{bin}}$, and the rule of (b) does the same for stability. Silence of an alarm from b is WLPO applied to $n \mapsto [\sigma(n) \neq b]$, and conversely the stream that starts at b and switches once an entry 1 of α has been seen is silent exactly when $\alpha \equiv 0$. The two-alarm statement is the argument of Lemma 24.38(a) for the interleaved trips, with the silence-so-far alarms of the even and odd parts of α for the converse. An alarm from b settles on b when it never trips and on the other value when it does, so LPO applied to its trips settles it; conversely the switching stream of α settles on b exactly when $\alpha \equiv 0$, and settles on the other value only after an entry 1, which a bounded search then finds. Bounded streams settle by the induction of (c). With $B = 0$ fixed in advance, the verdict is the constant g of the empty record, which settles, and soundness decides Q; for $B \geq 1$ the induction of (c) uses LPO, and the confirming alarm of (b) has $B = 1$. □

Finally, deadlines. Section 17.7 showed, classically, that a question about binary runs settled by a recorder is fixed by a prefix of bounded length (Theorem 17.16). What does that bound cost, and when does a bound fixed in advance exist? A recorder in the sense of Definition 17.12 *announces* b at stage n on a run α when its answer at $\alpha{\restriction}n$ is b and it reads on at every shorter record. It *always answers* when it announces at some stage on every binary run, and it has a *deadline* N when it announces at a stage $n \leq N$ on every binary run.

Definition 24.42 (Finite-memory recorders)**.** A *recorder with $s+1$ memory states* has states $\{0, \dots, s\}$, an initial state, a transition map from a state and a bit to a state, and an output map from states to *yes*, *no* or "read on"; its answer at a record is the output of the state reached by reading the record from the initial state.

Theorem 24.43 (A deadline costs the fan principle)**.**

(a) "Every recorder that always answers on binary runs has a deadline" is equivalent to the decidable fan theorem FAN_{Δ} *(Definition 13.2).*

(b) There is a computable recorder that announces on every computable binary run while, for every N, some computable run leaves it reading on through stage N. So the computable form of the deadline principle is false.

(c) "Every question about binary runs settled by a recorder is fixed by the first N examinations, for some N" is equivalent to $\mathrm{FAN}_{\Delta} \wedge \mathrm{MP}_{\mathrm{bin}}$*. For questions settled by a recorder that always answers, the same statement is equivalent to* FAN_{Δ}*; for recorders that only ever answer* yes *and cannot fail to answer on any run, the statement that runs agreeing up to some N receive the same answer is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$*.*

(d) A recorder with $s+1$ memory states that always answers announces at a stage at most s on every run, and for every s some recorder with $s+1$ states announces yes *exactly at stage s on every run. If such a recorder announces on every computable run, it announces at a stage at most s on every run.*

Parts (a), (c) and the first two statements of (d) are proved with no choice principle and no omniscience principle beyond those named. Part (b) and the last statement of (d) concern computable runs and are proved classically.

Conditions and scope.

Base and premises

Binary runs, recorders as rules on finite records, and the decidable fan theorem of Chapter 13.

Conclusion

A deadline fixed in advance for every always-answering experiment costs exactly what Heine–Borel for $[0, 1]$ costs (Theorem 13.6); the classical passage from "settled" to "fixed by a prefix" costs $\mathrm{FAN}_\Delta \wedge \mathrm{MP}_{\mathrm{bin}}$, the fan principle paying for experiments that always answer and Markov's principle for those that only ever say yes. Experiments with finite memory carry their deadline with them, and the bound is sharp.

Identification

A run is a system under repeated binary examination, a recorder an experiment with a stopping rule, and a deadline a number of examinations fixed before the run.

Not claimed

Whether FAN_Δ alone gives the passage of (c); by (c) it does exactly when FAN_Δ implies $\mathrm{MP}_{\mathrm{bin}}$, a question about the two principles alone that we leave open.

Proof. (a) Let R always answer. The strings at which R answers form a decidable bar, so FAN_Δ gives N such that every run has an answering record of length at most N; a search through the shorter records finds the first answer, at a stage at most N. Conversely, for a decidable bar D, the recorder that answers *yes* at the strings of D always answers, and a deadline for it is a uniform bound for D.

(b) Let T_K be Kleene's tree (Lemma 16.29), and let R read on at the members of T_K and answer *yes* elsewhere. Membership is decided by a program, so R is computable. Every computable run leaves T_K, so R announces on it. For each N, T_K has a member g_N of length N; the run that begins with g_N and continues with zeros is computable, and its records of length at most N are initial segments of g_N, members of T_K, where R reads on.

(c) Suppose FAN_Δ and $\mathrm{MP}_{\mathrm{bin}}$, and let R settle Q. On each run R cannot fail to answer: with no answer, neither Q nor $\neg Q$ could hold. So the binary sequence "R has answered by stage n" is not identically 0, and $\mathrm{MP}_{\mathrm{bin}}$ finds a stage: R always answers. By (a) it has a deadline N, and runs that agree up to N receive the same first answer, hence agree on Q. If R always answers, FAN_Δ alone suffices.

For FAN_Δ from the forward statement, let D be a decidable bar, and let the question ask for the value $\alpha(k)$ of a run at its first hit k, the least k with $\bar{\alpha}k \in D$. The recorder that announces $\alpha(k)$ at stage $k + 1$ always answers and settles this question. Let N fix it. If some run had its first hit at $k \geq N$, flipping its entry k would keep its first N entries and its first hit and change the answer. So every first hit comes before N, and N is a uniform bound.

For $\mathrm{MP}_{\mathrm{bin}}$, let ξ be a binary sequence that is not identically 0, and let $Q(\alpha)$ say that ξ or α has an entry 1. The recorder that answers *yes* at a record of length n once ξ or the record shows a 1 below n, and reads on otherwise, confirms Q; it never answers *no*, and $\neg Q(\alpha)$ never holds, because it would give $\xi \equiv 0$. So it settles Q, it only answers *yes*, and it cannot fail to answer. Let N fix Q, or the answer. The run of zeros agrees up to N with the run whose only 1 is at N, for which Q holds. So Q holds for the run of zeros, and ξ has an entry 1. Conversely, given $\mathrm{MP}_{\mathrm{bin}}$, a recorder that only answers *yes* and cannot fail to answer does answer on every run, so all runs receive the same answer and $N = 0$ serves.

(d) Let a recorder with $s + 1$ states always answer, and let α be a run. Whether it reads on at every stage up to s is decided by inspection; suppose it does. Among the $s + 2$ states reached after $0, 1, \dots, s + 1$ entries, two coincide, at stages $i < j \leq s + 1$. The run that copies α up to place j and then repeats the block of places i to $j - 1$ forever passes only through the states of stages $0, \dots, j - 1$, all of them reading on, so it never answers, a contradiction. Hence the recorder answers at some stage at most s. The counter that moves from state q to $\min(q + 1, s)$ and answers *yes* exactly in state s announces at stage s on every run. The repeating runs used are eventually periodic, hence computable, which gives the last statement. □

24.11 From records to time, quantum, matter and space

How far does a post reach toward a clock that returns, complex amplitudes read by a square law, conserved charges, and a space of cells with a speed limit? We go one step at a time. Either posting decides the step, and we prove the answer, or the step is a premise: we name it, every result above it carries it, and where we can we exhibit two models that agree below the step and differ on it. Results we call free are proved with no omniscience principle and no choice principle; the others in classical mathematics, and we do not claim them on $\mathbb{R}_\delta$. Counts are integers here, so that a count can also be lowered.

A post flips one bit

For a ledger L of d accounts (Definition 24.1) let $x(L) = (D_k - C_k)_k \in \mathbb{Z}^d$ be its balance vector and $p(L) \in \{0, 1\}^d$ its parity pattern, $p_k(L) = x_k(L) \bmod 2$. Two patterns are *adjacent* when they differ in exactly one bit, as along an edge of the d-cube. For $d = 3$ the *weight* $|x|$ of a pattern is its number of ones, e_0, e_1, e_2 are the patterns of weight one, and a *signed permutation* is a map $x \mapsto (x_{\pi(0)} \oplus t_0,\ x_{\pi(1)} \oplus t_1,\ x_{\pi(2)} \oplus t_2)$ with π a permutation of $\{0, 1, 2\}$, $t \in \{0, 1\}^3$ and $\oplus$ addition modulo 2.

Proposition 24.44 (One post flips one bit)**.** *Let L be a ledger of d accounts.*

(a) A debit at account k adds the unit vector e_k to $x(L)$ and a credit subtracts it; no other balance changes. From every ledger, each of the $2d$ unit steps $\pm e_k$ of $\mathbb{Z}^d$ is the change of x made by a post.

(b) A post at account k changes bit k of the parity pattern and no other bit.

(c) For every pattern q, some post takes L to a ledger with pattern q if and only if q is adjacent to $p(L)$.

(d) Let $d = 3$. The bijections f of $\{0,1\}^3$ for which $f(x), f(y)$ are adjacent exactly when x, y are adjacent are the 48 *signed permutations, and they carry every pattern to every pattern. Exactly six of them fix* 000*, the six permutations of the accounts. A signed permutation fixes* 000 *if and only if it keeps the weight of every pattern, and two patterns are carried to each other by one of the six if and only if they have equal weight; the four weight classes have* 1*,* 3*,* 3 *and* 1 *members.*

Proof. (a), (b) A debit at k raises D_k by one and changes no other count, so x_k rises by one and its parity changes; a credit lowers x_k by one. The step $+e_k$ is a debit at k, and $-e_k$ a credit. (c) follows from (b): if q differs from $p(L)$ in bit k only, a debit at k reaches it.

(d) A signed permutation is a bijection and keeps the number of places in which two patterns differ, so it preserves adjacency both ways. It sends 000 to t, and the images of e_0, e_1, e_2, shifted by t, give π; so the $6 \cdot 8 = 48$ signed permutations are distinct, and the maps $x \mapsto x \oplus t$ carry 000 anywhere. Let f preserve adjacency both ways, put $t = f(000)$ and $g(x) = f(x) \oplus t$. Then g fixes 000 and keeps the length of a shortest path from 000, which is the weight, so $g(e_i) = e_{\sigma(i)}$ for a permutation σ. As $e_i \oplus e_j$ is the only pattern of weight two adjacent to both e_i and e_j, $g(e_i \oplus e_j) = e_{\sigma(i)} \oplus e_{\sigma(j)}$, and $g(111) = 111$. So g moves the ones of every pattern by σ, and f is a signed permutation; it fixes 000 exactly when $t = 000$, which leaves the six permutations. With $t \neq 000$ the image of 000 has positive weight, while permutations keep weight and carry any pattern with k ones to any other; there are $\binom{3}{k}$ of them. □

The proposition is free. Eight, here, is a count of patterns; that a recognizer passes through all eight in turn and returns is the premise of Theorem 24.47. Reading the weight as the cost of a state charges the three accounts equally, and that is a premise; taking one account per axis of space is an identification.

Proposition 24.45 (Symmetric charges count odd accounts)**.** *Let G be a commutative monoid, written additively. Call $x, y \in \{0,1\}^3$* independent *when no bit is* 1 *in both, and let $x \vee y$ be their bitwise union. A map $Q : \{0,1\}^3 \to G$ is an* additive charge *when $Q(000) = 0$ and $Q(x \vee y) = Q(x) + Q(y)$ for all independent x, y.*

(a) Q is an additive charge if and only if $Q(x) = x_0 q_0 + x_1 q_1 + x_2 q_2$ for some $q_0, q_1, q_2 \in G$; then $q_i = Q(e_i)$.

(b) An additive charge is unchanged by the six permutations of the accounts if and only if $q_0 = q_1 = q_2$, and then $Q(x) = |x|\, q_0$. In that case $Q(111) = 3Q(x)$ when $|x| = 1$ and $2Q(111) = 3Q(x)$ when $|x| = 2$; for an integer charge, 3 *divides* $Q(111)$.

Proof. (a) A pattern is the union of the pairwise independent e_i with $x_i = 1$; conversely the bits of independent patterns add. (b) The transposition of accounts i and j sends e_i to e_j; conversely $|x| q_0$ is invariant, and $|111| = 3$. □

The proposition is free. The pattern of a ledger marks its accounts with odd balance, so a symmetric additive charge counts the odd accounts. The thirds are arithmetic; we identify these charges with no physical charge.

A process returns exactly when its item time is uniform

Definition 24.46 (Processes and items)**.** A *process* on d accounts is a sequence $w = (w_n)_{n\geq 0}$ in $\{0,1\}^d$. The pass of T ticks from n, $(w_n, \dots, w_{n+T-1})$, is *read as one item* when it contains every pattern. The process *advances by finest changes* when w_n and w_{n+1} are adjacent for every n; it *completes* when from every n some pass is read as one item; it is *state-local* when $w_i = w_j$ implies $w_{i+1} = w_{j+1}$. It has a *uniform item time* L when for every n the pass of L ticks from n is read as one item and no shorter pass from n is.

Theorem 24.47 (A process returns after 2^d ticks exactly when its item time is uniform)**.** *For a process w on d accounts the following are equivalent: (i) w has a uniform item time; (ii) every pass of 2^d ticks is read as one item; (iii) $w_{n+2^d} = w_n$ for every n, and $(w_0, \dots, w_{2^d-1})$ contains every pattern; (iv) w completes and is state-local. Then the item time is 2^d and the least period of w is 2^d. The Gray process, which repeats the patterns of three accounts in the order $0, 1, 3, 2, 6, 7, 5, 4$ (a pattern read as $x_0 + 2x_1 + 4x_2$), advances by finest changes and meets these conditions. The process on two accounts that repeats $00, 01, 11, 10, 11, 01, 00, 10$ advances by finest changes and reads every pass of four ticks from a multiple of four as one item, and meets none of them.*

Proof. A pass read as one item has at least 2^d ticks, and a pass of 2^d ticks is read as one item exactly when it repeats no pattern. (i)⇒(ii): let the item time be L. If $w_n = w_{n+j}$ with $1 \leq j < L$, the pass of $L-1$ ticks from $n+1$ would contain every pattern, which the item time from $n+1$ forbids. So windows of L ticks repeat no pattern, $L \leq 2^d$, and $L = 2^d$. (ii)⇒(iii): w_n does not recur among $w_{n+1}, \dots, w_{n+2^d-1}$, and the pass from $n+1$ contains it, so $w_{n+2^d} = w_n$. (iii)⇒(ii): the pass from n is a cyclic shift of the first. (ii)⇒(i) with $L = 2^d$. (iii)⇒(iv): the first pass repeats no pattern, so $w_i = w_j$ gives $i \equiv j \pmod{2^d}$ and $w_{i+1} = w_{j+1}$. (iv)⇒(iii): state-locality gives a map s with $w_{n+1} = s(w_n)$. Completion from 1 makes w_0 recur; let $m > 0$ be least with $w_m = w_0$. Then w has period m, and $w_0, \dots, w_{m-1}$ are distinct (a repeat $w_i = w_j$, $i < j < m$, would give $w_{i+m-j} = w_0$). By completion they are all 2^d patterns, so $m = 2^d$. A period $p < 2^d$ would repeat a pattern inside the first pass. The Gray order changes one bit per step, also from 4 back to 0, and lists all eight patterns. In the two-account process each block of four contains every pattern, and $w_4 = 11 \neq 00 = w_0$. □

Conditions and scope.

Base and premises

Sequences of patterns; finite counting, in classical mathematics.

Conclusion

A uniform item time, return after 2^d ticks with a complete first pass, and completion with a next state fixed by the present one are one premise in four forms; under it the period is 2^d, eight for three accounts.

Not claimed

That a recognizer's ticks have a uniform item time; the two-account process shows posting does not force it.

The finest changes, and the ones that count

A change $L \to L'$ of a ledger of d accounts is *finest* when $\sum_k |D'_k - D_k| + \sum_k |C'_k - C_k| = 1$. The *unrecord* at account k on a side lowers that count by one, and the *record total* is $|L| = \sum_k (D_k + C_k)$. For a finite set V of recognizers, each v with its own ledger M_v, a *joint tick* $M \to M'$ is a change in which every recognizer either holds or makes a finest change raising its own record total by one; it is *serial* when exactly one recognizer changes.

Theorem 24.48 (The finest changes are posts and unrecords, and only posts count)**.** *Let L, L' be ledgers of d accounts.*

(a) $L \to L'$ is finest if and only if L' is a post or an unrecord of L. Every unrecord has step cost $G(1)$, by the formula of Definition 24.18, as a debit does; posts and unrecords each change exactly one bit of the parity pattern, and each is a bijection of the set of ledgers.

(b) A finest change raises the record total by one if and only if it is a post, and then it lowers no count. A change is monotone with $\sum_k |D'_k - D_k| + \sum_k |C'_k - C_k| = 1$ if and only if it is finest and raises the record total by one.

(c) After a list of h finest changes the record total has risen by exactly h if and only if every change in the list is a post; then no count was lowered.

(d) The joint ticks are exactly the changes in which each recognizer holds or posts one unit. If m recognizers post, the joint total $\sum_v |M_v|$ rises by m, and the individual unit counts sum to m. So a joint tick raises the joint total by one, and is a finest change of the joint ledger, exactly when it is serial; over a history of joint ticks in each of which someone posts, the joint total rises by the number of ticks exactly when every tick is serial.

Proof. (a) A sum of absolute values of integer differences is 1 exactly when one difference is ± 1 and the others vanish. A change of one count by ± 1 costs $G(\pm 1) = G(1)$, moves one balance by ± 1 and so one parity bit, and is inverted by the opposite change. (b) A post raises the total by one, an unrecord lowers it by one, and a monotone change of unit size is a post. (c) Each change moves the total by ± 1. (d) By (b) a recognizer that does not hold posts; each poster adds one to its total and to its unit count. Over a history the joint total rises by the sum of the numbers of posters, each at least one, which equals the number of ticks exactly when each is one. □

The theorem is proved by integer arithmetic and claimed in classical mathematics. Counting occurrences selects the posts among the finest changes, and a joint record counts events, not ticks, unless the ticks are serial. That nature's finest changes are posts is the posting premise itself, read on counts (the count reading); the ledgers of Proposition 24.44 change by posts, and cost, the one-bit flip and invertibility do not tell a post from an unrecord. Seriality is a premise: one poster and two posters both make joint ticks.

Two ticks are the imaginary unit

A *tick register* is a real vector space with a linear map T, the tick. A recognizer whose state is a function on its eight patterns has the tick register $\mathbb{R}^8$ of functions on $\mathbb{Z}/8$ with the shift $(Sf)(t) = f(t+1)$, and its *core* is $\mathscr{C} = \{f : f(t+4) = -f(t) \text{ for all } t\}$.

Theorem 24.49 (Four ticks reverse, and two ticks are i). *Let T be a linear map of a vector space V over a field in which $2 \neq 0$, with $T^8 = 1$.*

(a) $T^4 v = -v$ for every v if and only if no nonzero v has $T^n v = v$ with $0 < n < 8$.

(b) If $T^4 = -1$, then $(T^2)^2 = -1$. Over $\mathbb{R}$, V is then a complex vector space with i acting as T^2, T is complex linear, and every v is uniquely $a + b$ with $Ta = \zeta a$ and $Tb = -\zeta b$, where $\zeta = (1 + i)/\sqrt{2}$, $\zeta^2 = i$ and $\zeta^8 = 1$.

(c) On $\mathbb{R}^8$, $S^4 f = -f$ exactly when $f \in \mathscr{C}$; a subspace invariant under S has no nonzero state returning before eight ticks exactly when it lies in $\mathscr{C}$; no linear J on $\mathbb{R}^8$ with $J^2 = -1$ commutes with S; and for $k < 8$, S^k squares to -1 on $\mathscr{C}$ exactly when $k = 2$ or $k = 6$.

Proof. (a) Let $T^4 = -1$ and $T^n v = v$ with $0 < n < 8$. Some multiple jn is congruent to $g = \gcd(n, 8)$ modulo 8, so $T^g v = v$; as g divides 4, $T^4 v = v = -v$, and $v = 0$. Conversely $w = v + T^4 v$ has $T^4 w = w$, so $w = 0$. (b) $(T^2)^2 = T^4 = -1$, so $(a + bi)v = av + bT^2 v$ makes V complex, and T commutes with T^2. As operators $\zeta^2 = i = T^2$, so $(T - \zeta)(T + \zeta) = 0$; then $a = (T + \zeta)v/(2\zeta)$ and $b = -(T - \zeta)v/(2\zeta)$ split v. If $a + b = 0$, then $\zeta a = Ta = -Tb = \zeta b = -\zeta a$, so $a = b = 0$. (c) $(S^4 f)(t) = f(t + 4)$; the second claim is (a) on the subspace. If J commutes with S, then $J\mathbf{1}$ is fixed by S, so $J\mathbf{1} = c\mathbf{1}$ with c real and $J^2\mathbf{1} = c^2\mathbf{1} \neq -\mathbf{1}$. On $\mathscr{C}$, $S^4 = -1$, and S^2 is not ± 1 (it sends $e_0 - e_4$ to $e_6 - e_2$), so $S^{2k} = -1$ exactly when $2k \equiv 4 \pmod 8$. □

The theorem is proved in classical mathematics, the identity $(T^2)^2 = -1$ with no choice principle. That a recognizer's state lives on this tick register is a premise, and so is the half turn: the shift fixes the constants of $\mathbb{R}^8$ and reverses every state of $\mathscr{C}$. Which complex structure a recognizer uses is not decided either: S^2 and S^6 both square to -1 on the core.

Proposition 24.50 (Pairs of recognizers and the sign of the pass).

(a) Let T_1, T_2 be commuting linear maps of a space U over a field in which $2 \neq 0$, with $T_1^4 = T_2^4 = -1$. Then $(T_1 T_2)^4 = 1$. Every v is uniquely the sum of $\frac{1}{2}(v - T_1^2 T_2^2 v)$ in $\ker(T_1^2 - T_2^2)$, where the imaginary units agree, and $\frac{1}{2}(v + T_1^2 T_2^2 v)$ in $\ker(T_1^2 + T_2^2)$, where they are opposite; $(T_1 T_2)^2$ is -1 on the first and $+1$ on the second.

(b) For signs $s(t) \in \{\pm 1\}$ let $(T_s f)(t) = s(t) f(t + 1)$ on $\mathbb{R}^8$. Then $T_s^8 = (\prod_t s(t)) \cdot 1$. Conjugating by multiplication with signs $g(t)$ replaces $s(t)$ by $g(t)s(t)g(t + 1)$, which keeps $\prod s$; for $g(t) = s(0) \cdots s(t - 1)$ the new signs are 1 except at $t = 7$, where the sign is $\prod s$. Eight ticks reverse every state exactly when $\prod s = -1$.

Proof. (a) With $A = T_1^2$, $B = T_2^2$: $A^2 = B^2 = -1$, $AB = BA$, $(T_1 T_2)^4 = A^2 B^2 = 1$, $(A - B)(1 - AB) = A - A^2 B - B + AB^2 = 0$ and likewise $(A + B)(1 + AB) = 0$. If $Av = Bv$ and $Av = -Bv$, then $Bv = 0$ and $v = -B^2 v = 0$. On the first kernel $ABv = A^2 v = -v$, on the second $ABv = -A^2 v = v$. (b) $(T_s^8 f)(t) = s(t) \cdots s(t + 7) f(t + 8)$; the product of $g(t)s(t)g(t + 1)$ is $\prod s \prod g^2$; and the cumulative g has $g(t + 1) = g(t)s(t)$ for $t < 7$. □

So two half-turn recognizers ticking together split their joint tick register into a part where their imaginary units agree, on which two joint ticks act as -1, and a part where the units

are opposite and two joint ticks act as +1. Up to sign convention there are two eight-tick passes, the plain one and the twisted one, which reverses every state after a full pass as a spin one-half state does under a full turn (an identification); both are passes on the same eight states, so the sign is a premise. Whether the exchange sign of two identical recognizers is tied to the twist, as in the spin-statistics connection, is open. The identity $(T_1T_2)^4 = 1$ and the values ∓ 1 of $(T_1T_2)^2$ are free; the rest is proved in classical mathematics.

The square law from phase blindness

In the complex structure $i = S^2$ of the core, multiplication by $\zeta = (1+i)/\sqrt{2}$ is $(Pf)(t) = \big(f(t) + f(t+2)\big)/\sqrt{2}$. What can a read of a tick register state be?

Definition 24.51 (Reads and the five read premises)**.** A *read* assigns a real number $\mu(f, A)$ to every state $f \in \mathbb{R}^8$ and every set $A \subseteq \mathbb{Z}/8$ of positions. The *read premises* are: (R1) there is one $\varphi : \mathbb{R} \to \mathbb{R}$ with $\mu(f, \{t\}) = \varphi(f(t))$ for all f and t; (R2) $\mu(f, A) = \sum_{t \in A} \mu(f, \{t\})$; (R3) $\varphi(0) = 0$; (R4) $|x| \le |y|$ implies $\varphi(x) \le \varphi(y)$; (R5) $\mu(Pf, \mathbb{Z}/8) = \mu(f, \mathbb{Z}/8)$ for every $f \in \mathscr{C}$: the total read of a core state does not see the phase made of ticks.

Lemma 24.52 (Monotone quadratic functions are squares)**.** *Let $g : \mathbb{R} \to \mathbb{R}$ satisfy $g(0) = 0$, $g(x+y) + g(x-y) = 2g(x) + 2g(y)$ for all real x, y, and $g(x) \le g(y)$ whenever $|x| \le |y|$. Then $g(x) = g(1)x^2$ for every real x.*

Proof. Monotonicity gives $g(-x) = g(x)$ and $g(1) \ge g(0) = 0$. Putting nx and x for x and y gives $g((n+1)x) = 2g(nx) + 2g(x) - g((n-1)x)$, so $g(nx) = n^2 g(x)$ by induction, $g(x/m) = g(x)/m^2$, and $g(q) = q^2 g(1)$ for rational $q \ge 0$. For real $x \ge 0$ and rationals $0 \le p \le x \le q$, $p^2 g(1) \le g(x) \le q^2 g(1)$; let $p, q \to x$. □

The equation is the parallelogram law of Jordan and von Neumann [143]; some regularity is needed, since $g = A^2$ solves it for every additive, possibly nonlinear, A [97].

Theorem 24.53 (The square law from phase blindness)**.** *If a read meets (R1) to (R5), then for every state $f \in \mathbb{R}^8$ and every set A of positions*

$$\mu(f, A) = \varphi(1) \sum_{t \in A} f(t)^2.$$

The square reads, $\varphi(x) = x^2$, meet (R1) to (R5). The magnitude reads, $\mu(f, A) = \sum_{t \in A} |f(t)|$, meet (R1) to (R4) and fail (R5).

Proof. By (R4), φ is even. For real a, b the core state $f_{a,b} = a(e_0 - e_4) + b(e_2 - e_6)$ has entries $a, b, -a, -b$ at $0, 2, 4, 6$ and 0 elsewhere, so its total read is $2\varphi(a) + 2\varphi(b)$, and $Pf_{a,b} = f_{(a+b)/\sqrt{2},\,(b-a)/\sqrt{2}}$. So (R5) gives $\varphi(a) + \varphi(b) = \varphi\big(\frac{a+b}{\sqrt{2}}\big) + \varphi\big(\frac{a-b}{\sqrt{2}}\big)$. With $b = 0$ this is $\varphi(\sqrt{2}u) = 2\varphi(u)$; with $a = x+y$, $b = x-y$ it becomes $\varphi(x+y)+\varphi(x-y) = \varphi(\sqrt{2}x)+\varphi(\sqrt{2}y) = 2\varphi(x)+2\varphi(y)$. Lemma 24.52 and (R1), (R2) give the formula, with $\varphi(1) \ge \varphi(0) = 0$. The square reads meet (R5) because $\sum_t (Pf)(t)^2 = \sum_t f(t)^2 + \sum_t f(t)f(t+2)$, and on $\mathscr{C}$ the last sum is its own negative under $t \mapsto t+2$. For the magnitude reads, $f_{1,0}$ has total 2 and $Pf_{1,0}$ has total $2\sqrt{2}$. □

Conditions and scope.

Base and premises

The classical real numbers; the read premises of Definition 24.51, with (R5) for the unit $i = S^2$; in classical mathematics. Applied to a recognizer, the theorem also needs its state to live on $\mathbb{R}^8$ with the shift.

Conclusion

A read that depends on the amplitude at each position by one rule, adds over positions, vanishes on empty positions, grows with the magnitude and does not see the phase made of ticks is proportional to the squared amplitude, the form of Born's rule [139]. No normalization, homogeneity or continuity is assumed.

Not claimed

A probability: no ratio form is proved, and $\varphi(1)$ is not fixed ($\varphi = 0$ meets every premise). The read premises remain premises.

Proposition 24.54 (Two recognizers: the square law and product records)**.** *On functions F on $(\mathbb{Z}/8)^2$ let $\mathscr{C}_2 = \{F : F(s{+}4,t) = -F(s,t) = F(s,t{+}4)\}$ and $(P_1F)(s,t) = \big(F(s,t){+}F(s{+}2,t)\big)/\sqrt{2}$, the first recognizer's phase. Let a read μ of $\mathscr{C}_2$ on sets of pairs of positions meet (R1) to (R4) for single pairs and (R5) in the form $\mu(P_1F, all) = \mu(F, all)$. Then $\mu(F, A) = \varphi(1)\sum_{p\in A} F(p)^2$ for every $F \in \mathscr{C}_2$, and for $f, g \in \mathscr{C}$, the product state $F(s,t) = f(s)g(t)$ and all sets A_1, A_2,*

$$\mu(F, A_1 \times A_2)\,\mu(F, all) = \mu(F, A_1 \times all)\,\mu(F, all \times A_2).$$

Proof. The product of $f_{a,b}$ with $e_0 - e_4$ has entries $\pm a$ at four pairs and $\pm b$ at four, total read $4\varphi(a) + 4\varphi(b)$, and P_1 acts on it as P on $f_{a,b}$; the proof of Theorem 24.53 applies. For a product state $\sum_{A_1\times A_2} f(s)^2 g(t)^2 = \sum_{A_1} f^2 \sum_{A_2} g^2$. □

Reading $\mathscr{C}_2$ as the joint tick register of two recognizers is a premise. Independence holds in this cross-multiplied form, for real product states, in classical mathematics; we do not prove that recognizers compose by the complex tensor product, nor independence at single positions for complex states without entanglement.

The premise (R1), that the read of a position depends only on the amplitude there, is the one the square law still rests on, and (R2) and (R5) do not imply it (Proposition 24.55). Such noncontextual reads also start Gleason's theorem, which needs complex dimension at least three [141]; the core has two.

Proposition 24.55 (A contextual read)**.** *For $f \in \mathscr{C}$ put $\|f\|^2 = \sum_t f(t)^2$ and, for $f \neq 0$,*

$$\kappa(f, \{t\}) = f(t)^2 + \frac{f(t)^2\big(f(t+1)^2 - f(t-1)^2\big)}{2\|f\|^2},$$

with $\kappa(0, \{t\}) = 0$, and $\kappa(f, A) = \sum_{t\in A} \kappa(f, \{t\})$. Then κ vanishes at positions where $f(t) = 0$, is nonnegative, and has total $\|f\|^2$, so it meets (R2) and (R5). No φ satisfies $\kappa(f, \{t\}) = \varphi(f(t))$ for all $f \in \mathscr{C}$ and t.

Proof. Since $f(t-1)^2 \le \|f\|^2$, $\kappa(f,\{t\}) \ge f(t)^2/2$. In the total the terms $f(t)^2 f(t+1)^2$ and $f(t)^2 f(t-1)^2$ cancel under $t \mapsto t+1$, and P keeps $\|f\|^2$ on $\mathscr{C}$ (proof of Theorem 24.53). Finally $e_0 - e_4$ and $e_0 + e_1 - e_4 - e_5$ have amplitude 1 at position 0, where κ reads 1 and $\frac{9}{8}$. □

Read across states, (R4) says that $|f(t)| \le |g(s)|$ implies $\mu(f,\{t\}) \le \mu(g,\{s\})$, and this is exactly (R1) with (R4): applied both ways to equal amplitudes it gives equal reads, so $\varphi(x) = \mu\big(x(e_0 - e_4),\{0\}\big)$ meets (R1) and (R4); the converse is immediate. The contextual read fails it at position 0. So the square law rests on (R1) with (R4), and the proposition shows that (R2), (R5), vanishing at empty positions and nonnegativity do not imply (R1). The proposition is proved in classical mathematics.

Conserved totals and charges

A *writing rule* on d accounts gives, for accounts $s \ne t$ and an integer n (a comparison of s with t taken n times), an increment $R(s,t,n) \in \mathbb{Z}^d$ of the balance vector x. It is *additive* when $R(s,t,n+m) = R(s,t,n) + R(s,t,m)$, *local* when $R(s,t,n)_k = 0$ for $k \notin \{s,t\}$, and *name-independent* when $R(t,s,n)_k = R(s,t,n)_{\tau(k)}$, τ the transposition of s and t. It *keeps the balance total* $\sum_k x_k$ when $\sum_k R(s,t,n)_k = 0$, and has the *reversal symmetry* when $R(s,t,n) = R(t,s,-n)$, for all $s \ne t$ and n. A *transfer* from t to s is $e_s - e_t$; made by a debit at s and a credit at t, it keeps the balance total and raises the record total $|L|$ by two.

Theorem 24.56 (Noether on the ledger)**.**

(a) An additive local rule has $R(s,t,n) = n(a\,e_s + b\,e_t)$ with $a = R(s,t,1)_s$ and $b = R(s,t,1)_t$, and changes the balance total by $n(a+b)$.

(b) For an additive, local, name-independent rule the following are equivalent: it keeps the balance total; it has the reversal symmetry; every event is an integer multiple of a transfer; $R(s,t,n) = n\,a(s,t)(e_s - e_t)$ for all $s \ne t$ and n.

(c) If $d \ge 2$, the one-sided rule $R(s,t,n) = n\,e_s$ and the two-sided rule $R(s,t,n) = n(e_s - e_t)$ are additive, local and name-independent; the second has the reversal symmetry and keeps the balance total, the first has neither.

Proof. (a) Additivity makes $n \mapsto R(s,t,n)$ a homomorphism from $\mathbb{Z}$, and locality leaves two entries. (b) Name-independence gives $R(t,s,1)_t = a$ and $R(t,s,1)_s = b$, so $R(t,s,-n) = -n(a\,e_t + b\,e_s)$. The reversal symmetry, the kept balance total and being a multiple of $e_s - e_t$ each say $a = -b$, which is the last form. (c) Direct substitution; the one-sided rule changes the balance total by n. □

Conditions and scope.

Base and premises

Integer vectors; additive, local, name-independent writing; in classical mathematics.

Conclusion

One discrete symmetry, reading a comparison the same from either end, is equivalent to one conserved quantity, the balance total, and to double entry: every event is a multiple

of one transfer. It is an equivalence of Noether's type [144] for one symmetry and one quantity.

Not claimed

The reversal symmetry: both rules of (c) meet everything else, so whether an event has a distinguished end is a premise, and with it double entry and conservation.

Above the reversal symmetry every event is a transfer. Let $N \geq 1$ recognizers each have one account per axis, so that accounts are pairs (s, a) of a site s and an axis $a \in \{0, 1, 2\}$, and let their ledgers sit side by side. A *transfer law* E is a set of ordered pairs of accounts between which a unit may move; a linear charge with integer weights q is $\sum_u q(u)x_u$. The law is *axis-covariant* when the six permutations of the axes, applied at every site at once, carry E into itself, and *site-connected* when a property of sites that holds at one end of each transfer exactly when it holds at the other, and holds at one site, holds at all.

Proposition 24.57 (One conserved charge or three, never two)**.** *A linear charge is unchanged by every transfer of E, from every ledger, exactly when $q(u) = q(v)$ for every $(u, v) \in E$. Let E be axis-covariant and site-connected. If every transfer keeps its axis, the conserved charges are exactly those with $q(s, a) = c(a)$: the three axis totals and their combinations. If some transfer changes axis, they are exactly the constant weights: the balance total. Both cases occur for every $N \geq 1$.*

Proof. A transfer along (u, v) changes the charge by $q(u) - q(v)$. Let q be conserved and $((s, a), (s', b)) \in E$; by covariance $q(s, \pi a) = q(s', \pi b)$ for the six permutations π. If $a = b$ this gives $q(s, c) = q(s', c)$ for all c; if $a \neq b$ it gives $q(s, c) = q(s', c')$ for all $c \neq c'$, so all six weights at s and s' are equal. Either way "$q(s, c) = q(s_0, c)$ for all c" passes along transfers and holds at every site, and an axis-changing transfer makes the three weights equal. The converses are immediate. The law of all axis-keeping transfers conserves the total of axis 0; the law of all transfers changes axes. □

The proposition is proved in classical mathematics and carries the reversal symmetry and the side-by-side composition of ledgers as premises. Which case holds depends on whether an exchange moves a unit between axes, a property of the joint law that posting does not decide.

Cells, a speed limit and linking

A *face gluing* of a set V of voxels is a triple of bijections $\sigma_0, \sigma_1, \sigma_2$ of V: the $+k$ face of v is glued to the $-k$ face of $\sigma_k(v)$. It is *connected* when every voxel is reached from every voxel across faces, *flat* when the σ_k commute, and *free* when no nonzero $x \in \mathbb{Z}^3$ fixes a voxel under $\sigma^x = \sigma_0^{x_0}\sigma_1^{x_1}\sigma_2^{x_2}$. Under *local transport* a debit on account k carries a located unit from v to $\sigma_k(v)$ and a credit to $\sigma_k^{-1}(v)$.

Proposition 24.58 (Flat gluings are lattices, and local transport has speed one)**.**

(a) Let a gluing be flat and connected, and $v_0 \in V$. The stabilizer $\Lambda = \{x : \sigma^x v_0 = v_0\}$ is the same for every v_0, and $x + \Lambda \mapsto \sigma^x v_0$ is a bijection $\mathbb{Z}^3/\Lambda \to V$ carrying $x + e_k$ to σ_k of the image of x; Λ is the only subgroup with such a bijection, and V has $[\mathbb{Z}^3 : \Lambda]$ voxels, both sides possibly infinite. A flat, connected, free gluing is $\mathbb{Z}^3$ with unit translations, unique up to a translation.

(b) Four voxels with $\sigma_0 = \sigma_2$ the rotation $(0\,1\,2\,3)$ and σ_1 the reflection $(0\,1)(2\,3)$ form a connected gluing that is not flat.

(c) Under local transport n posts move a unit across at most n faces; on $\mathbb{Z}^3$ at most ℓ^1 distance n, and n debits on one axis move it exactly n. The rule that carries the unit across two faces per post gives every unit the same balance history as local transport, and is not local.

Proof. (a) Flatness makes $x \mapsto \sigma^x$ an action of $\mathbb{Z}^3$, transitive by connectedness. For $w = \sigma^y v_0$, $\sigma^x w = w$ exactly when $\sigma^x v_0 = v_0$, since the σ^x commute; so all stabilizers are equal, and the map is well defined, injective, onto and equivariant. An equivariant bijection from $\mathbb{Z}^3/\Lambda'$ sends 0 to a voxel with stabilizer Λ', so $\Lambda' = \Lambda$. A free gluing has $\Lambda = 0$, and two equivariant bijections from $\mathbb{Z}^3$ differ by a translation. (b) $\sigma_0\sigma_1(0) = 2 \neq 0 = \sigma_1\sigma_0(0)$, and σ_0 alone connects the voxels. (c) Each post crosses one face, and on $\mathbb{Z}^3$ changes one coordinate by one; the balance moves by the same unit step under either rule. □

The proposition is proved in classical mathematics, the bound in faces crossed, on every gluing, with no choice principle. Consistently glued voxels form the cubic lattice or a periodic quotient, and a locally carried unit moves at most one face per post. Flatness is a premise, and (b) shows that posting does not decide it. Local transport and the reading of a voxel's six posts as its six faces are identifications: by (c) the balances do not see how a unit is carried.

Last, three dimensions. In the cubical cell structure of $\mathbb{R}^D$ a cell is a unit cube spanned by a set of coordinate directions at an integer base point, and its *dual cell* is the unit cube spanned by the other directions, centred at the cell's centre. A configuration of a posted pair is a primal trace b, a finite integer combination of edges with zero boundary, and a dual trace $a = \delta c$, the coboundary of a finite integer combination c of $(D-2)$-cells. A *move* is $a \mapsto a \pm \delta \mathbf{1}_f$ for a $(D-2)$-cell f whose dual cell meets no edge of b, or $b \mapsto b \pm \partial p$ for a plaquette p that meets the dual cell of no cell q with $a(q) \neq 0$; configurations are *deformable* into each other when moves and reversed moves join them. The *elementary pair* is $b_0 = \partial p_0$, p_0 the unit square at the origin in directions $0, 1$, with $a_0 = \delta \mathbf{1}_{f_0}$, f_0 the $(D-2)$-cell at the origin spanning every direction except 1 and 2; the *split* configuration is $(0, 0)$.

Proposition 24.59 (A posted pair stays linked exactly in three dimensions)**.** *Let $D \geq 3$.*

(a) For $D = 3$ the pairing $\langle c, b \rangle$ depends only on the traces $a = \delta c$ and b, and no move changes it. It is 1 on the elementary pair and 0 on the split configuration, so the elementary pair is not deformable into the split configuration.

(b) For every $D \geq 4$ the elementary pair reaches the split configuration in two moves.

Proof. A cell meets the dual cell of τ only if it spans every direction of τ, and every cell meets its own dual at its centre. (a) If $\delta c = \delta c'$, then $c - c'$ is a cocycle on the edges of $\mathbb{Z}^3$, hence δg for a function g on vertices, since every closed edge path in the cubical lattice bounds a sum of plaquettes; so $\langle c - c', b\rangle = \langle g, \partial b\rangle = 0$. A move of a by the edge f changes the pairing by $\pm b(f)$, and $b(f) = 0$, or f would be an edge of b meeting its own dual. A move of b by p changes it by $\pm\langle c, \partial p\rangle = \pm a(p)$, and $a(p) = 0$ since p meets its own dual. On the elementary pair f_0 is the edge from the origin in direction 0, which ∂p_0 traverses once. (b) For $D \geq 4$, f_0 spans $D - 2 \geq 2$ directions, so no edge meets its dual cell and $a_0 \mapsto 0$ is a move; then $b_0 \mapsto 0$ is a move. □

Conditions and scope.

Base and premises

The integer cubical lattice of $\mathbb{R}^D$; in classical mathematics. Reading a posted pair as two traces, space as $\mathbb{Z}^D$, and free motion as exactly the unblocked one-cell moves are identifications.

Conclusion

The linking number of the traces [146] is kept by every move in three dimensions, and the smallest linked pair cannot be separated; from four dimensions up it comes apart in two moves, because an edge meets the dual cell of a $(D-2)$-cell only when $D - 2 \leq 1$. So the premise that free motion cannot erase a posted pair holds for this realization exactly when $D = 3$.

Not claimed

Why traces are curves, why crossing is forbidden, why space is a lattice, and dimensions below three.

Posting decides the first step outright, for ledgers that change by posts: the count reading. Above it the premises are a uniform item time, serial ticks, the tick register with the sign of its pass and its half turn, the read premises, the joint tick register of two recognizers (commuting ticks, and $\mathscr{C}_2$ for the square law), equal account costs, the reversal symmetry, the side-by-side composition of ledgers and flatness; one account per axis, local transport, the six faces and the trace kinematics are identifications. For a uniform item time, serial ticks, the half turn, the sign of the pass, (R1), (R5), the reversal symmetry and flatness, the results above exhibit two models that differ on the premise.

24.12 Which values the world keeps real

Chapter 20 named the identification of access: the physically real collections are those whose members each leave a record from which they are read back. That identification is a statement about a world, about which histories of acts can occur in it. This section makes the world explicit and asks the concrete question: in which worlds are the natural numbers physically real? The answer is a statement about storage. A world in which comparisons reach a patch of records keeps the natural numbers real exactly when the patch's capacity grows without bound; for the patch of the Hubble sphere, exactly when the expansion rate at the acts comes arbitrarily close to 0. Deciding that, for every capacity, costs exactly Σ_2 excluded middle.

Definition 24.60 (Acts, worlds and real collections)**.**

1. A *record* is a finite binary word. An *act* is one of: post a record p; retain (advance the stage, keeping every record); compare the records at positions i and j. A *history* is a finite list of acts. Its *ledger* lists the posted records in order, the outcomes of the comparisons (a comparison of two present records registers whether they agree, and one with an absent term registers nothing), and the stage.

2. A *world* W is a set of histories, its *permitted* ones, that contains the empty history and every prefix of a permitted history.

3. A *recognition observable* in W on a set X assigns to each $x \in X$ a permitted history $o(x)$ such that for $x \neq y$ some continuation c and some act a, permitted after both $o(x)c$ and $o(y)c$, give different results. X is *real in* W when such an observable on X exists. Let $\mathscr{A}$ be the world in which every history is permitted. *Access holds in* W when every set real in $\mathscr{A}$ is real in W and conversely.

4. The *window cost* of a list of records is the number of their bits plus one per record. Position p of a list is *within* N when it holds a record and the records from p on have window cost at most N.

5. For a *capacity* $\mathrm{cap} : \mathbb{N} \to \mathbb{N}$ the *patch world* W_{cap} permits the histories whose posts are single bits and whose every comparison, made after t acts, addresses two positions within $\mathrm{cap}(t)$.

Three statements about a world are identifications, physical premises that the theorems take as hypotheses. *Patch reach*: every history of W_{cap} is permitted in W; the patch can carry out every comparison its records allow, after any number of acts that post nothing. *Locality* (the time window): in W, every comparison made after t acts addresses two positions within $\mathrm{cap}(t)$. *Posting reach*: every history of W_{cap} that consists of one-bit posts followed by one comparison is permitted in W. Access holds in W exactly when the natural numbers are real in W; this is the form in which the theorems below state realness.

Theorem 24.61 (The capacity decides the natural numbers)**.** *Let W be a world and* cap *a capacity.*

1. *With patch reach, if for every N some t has $\mathrm{cap}(t) \geq N$, the natural numbers are real in W and access holds.*

2. *With posting reach, if for every T some $t \geq T$ has $2t \leq \mathrm{cap}(t)$, access holds.*

3. *With locality, if* cap *is bounded, every set real in W is finite, and access fails.*

4. *With patch reach and locality, access holds exactly when* cap *is not bounded.*

Parts 1 and 2, with the growth stated as in their hypotheses, are free. Parts 3 and 4 are proved in classical mathematics.

Proof. 1. Let the value n occur as $n+1$ one-bit marks and a blank, followed by retain acts up to the first stage $t(n) \geq n+2$ with $\mathrm{cap}(t(n)) \geq 2(n+2)$. The search for $t(n)$ terminates: by hypothesis some t has $\mathrm{cap}(t)$ above $2(n+2)$ and above $\mathrm{cap}(s)$ for every $s < n+2$, and such a t is at least $n+2$. So nothing is chosen, and the whole record, of window cost $2(n+2)$, is within the capacity at that stage. Patch reach permits these histories and, at their end, every comparison of two of their positions. For $n < m$ compare positions $n+1$ and 0, with the empty continuation: in the run of n they hold the blank and a mark and disagree; in the run of m they hold two marks and agree. So the natural numbers are real in W. Access follows: a set real with every act available is the image of an injection into the natural numbers, through its records, and a recognition observable restricts along an injection.

2. The same, with the occurrence of n continued by marks, not retain acts, up to the first stage $t(n) \geq n+2$ with $2t(n) \leq \mathrm{cap}(t(n))$; the record then has window cost $2t(n)$.

3. Let $\mathrm{cap} \leq N$. If two runs hold record counts that differ by more than N, no position lies within N in both after any common continuation, so no comparison is permitted after both, and posts and retains register nothing: the two values are never told apart. So the values of a real set have record counts within N of one another, and two of them with equal counts and equal records within the window are never told apart, since every comparison after a common continuation reads positions that are either in that window or posted by the continuation. The counts of a real set lie in an interval of length N and the windows hold boundedly many bits, so finitely many classes remain, and the natural numbers are not real.

4. Parts 1 and 3, with "not bounded" turned into "exceeds every bound", a step whose price Theorem 24.62 computes. □

Whether a capacity is unbounded is a Π_2 question about the infinite future: no finite list of capacities decides it, since every finite list extends both to a bounded and to an unbounded capacity. Its price is exact.

Theorem 24.62 (The price of availability)**.** *With no choice principle in either direction:*

1. Deciding availability, *"every capacity* $\mathrm{cap} : \mathbb{N} \to \mathbb{N}$ *exceeds every bound at some act, or stays below some bound", is equivalent to* Σ_2 *excluded middle (Definition 29.26), and implies LPO.*

2. The unbounded witness, *"every capacity that is not bounded exceeds every bound at some act", is equivalent to Markov's principle.*

No omniscience principle and no choice principle is used in any of the implications.

Proof. The Π_2 *split* says: for every binary double sequence β, every row has a 1, or some row is all 0.

Deciding availability gives LPO. For a binary sequence α let the flag capacity be 0 at stage t until α has shown a 1, and $t+1$ from then on. It is unbounded exactly when α has a 1; if it stays below N, α has no 1, since a 1 at place n would give $t+1 \geq N$ at $t = \max(n, N)$.

Deciding availability gives the split. For β let $\mathrm{cap}(t)$ count the leading rows $0, 1, \ldots$ that have each shown a 1 by stage t. If every row has a 1, the capacity exceeds every bound. If it stays

below N, the rows $0, \dots, N-1$ do not all have a 1; LPO, available by the previous step, decides each of these finitely many rows, and the first row without a 1 is all 0.

The split gives availability. Apply it to $\beta(N,t) = 1$ exactly when $N \le \mathrm{cap}(t)$.

The split is Σ_2 excluded middle. The split gives the excluded middle: a row with a 1 in every row refutes "some row is all 0". Conversely, Σ_2 excluded middle applied to $\beta(N,m) = 1 - \alpha(N)$ is LPO for α; then if no row is all 0, LPO finds a 1 in each row.

The unbounded witness. Given Markov's principle and a capacity that is not bounded: for each N, "some t has $\mathrm{cap}(t) \ge N$" is not false, since otherwise N would bound it, and Markov's principle finds t. Conversely, given the witness and a binary sequence α that is not all 0, the flag capacity of α is not bounded, by the argument above, so it reaches 1 at some stage, and α has shown a 1 by then. □

So the question whether the natural numbers are physically real in a world with patch reach and locality is decided, for every capacity, at exactly Σ_2 excluded middle, one level above LPO; and the step from "no bound holds" to "every bound is exceeded" is Markov's principle. Stated positively, as in Theorem 24.61, parts 1 and 2, the step from growth to realness costs nothing.

The Hubble patch

For the patch of the Hubble sphere the capacity is fixed by the expansion. Let the expansion rate at scale factor $a \ge 1$ (today is $a = 1$) be

$$H(a) = H_0 \sqrt{\Omega_m a^{-3} + \Omega_\Lambda \rho(a)}, \qquad H_0 > 0,\ \Omega_m \ge 0,\ \Omega_\Lambda > 0,$$

where the dark-energy density ρ has $\rho(1) = 1$ and $\rho'(a) = -3\,\Delta w(a)\rho(a)/a$ for the deviation $\Delta w = 1 + w$ of its equation of state. The record count of the Hubble sphere at rate H is $N(H) = 4\pi c^2/(H^2 \lambda_{\mathrm{rec}}^2)$, one bit per λ_{rec}^2 of horizon area, and the *Hubble capacity* at the tth act, which occurs at scale factor $a_t \ge 1$, is $\lceil N(H(a_t)) \rceil$. *Count-only aging* says that the deviation $\Delta w(a)$ is a nondecreasing function of the number of records posted by the epoch a, along histories that extend as a grows; Recognition Science's present deviation is $\Delta w(1) = A_{\mathrm{RS}} > 0$.

Theorem 24.63 (Storage decides the horizon)**.** *In classical mathematics, for the Hubble capacity:*

1. *With patch reach and locality, access holds exactly when for every $\varepsilon > 0$ some act has $H(a_t) < \varepsilon$.*

2. *Let $a_t \to \infty$. With patch reach, $H \to 0$ gives access; with locality, a positive asymptotic rate, $H(a) \to H_\infty > 0$, excludes it; and with patch reach, count-only aging with $\Delta w(1) = A_{\mathrm{RS}}$ gives access.*

3. Storage. *Suppose a world posts bits forever (after every permitted history either bit can be posted) and keeps its whole ledger within its capacity (after every permitted history of length t the ledger's window cost is at most $\mathrm{cap}(t)$). Then $\mathrm{cap}(n) \ge 2n$ for every n. For the Hubble capacity the rate at the acts tends to 0, and if $a_t \to \infty$ there is no positive asymptotic rate. With posting reach, access holds.*

4. Posting branch. *Let $a_t \to \infty$, let at most one act fall in each tick of a clock of any positive tick length, run along the cosmic time of the expansion, and let the future age count-only with $\Delta w(1) = A_{\mathrm{RS}}$. Then the Hubble capacity eventually exceeds twice the number of acts, and with posting reach access holds.*

5. Volume acts. *If instead the acts keep pace with the Hubble volume, $\kappa H(a_t)^{-3} \le t + 1$ for every t and some $\kappa > 0$, then in every future the Hubble capacity at the tth act is eventually below $2t$, and no world that posts bits forever keeps its whole ledger within it.*

The step from a rate tending to 0 to access is free when it is read on $\mathbb{R}_\delta$ (Proposition 24.65).

Proof. 1. $N(H)$ is a decreasing function of $H > 0$ and unbounded as $H \to 0$, so the capacity is unbounded exactly when the rate comes arbitrarily close to 0; Theorem 24.61, part 4.

2. The first two claims are parts 1 and 3 of Theorem 24.61. For the third: posted records accumulate, so $\Delta w(a) \ge \Delta w(1) = A_{\mathrm{RS}}$ for $a \ge 1$, and $\rho(a) = \exp\bigl(-3\int_1^a \Delta w(s)\, ds/s\bigr) \le a^{-3A_{\mathrm{RS}}}$, which tends to 0; so $H(a) \to 0$.

3. The history of n one-bit posts is permitted and has window cost $2n$. Then $\lceil N(H(a_t))\rceil \ge 2t$ gives $H(a_t)^2 \le 4\pi c^2/(\lambda_{\mathrm{rec}}^2(2t-1))$, which tends to 0; along $a_t \to \infty$ this excludes a positive limit. The last claim is Theorem 24.61, part 2.

4. Under count-only aging H decreases and $H(a) \le Ca^{-3\min(1,A_{\mathrm{RS}})/2}$, by the bound on ρ in part 2 and the a^{-3} fall of matter. The elapsed cosmic time is $\int_1^a ds/(sH(s)) \le \log a/H(a)$, and one act per tick bounds the number of acts by that time over the tick, while $N(H(a)) = 4\pi c^2/(\lambda_{\mathrm{rec}}^2 H(a)^2)$. The ratio of the capacity to the elapsed time is at least a constant times $1/(H(a)\log a)$, which tends to infinity; so $\mathrm{cap}(t) \ge 2t$ eventually, and part 2 of Theorem 24.61 applies.

5. $\kappa H(a_t)^{-3} \le t + 1$ gives $H(a_t)^{-2} \le ((t+1)/\kappa)^{2/3}$, so the capacity is at most a constant times $(t+1)^{2/3}$, below $2t$ for large t; and part 3 needs $\mathrm{cap}(t) \ge 2t$. □

Conditions and scope.

Base and premises

Classical real numbers; the identifications patch reach, locality and posting reach; the record law $H^2 N_H = 4\pi c^2/\lambda_{\mathrm{rec}}^2$; count-only aging; one act per tick in part 4.

Conclusion

The natural numbers are physically real in the Hubble patch exactly when the expansion slows without bound at the acts. A patch that keeps its whole ledger while posting forever needs capacity that grows at least linearly in its acts, so it forbids a Hubble sphere of bounded area. One act per tick with count-only aging gives that growth; acts in proportion to the volume never fit.

Not claimed

Which act-rate law nature follows (Remark 24.75). Locality itself is not derived from the light cone of Sections 24.1 and 24.5: the light cone orders postings and does not fix which retained records a later comparison addresses.

The "permanent horizon" of part 2 means a Hubble sphere of bounded area; the count-only future still has a cosmological event horizon. A future in which dark energy is static from today is excluded in a precise sense.

Proposition 24.64 (A future static from today jumps at today)**.** *In classical mathematics, with $H_0 > 0$, $\Omega_m \geq 0$, $\Omega_\Lambda > 0$:*

1. *If the rate from today on equals the static rate, $H(a) = H_0\sqrt{\Omega_m a^{-3} + \Omega_\Lambda}$ for $a \geq 1$, then $\Delta w(a) \to 0$ as $a \to 1^+$; so Δw jumps at today from the past value A_{RS}, and the static future is excluded by the premise that w has no jump at the present epoch.*

2. *Some future has $\Delta w(a) \to A_{\mathrm{RS}}$ as $a \to 1^+$, one deviation function equal to $A_{\mathrm{RS}}/(1+z)$ for redshifts $z \geq 0$ and to Δw in the future, and a positive asymptotic rate.*

Proof. 1. The static rate forces $\rho \equiv 1$ for $a \geq 1$, so $\rho' = 0$ and $\Delta w = 0$ for $a > 1$. 2. Take $\Delta w(a) = A_{\mathrm{RS}}/a$; then $\rho(a) = \exp(3A_{\mathrm{RS}}(a^{-1} - 1)) \to e^{-3A_{\mathrm{RS}}} > 0$, and $A_{\mathrm{RS}}/a = A_{\mathrm{RS}}/(1+z)$ at $a = (1+z)^{-1}$ joins the past law continuously. □

So continuity at today excludes a static future, but the continuity of the deviation alone does not exclude a Hubble sphere of bounded area; count-only aging does (Theorem 24.63, part 2).

On $\mathbb{R}_\delta$ the same criterion can be stated without square roots and without choice.

Proposition 24.65 (The Hubble criterion on the line)**.** *Let $H_t > 0$ be points of $\mathbb{R}_\delta$ (the rate at the tth act), $K > 0$ a point and* cap *a capacity. Say the capacity is* calibrated from below *when $NH_t^2 < K$ gives $N \leq \mathrm{cap}(t)$, and* from above *when $N < \mathrm{cap}(t)$ gives $NH_t^2 < K$; the rate* comes near 0 *when for every n some t has $(n+1)H_t < 1$.*

1. *With patch reach and the calibration from below, a rate that comes near 0 gives access. Free.*

2. *Given the calibration from above, a capacity that exceeds every bound makes the rate come near 0. Free.*

3. *With patch reach, locality and both calibrations, access holds exactly when the rate comes near 0.*

4. *For $a \geq 0$, $a < 1$ exactly when $a^2 < 1$, free; so "the rate comes near 0" is the same statement read on H_t^2, and in particular on $H_0^2(\Omega_m a_t^{-3} + \Omega_\Lambda \rho_t)$: no square root of a measured quantity is needed. Part 3 holds with calibrations stated on any positive G_t in place of H_t^2, and the step from G to access is free.*

5. *The rate $H_t = 1/(t+1)$ with capacity $(t+1)^2$ meets both calibrations at $K = 1$, comes near 0, and gives access with patch reach.*

Parts 1 and 2, the first two claims of part 4 and its step from G to access are free; part 3, the rest of part 4 and part 5 are proved in classical mathematics.

Proof. 1. For each N pick n with $(n+1)^2 \geq N/K$ computed from a bound for $1/K$; a t with $(n+1)H_t < 1$ has $NH_t^2 < K$, so $\mathrm{cap}(t) \geq N$, and Theorem 24.61, part 1, applies. 2. Take a natural number $K' \geq K$, $N = (n+1)^2K'$ and t with $\mathrm{cap}(t) > N$; then $NH_t^2 < K$ gives $(n+1)^2H_t^2 < 1$, and part 4 gives $(n+1)H_t < 1$. 3. Parts 1, 2 and Theorem 24.61. 4. For $a \geq 0$, $a^2 - 1 = (a-1)(a+1)$ with $a+1 \geq 1$. 5. $N/(t+1)^2 < 1$ exactly when $N < (t+1)^2$, which gives $N \leq (t+1)^2$; and $N < (t+1)^2$ gives $N/(t+1)^2 < 1$. □

24.13 The eight-tick comparison at its exact scope
