Section 21.7 took the reference action of a comparison to be one full cycle, $A_0 = 2\pi\hbar$, as an identification. What physical statement is that identification? A comparison is timed by its reference record: it stops when the reference has accumulated the action A_0.

Definition 24.66 (Self-timed comparisons)**.** In classical mathematics, a *stop rule* assigns to every residual $d \geq 0$ and reference energy $r > 0$ a duration $S(d,r) \geq 0$. It is *reference-clocked* with action A_0 when $rS(d,r) = A_0$ for all $d, r > 0$. It *stops at the first return* at the scale $\hbar'$ when, for all $d, r > 0$, $S(d,r) > 0$, the phase $e^{-\mathrm{i}rS(d,r)/\hbar'}$ equals 1, and $e^{-\mathrm{i}rt/\hbar'} \neq 1$ for $0 < t < S(d,r)$. The *fundamental clock mode* has energy $E_1 = \hbar\pi/(4\tau_0)$, a quarter turn per tick τ_0.

Theorem 24.67 (A comparison lasts eight ticks exactly when $A_0 = 2\pi\hbar$)**.** *In classical mathematics, let S be reference-clocked with action A_0.*

1. *For every $d > 0$: $S(d, E_1) = 2^3\tau_0$ exactly when $A_0 = 2\pi\hbar$.*
2. *Some $d > 0$ has $S(d, E_1) = 2^3\tau_0$ exactly when S stops at the first return at the scale $\hbar$.*
3. *The duration does not fix the scale at which the comparison's own phase is counted: at $\hbar' = \hbar/9$ the clock mode has the same phase at every whole tick as at $\hbar$, and a rule with $A_0 = 2\pi\hbar$ lasts eight ticks, but it does not stop at the first return at $\hbar'$. If S stops at the first return at its own scale $\hbar'$ and some $d > 0$ has $S(d, E_1) = 2^3\tau_0$, then $\hbar' = \hbar$.*
4. *For every $A_0 > 0$ there is a comparison controller with reference action A_0 (Definition 21.35: pooled records drive the sum, a record read against itself drives the reference), and some reference-clocked rule with $A_0 > 0$ lasts other than eight ticks for every $d > 0$. So those laws leave A_0 free, and the eight-tick duration is not a consequence of them.*

Proof. 1. $E_1 S(d, E_1) = A_0$, and $E_1 \cdot 2^3\tau_0 = 2\pi\hbar$. 2. At the scale $\hbar$ the phase $rS/\hbar = A_0/\hbar$ is the same for every d, r; it first returns to 1 when it reaches 2π, so the first-return stop is $A_0 = 2\pi\hbar$, which is part 1. 3. At $\hbar' = \hbar/9$ the phase of the clock mode per tick is $9\pi/4 \equiv \pi/4$ modulo 2π. The phase of the rule at its stop, read at $\hbar'$, is $e^{-2\pi\mathrm{i}\hbar/\hbar'} = 1$, but it has already returned to 1 at the time $S/9$, so the stop is not the first return. With the first-return stop at $\hbar'$, the phase $rS/\hbar'$ first reaches 2π at the stop, so $A_0 = 2\pi\hbar'$, and the eight-tick duration with part 1 gives $A_0 = 2\pi\hbar$. 4. The controller that selects, for records d and r, a phase loop of generator cost $A_0 d/(\hbar r)$ obeys both laws at every $A_0 > 0$ (Corollary 21.38, proof of part 2), and the rule $S(d,r) = \hbar/r$, reference-clocked with $A_0 = \hbar$, lasts $\hbar/E_1 = 4\tau_0/\pi$. □

Conditions and scope.

Base and premises
Classical real numbers; a reference-clocked comparison; the fundamental clock mode of energy $\hbar\pi/(4\tau_0)$.

Conclusion
$A_0 = 2\pi\hbar$, Planck's constant h in native units, is exactly the statement that one comparison against the fundamental clock mode lasts eight ticks. That statement is an independent physical premise: the laws of the controller leave A_0 free, and the posed derivation of the eight-tick duration from those laws is false.

Not claimed
The scope is the duration of one comparison. The theorem does not derive, or use, the cycle of 2^3 states of three binary channels; and the duration does not fix the scale at which the comparison's own phase is counted, which records taken at whole ticks cannot tell from $\hbar/(1+8j)$. Read at a scale $\hbar'$, the phase at the stop of a rule with $A_0 = 2\pi\hbar$ is 1 exactly when $\hbar/\hbar'$ is a whole number.

Read with Theorem 21.37: a certain change costs a quarter of the reference cycle, and the reference cycle is h exactly when one comparison of the clock mode lasts eight ticks. The binary gain sits at the threshold.

24.14 What a store with few addresses keeps real

Locality bounds what a comparison can reach by recency. A different law bounds it by address: a comparison reaches only certain positions. Which address laws keep the natural numbers real? The answer turns on whether the addresses depend only on how many records are held, and on whether the store forgets.

Definition 24.68 (Count-only stores)**.** A *count-only store* is a map addr from natural numbers to finite sets of positions. Its world permits the histories whose posts are single bits and whose every comparison, made when L records are held, addresses two present positions in $\mathrm{addr}(L)$. The store *settles* when from some L_0 on $\mathrm{addr}(L)$ is one fixed set of positions below L_0; it *keeps* when $\mathrm{addr}(L) \subseteq \mathrm{addr}(L+1)$, every position in $\mathrm{addr}(L)$ is below L and $|\mathrm{addr}(L)| \le k$ for a fixed k. It *serves the lag d beyond P* when some L and positions $P \le j, i < j < L$ have $i, j \in \mathrm{addr}(L)$ and $i, j \in \mathrm{addr}(L+d)$. It has a *persistent anchor* when for all B, D some $p < s$ with $s \ge B$ have $p, s \in \mathrm{addr}(s+1)$ and $p, s \in \mathrm{addr}(s+1+D)$. Its *depth* is bounded by w when every addressed present position is among the newest w records.

Theorem 24.69 (Count-only stores)**.** *For count-only stores, and the world of each, with one store whose addresses depend on content for comparison in part 5:*

1. Sufficient. *If for some increasing sequence of counts $s_0 < s_1 < \cdots$ every difference $s_b - s_a$ is served beyond s_a, the natural numbers are real and access holds. In particular this holds when every positive lag is served beyond every bound, and when the store has a persistent anchor. Free.*

2. Necessary. *If the natural numbers are real, then for all P and D some lag of at least D is served beyond P; for every P an infinite set of counts has all its differences served beyond P; the store does not settle; and its depth is unbounded. A store that serves no lag of D or more, or has depth bounded by w, or settles, keeps only finite collections real.*

3. Keeping truncates. *A store that keeps keeps only finite collections real, and values that share a record count number at most 2^k.*

4. Examples. *The store of the first record and the largest square position below the count, $\{0, \lfloor\sqrt{L-1}\rfloor^2\}$, has a persistent anchor and keeps the natural numbers real. The store of the first and the newest record, $\{0, L-1\}$, does not settle and has unbounded depth, yet exactly four values are real: two bits are real, five values are not. The store of the first two records, the positions $p < \min(L, 2)$, keeps, and exactly five values are real. The newest record alone keeps at most one value real, and the two newest at most four. The store $\{L-1, L \bmod 3\}$, which has two addresses and does not keep, tells apart all eight three-record words. The store $\{0, 1, L-1, L-2\}$ serves lag one beyond every bound and every lag beyond 0, yet no lag of two or more beyond 2, and the natural numbers are not real there. The store $\{0, L-1, L-2, L-3\}$ serves the lags one and two beyond every bound and none of three or more, so serving some lag beyond every bound is not enough, and it keeps only finite collections real.*

5. Content beats count. *The store that addresses the first record, the newest record and the last blank, which is not count-only, and which after each act keeps only positions it held before and the newest one, keeps the natural numbers real; the address of the blank carries the value.*

Parts 1 and 5 are free; the rest is proved in classical mathematics.

Proof. 1. Let the value n occur as s_n blanks. For $n < m$ the lag $d = s_m - s_n$ is served beyond s_n: some count L and positions $i < j < L$ with $j \geq s_n$ have i, j addressed at L and at $L + d$. Continue both runs with blanks, one mark at the post that lands at position j of the shorter run, and blanks up to count L of the shorter run; then compare i with j. In the shorter run, at count L, position j holds the mark and i a blank: they disagree. The longer run is d records ahead, at count $L + d$, where i and j are again addressed; its mark sits at $j + d$, so i and j are both blank and agree. If every positive lag is served beyond every bound, take $s_n = n$. A persistent anchor serves every lag D beyond every bound, at the counts $s + 1$ and $s + 1 + D$.

2. If no lag $d = b - a$ is served beyond P, two values with record counts $a < b$, both at least P, that agree on their first P bits are never told apart: every comparison the two runs can both make reads positions that agree. Grouping values by their first P bits, an infinite group has its counts in an infinite set whose differences are all served beyond P, and so arbitrarily large lags are served. A store of depth w is a window of $2w$ bits, and a settled store reads a fixed finite set of positions.

3. A keeping store's address sets grow and are bounded in size, so they settle; values sharing a count and agreeing at the settled set agree on every test.

4. Direct computations from parts 1–3 and the definition; for $\{0, L-1\}$, values told apart must share their record count, and then only the first and newest bits can differ.

5. Value n is $n+1$ marks and a blank; for $n < m$ post $m-n$ further marks and compare position $m+1$ with the first record: the newest record, a mark, in the shorter run, and the blank in the longer one. □

Whether every count-only store with an infinite difference set beyond every bound keeps the natural numbers real is open. With the stores of the theorem, what limits realness is a bound on stored information or a window of addresses, not the number of addresses.

A different count concerns one cell of the cosmogenesis lattice.

Proposition 24.70 (A cell holds exactly three bits)**.** *In classical mathematics: the basis measurement of an eight-level site is a valid instrument, and decoding its outcome as the basis index separates the 2^3 basis preparations with certainty; and no reader that decodes the outcome of a valid instrument on the site separates more than 2^3 normalized preparations with certainty. So a cell holds exactly three bits.*

Proof. The outcome effects of the basis measurement are the diagonal projections, which sum to the identity. If a reader separates preparations $\rho_1, \dots, \rho_M$ with certainty, its decoded effects $E_1, \dots, E_M$ have $\operatorname{tr}(E_i\rho_i) = 1$ and sum to at most the identity; since $\operatorname{tr}(E\rho) \le \operatorname{tr} E$ for a normalized ρ, $M \le \sum_i \operatorname{tr} E_i \le 8$. □

That a cosmogenesis cell's preparations and readers are these is an identification.

24.15 Certifying a law at finite precision

Theorem 17.22 shows that a closed law, built from equations and $\le$ by conjunctions, holds exactly when it passes the test at every tolerance, and that the law $x \le y \vee y \le x$ passes every test at every state but holds at every state only under LLPO. What does passing every test certify, for laws with disjunctions?

Theorem 24.71 (Certification by tolerance tests)**.** *Call a law* non-strict *when it has no atom $x < y$; it may use $=$, $\le$, $\wedge$, $\vee$ and finite conjunctions and disjunctions. A class V of points is* tolerance complete *when every non-strict law whose quantities take values in V holds at every state at which it passes the test at every tolerance.*

1. *The whole line is tolerance complete exactly when LLPO holds.*
2. *A class on which $x < y$, $x = y$ or $y < x$ is decided for any two of its points, in particular $\mathbb{Z}[\varphi]$, $\mathbb{Q}(\varphi)$ and the ratios, whose order is decided by integer arithmetic, is tolerance complete. Free.*
3. *Every tolerance complete class has the dichotomy $x \le y \vee y \le x$ for its points. Conversely, a class that contains 1 and is closed under sums and negatives is tolerance complete exactly when it has the dichotomy, and that direction is free.*

No choice principle is used.

Proof. A free step. A law that passes every test is not refuted: a strict refutation has a margin $a < b$, and at a tolerance below $b - a$ the refuted atom fails the test, and smaller tolerances keep it failing.

1. The dichotomy law passes every test, so completeness gives LLPO by Theorem 17.22, part 4. Conversely, by the free step it suffices that "not refuted" gives "holds" for non-strict laws. At an atom $x \leq y$ it is the definition of $\leq$, and at $x = y$ tightness of the line. At $\vee$ it is de Morgan's law for two statements each certified by a record, which LLPO gives: the binary sequence that marks the first record of each statement, the first at even places and the second at odd places, has at most one mark.

2. On such a class a non-strict law holds or is refuted, decided by integer arithmetic on the values, and by the free step it is not refuted.

3. The dichotomy law of two constant quantities passes every test. Conversely, under the dichotomy the class is closed under the maximum, which is one of the two points. Every law has a margin in the class: the difference of the sides of an inequality, the larger of an equation's two differences, the maximum over conjunctions and the minimum over disjunctions, with -1 and 1 for empty families. The law is refuted exactly when its margin is positive. Two margins are ordered by the dichotomy, so "not both refuted" splits into "one is not refuted", which is the de Morgan step of part 1 with no principle. □

On the values the ledger carries, the golden integers and rationals, passing every finite-precision test certifies an exact law, disjunctions included, at no price. Over the whole line the same certification costs exactly LLPO.

A window on records changes what a fixed apparatus can settle.

Proposition 24.72 (A window loses the first examination)**.** *In classical mathematics, consider the question whether the first and the Kth examination of a binary world agree, settled by the first $K + 1$ entries. A* passive *apparatus answers from the ledger of one fixed continuation after the examinations.*

1. *In a world whose comparisons reach only within a window of size $N \leq K$, every passive apparatus answers the same for two ledgers with the same record count and the same recent tail, and no passive apparatus settles the question.*

2. *In every world that extends every run and permits the examinations, in particular in $\mathscr{A}$, the apparatus that compares positions 0 and K once $K + 1$ records are in is passive and settles it.*

Proof. 1. After a common continuation every comparison outcome agrees for two ledgers with the same count and recent tail, by induction along the continuation. On the all-blank world the apparatus must answer after the Kth entry; on the world with a mark at the first entry it cannot answer earlier; and from the $(K + 1)$st entry on the recent tail no longer holds the first entry, so it confirms agreement where the entries differ. 2. The outcome of the comparison is whether the two records agree, which for injective records is whether the examinations agree. □

24.16 Crossings and postings

A patch holds located units on cubes of $\mathbb{Z}^3$, and its accounts are books: a map from cubes to finitely many accounts. When does the patch act once per tick?

Definition 24.73 (Crossing ledgers)**.** A *unit path* gives a cube at every tick, moving to an adjacent cube or staying. For a family of unit paths and a book map, the *crossing ledger* posts at each tick, for each unit whose book changes, a debit at the book it leaves and a credit at the book it enters. A ledger on several accounts is *pair-serial* when at each tick it holds or takes exactly one double entry, a debit at one account and a credit at another. A family is a *unit system* when at most one unit moves at each tick. A *legal atomic tick* posts exactly one entry.

Proposition 24.74 (Crossings, double entries and ticks)**.** *In classical mathematics:*

1. *The crossing ledger's record total grows by twice the number of crossings, and the net credit at an account is its change of occupancy.*
2. *A crossing ledger is pair-serial exactly when at most one unit crosses at each tick; the crossing ledger of a unit system is pair-serial. Two units that are each a unit system on their own and cross at the same tick have a crossing ledger that is not pair-serial, under every reading on accounts. A ledger that posts one fixed double entry at every tick is pair-serial and is the crossing ledger of no finite family of units.*
3. *A double entry is two postings and never a legal atomic tick, and a legal atomic tick never joins two ledgers whose columns balance. So the statement that the patch's ledger advances by one legal atomic tick per tick is false for every stream of events read with balanced columns; the corrected statement, proved, is that under the source and target reading (each paired event posts a debit at its source's account and a credit at its target's) it advances by exactly one double entry per tick.*
4. *A pair-serial ledger gains at most two entries per tick; if each act posts one double entry and acts are clocked, there is at most one act per tick.*
5. *If each move of a unit is a post at a site of one recognition structure and a post moves exactly one unit, then Recognition Science's atomic tick (exactly one site posts per tick) makes the units a unit system; conversely every unit system carries such an atomic tick. The atomic tick alone constrains nothing: it is a schedule, and two units crossing at one tick are not a unit system under any schedule.*
6. *When the units' own ledgers are run jointly, each tick posting on one unit's ledger, which moves that unit one hop, the crossing ledger is the fold of the schedule through the book step: at each tick it holds, or takes one double entry from the old book to the new, and the two cubes are adjacent.*

Proof. 1. Each crossing posts one debit and one credit, and the occupancy of a book changes by the units entering minus those leaving. 2. One crossing gives one double entry, two give four entries at one tick, which no hold or double entry is; a fixed double entry would lower the debited book's occupancy below 0 after more ticks than there are units. 3. A legal atomic

tick changes one column by one, so it cannot preserve column balance. 4. Count entries. 5. Two units that move at one tick post at sites the atomic tick identifies, so they are one unit; a unit system's moving unit, or an idle site, gives the schedule. 6. A post moves its unit one hop, so its old and new cubes are adjacent, and every other unit stays; part 1 and induction along the schedule. □

So the one-tick question of the patch is reduced to one physical identification: the patch's units are carried by one recognition structure, with their moves as its posts. That identification is the joint net-flow position in which each unit sits at the balance of its own ledger; with it the book ledger is a faithful image of the units' own posting run, and the patch moves one unit per tick, recorded at two books.

Remark 24.75 (What stays open in the world's records)**.** The following are stated exactly and are open.

(a) *Locality from the light cone.* No accepted result fixes which retained records a comparison addresses; the missing law is chronological coverage, equivalent to locality (the time window). The light cone of Sections 24.1 and 24.5 orders postings and does not supply it.

(b) *The act-rate law.* Whether the Hubble patch acts at most once per tick of the cosmic clock or in proportion to its volume is fixed by no accepted result; Theorem 24.63 proves what each gives.

(c) *One crossing per tick.* Reduced to the identification that the patch's units form one unit system, read on the patch's accounts (Proposition 24.74), and that in turn to the identification that moves are posts.

(d) *The price of access from locality.* In classical mathematics, access with locality makes the capacity exceed every bound; the price of that step on the line is open.

(e) *Certain flips.* Whether some native word flips a register configuration with certainty, at zero boundary flux and unit action scale; and whether the integer parameter m of the register drops out of that question (if a certain flip at $m = 0$ gives one at every m, the question reduces to $m = 0$ and zero flux).

(f) *Count-only stores.* Whether a count-only store with, beyond every bound, an infinite set of counts whose differences are all served keeps the natural numbers real.

24.17 Controlled posts and the coherence of a side

Section 24.7 left one premise open: the directions x_1, x_2 of the record cone need posts whose side is held coherently, and posting does not produce them. The obvious way to try is to let a coherent register choose the side. Put a *side register* in a superposition of debit and credit, and let it control which post is written to the ledger. Does the side then stay coherent? The answer is no, for an exact reason: the ledger records which side was posted. This section proves that, says what erasure can and cannot repair, and identifies the one kind of controlled law that keeps the side coherent: the kind whose ledger records nothing. The results are proved in classical mathematics over the complex numbers.

Definition 24.76 (Controlled posts)**.** A *code register* has the basis states $1, \dots, n$; in the census encoding of Section 24.7 they are the ledger codes, and a post at account k on side s is the map $y \mapsto \mathrm{bump}_{k,s}(y)$ that raises that count by one modulo $N+1$. A *controlled law* is a pair $f = (f_0, f_1)$ of maps of the codes, one for each side. For amplitudes $v \in \mathbb{C}^2$ of the side register and a code state $c \in \mathbb{C}^n$, the *controlled state* is $\sum_{s,k} v_s\, c_k\, |s\rangle|f_s(k)\rangle$, and the *side record* is its reduction to the side register, the 2×2 matrix $\rho_{ss'} = v_s \bar{v}_{s'} \langle f_{s'}c, f_s c\rangle$ with $f_s c = \sum_k c_k |f_s(k)\rangle$. The *overlap* of the law on c is $\langle f_1 c, f_0 c\rangle$. When c is a single code k we say the code is *definite*.

The side record is a coherent record (Definition 24.13); it is null, a coherent post, exactly when its determinant vanishes, and timelike, a classical mixture of the two posts, when its determinant is positive.

Proposition 24.77 (A controlled post records its side)**.** *In classical mathematics, for every controlled law f on n codes, every definite code k and all amplitudes v:*

(a) with a definite side, $v = e_s$, the controlled state is the classical post $|s\rangle|f_s(k)\rangle$;

(b) $\rho_{ss'} = v_s \bar{v}_{s'}$ if $f_s(k) = f_{s'}(k)$, and $\rho_{ss'} = 0$ otherwise;

(c) the side record is null exactly when $v_0 = 0$, $v_1 = 0$ or $f_0(k) = f_1(k)$;

(d) if $f_0(k) \neq f_1(k)$ and $v_0, v_1 \neq 0$, the side record is timelike, while the joint state of side and ledger stays pure; if $f_0(k) = f_1(k)$ it is the pure record $v v^\dagger$;

(e) δ's two posts at one account, $f_s = \mathrm{bump}_{k,s}$ on the codes with count bound $N \geq 1$, never leave the same code: so a controlled post whose branches are δ's two posts leaves every superposed side a timelike record.

Proof. (a) and (b) are the partial trace of $\sum_s v_s |s\rangle|f_s(k)\rangle$: the entry (s, s') is $v_s \bar{v}_{s'} \langle f_{s'}(k)|f_s(k)\rangle$. (c) The determinant is $|v_0|^2|v_1|^2(1 - [f_0(k) = f_1(k)])$. (d) follows from (b) and (c). (e) A debit post changes the debit count of the account and a credit post does not, and raising a count by one modulo $N+1$ changes it (Proposition 24.21(b)). □

It is locality and census certainty together that make the two codes differ: the census count is the same after a debit and after a credit. Can the coherence be restored afterwards?

Proposition 24.78 (Erasure, and what it writes)**.** *In classical mathematics, for controlled laws whose maps f_0, f_1 are permutations of the codes:*

(a) the side record has the off-diagonal entry $v_0 \bar{v}_1$ times the overlap and the diagonal entries $|v_s|^2 \|c\|^2$;

(b) no unitary acting on the code register alone changes the side record;

(c) on a definite code that the two branches move apart the overlap is 0; on the uniform code state, $c_k = 1$ for all k, it is n, and the side record is $n\, v v^\dagger$;

(d) if each branch moves every code apart, $\|c\| = 1$ and some code has probability above one half, then the overlap has modulus below 1: coherence cannot be full when the code is that certain;

(e) a second controlled post of the other side restores full coherence on a definite code: since δ's debit and credit posts commute, the branches debit-then-credit and credit-then-debit end in the same code. The side register returns to its prepared record $vv^\dagger$, but each branch has written one debit and one credit at the account: below the count bound both counts rise by one and nothing else changes, the same in both branches. The result is a balanced pair, not a coherent unit post.

Proof. (a) As in Proposition 24.77, with $\langle f_s c, f_s c\rangle = \|c\|^2$ for a permutation. (b) The partial trace over the code register is invariant under unitaries of that register. (c) The two posted code states of a definite code are distinct basis states; on the uniform state each $f_s c$ is the uniform state. (d) By Cauchy–Schwarz the overlap has modulus at most $\|c\|^2 = 1$, with equality only if $f_0 c = \mu f_1 c$, that is $c(f_0^{-1}(z)) = \mu\, c(f_1^{-1}(z))$ for every code z and some $|\mu| = 1$. At $z = f_0(y)$ this gives the code $y' = f_1^{-1}(f_0(y)) \neq y$ the same probability as y, and two codes of probability above one half are impossible. (e) $\mathrm{bump}_{k,d}$ and $\mathrm{bump}_{k,c}$ change different counts, so they commute; then apply Proposition 24.77(b), and count the changes. □

Proposition 24.79 (Which controlled laws keep the side coherent)**.** *In classical mathematics:*

(a) on a definite ledger code, no controlled law writes a coherent single post whose side follows the side register; a debit-versus-credit post at one account keeps the coherence strictly below full on every legal ledger state; changes that do not depend on the side keep it coherent;

(b) for permutations f_0, f_1, a code state $c \neq 0$ and amplitudes with $v_0, v_1 \neq 0$, the side record is null exactly when $c \circ f_0^{-1} = \mu\, c \circ f_1^{-1}$ for some $\mu \in \mathbb{C}$; then $|\mu| = 1$, the joint state is a product, the ledger ends in one state whatever the side, and the side picks up the phase μ.

Proof. (b) The determinant of the side record is $|v_0|^2|v_1|^2(\|c\|^4 - |\langle f_1 c, f_0 c\rangle|^2)$, which vanishes exactly in the equality case of Cauchy–Schwarz, $f_0 c = \mu f_1 c$; equal norms give $|\mu| = 1$, and then the controlled state is $(v_0\mu|0\rangle + v_1|1\rangle) \otimes f_1 c$. (a) A change that does not depend on the side gives the side record $\|c\|^2 vv^\dagger$. On a definite code (b) asks for $f_0(k) = f_1(k)$, and two single posts leave the same code only if they are the same post. For a debit-versus-credit post at one account that is legal, the debit being allowed on every code of the state, take the code y^* of the support with the largest debit count: the debit branch puts weight on a code with a larger debit count, which the credit branch never reaches, so the two posted states are not proportional and the inequality of (b) is strict. There is no uniform gap: a state spread evenly over a chain of L codes has overlap $(L-1)/L$. □

So a controlled law keeps the side coherent exactly when its ledger does not record the side. Branches may post differently on every code and stay coherent, but only if the code state is spread so that the two posted states agree up to a phase; a ledger in a definite state always records the side. The open premise of Section 24.7 is therefore not supplied by controlling δ's posts: the coherent directions of the record cone need a carrier that does not record the side.

24.18 Charts of the causal order of postings

Section 24.5 proved that separate accounts reach only the taxicab cone, and Section 24.6 that the record cone of one coherent distinction is the round cone of one time and three space dimensions. The two cones are different shapes. This section asks how far the order of postings can still be drawn in the round cone, if the coordinates are allowed to bend. The answer has three parts: no affine chart works anywhere; the finite pieces listed in Theorem 24.83 have exact cone charts, while large grids have none [201]; and the whole order has none, already in its integer part, while long runs crowd every chart toward the light cone. First the record cone's own scale.

Proposition 24.80 (The record cone is a calibration of the light speed)**.** *In classical mathematics, let a world meet the foundation's facts with a light speed $c > 0$ in lengths of J per tick and the causal bound $c^2 \geq \frac{3}{4}$, so that its lattice parameter is $\kappa = \frac{1}{4} + c^2$. Read record time t as t ticks and record space x as σx lengths. The classical posts' records are null directions of time one, and every null record direction is a light-like displacement of the world exactly when $c = \sigma$. At the posting scale $\sigma = \frac{\sqrt{3}}{2}$ this is the statement $\kappa = 1$; at $\sigma = 1$ it holds in the world with $\kappa = \frac{5}{4}$; and every such world meets it at its own scale $\sigma = c$.*

Proof. A null record direction $(1, x)$, $|x| = 1$, is read as a displacement of σ lengths in one tick, which is light-like exactly when $\sigma = c$. $\sigma = \frac{\sqrt{3}}{2}$ is the space leg of one posting, and $\frac{1}{4} + \frac{3}{4} = 1$. □

So the record cone makes the posts null; it does not fix κ, which stays the named premise of Section 27.8. The objects of the rest of this section are the stage events of the lattice of postings.

Definition 24.81 (Stage events, the physical causal order and record-cone charts)**.**

1. A *stage event* is an event of the four-account ledger whose position spends no tick; its *content* $c(e) \in \mathbb{R}^4$ is what the accounts spend from a reference event to it, and the content of a pair is $c(f) - c(e)$. The *physical causal order* puts f after e exactly when the pair spends a nonnegative content on every account: in content space it is the *account orthant*, a cone with four flat faces whose edges are the single postings. The *posting lattice* is the set of stage events with integer content from the origin.

2. For a set P with an order $\preceq$, a *record-cone chart* is a map $\varphi : P \to \mathbb{R}^4$ with $p \preceq q$ exactly when $\varphi(q) - \varphi(p)$ lies in the future cone K of Definition 24.13. A *cone chart in* a real inner product space E is a map $p \mapsto (t(p), x(p)) \in \mathbb{R} \times E$ with $p \preceq q$ exactly when $\|x(q) - x(p)\| \leq t(q) - t(p)$.

3. For sides $a, b, c, d \geq 1$ the *grid* $a \times b \times c \times d$ is the product of the chains $\{0, \dots, a-1\}$ and so on, ordered componentwise; three-account grids have $d = 1$; $[n] = \{0, \dots, n-1\}$ and $\mathbb{N}$ are chains. A grid is *read on stage events* when stage events realize it, with contents the grid points and the physical causal order equal to the grid order.

Proposition 24.82 (No affine chart; the orthant is two light cones)**.** *In classical mathematics:*

(a) no linear map of $\mathbb{R}^4$ *carries the account orthant onto the record cone K, so no coordinates on stage events whose differences are a linear function of the content make the physical causal order the record-cone order;*

(b) an explicit invertible linear map sends every nonnegative content into K and the four single postings to the null directions $(1,1,0,0)$, $(1,-1,0,0)$, $(1,0,1,0)$, $(1,0,0,1)$*: physical precedence implies record-cone precedence of the mapped content, and not conversely;*

(c) the account orthant is exactly the intersection of the two pair cones: with $\pi_{ij}(v) = (v_i + v_j,\ v_i - v_j)$*, a content v is nonnegative exactly when* $\pi_{01}(v)$ *and* $\pi_{23}(v)$ *both lie in the* $1+1$ *light cone; so on all stage events physical precedence is the conjunction of two* $1+1$ *light-cone readings, one for each pair of accounts.*

Proof. (a) Such coordinates are a linear map L with $v \geq 0$ exactly when $Lv \in K$; L is injective, since a nonzero v with $Lv = 0$ would make both v and $-v$ nonnegative, so L carries the orthant onto K. A linear image of the orthant is the cone spanned by four vectors, hence polyhedral, and a polyhedral cone of dimension four with no line in it has a two-dimensional face, a flat sector of its boundary spanned by two independent vectors. K is not polyhedral, since ∂K has no two-dimensional face: if u, w and $u + w$ are all null then $\langle u, w\rangle = 0$, and two orthogonal null vectors are parallel. (b) The map is explicit and checked on the four edges, which span. (c) $|v_i - v_j| \leq v_i + v_j$ exactly when $v_i, v_j \geq 0$. □

So the influence order of four accounts is two $1 + 1$ light cones, not one $1 + 3$ cone. Curved charts can still draw some finite pieces of it in one round cone.

Theorem 24.83 (Some finite pieces have exact curved charts)**.** *In classical mathematics, each of the following orders has a record-cone chart with integer coordinates, and each is read on stage events, so on those events the physical causal order is a record-cone order:*

(a) the sixteen corners of a unit posting cube, $2 \times 2 \times 2 \times 2$*, where no affine chart exists;*

(b) the three-account grids $3 \times 3 \times 3$ *and* $4 \times 4 \times 4$*, the latter with a chart in one plane;*

(c) the truncations $2 \times 3 \times [n]$ *of* $2 \times 3 \times \mathbb{N}$*, for every* $n \leq 20$*;*

(d) every four-account grid with all sides at least two and at most forty-eight events, in every order of the accounts, and $2 \times 2 \times 2 \times m$ *for every* $m \leq 8$*.*

Conditions and scope.

Base and premises

Finite orders and integer charts; classical real numbers.

Conclusion

Each of these finite pieces of the posting lattice can be drawn exactly in one round light cone, with curved coordinates; affine coordinates never suffice (Proposition 24.82).

Not claimed

Any grid not listed: $2 \times 3 \times 3 \times 3$ (fifty-four events) and $3 \times 3 \times 3 \times 3$ are open, and so are the truncations $2 \times 3 \times [n]$ for $n > 20$.

Proof. Each chart is an explicit table of integer points, and the claim that the grid order equals the record-cone order of the table is a finite check over all ordered pairs (256 pairs for the cube, 729 and 4096 for the three-account grids, 1296 for $2 \times 2 \times 3 \times 3$), each pair an integer comparison of t with $|x|$ through $t \geq 0$ and $t^2 \geq |x|^2$, done by exact computation. A chart of a grid restricts to a chart of every subgrid, which gives every $n \leq 20$ from $n = 12, 16, 20$ and every $m \leq 8$ from $m = 8$. Exchanging two neighbouring accounts carries a chart to a chart, by relabelling the grid points, which gives every order of the accounts. Realization on stage events uses that the content is a linear bijection of stage differences. For (a), the chart puts the empty corner at time -8, the single postings at time -3 in four tetrahedral directions, the pairs at time 0, the triples at time 3 and the full corner at time 8. No affine chart exists: with u_d the image of account d's posting and $s = \sum_d u_d$, the Minkowski form Q satisfies $\sum_d Q(s - 2u_d) = 4 \sum_d Q(u_d) \geq 0$, so some pair of a triple and the fourth single posting would be causal although neither contains the other. □

The charts were found numerically and their best margins fall quickly as the pieces grow: for the truncations $2 \times 3 \times [n]$ the least distance of an incomparable pair from the light cone was 0.0118 at $n = 12$, 0.0029 at 16 and 0.00025 at 20, and searches at $n = 22$ and 24 found none. Those numbers are not part of any proof. The next theorem shows that the whole order has no chart at all.

Theorem 24.84 (No chart of the whole posting order)**.** *In classical mathematics:*

(a) no map of $2 \times 2 \times \mathbb{R}$ *into* $\mathbb{R} \times E$*, for any real inner product space* E*, is a cone chart; the stage order with real contents contains* $2 \times 2 \times \mathbb{R}$ *(contents* $(i, j, t, 0)$*), so no chart of all stage events reads the physical causal order as the record cone;*

(b) no cone chart of $2 \times 3 \times \mathbb{N}$ *with the order of* $\mathbb{N}$ *reversed has times bounded below, in any complete real inner product space;*

(c) $2 \times 3 \times \mathbb{N}$ *has no cone chart in any complete real inner product space and no record-cone chart; it is read on stage events of the posting lattice (contents* $(i, j, k, 0)$*), so the posting lattice has no record-cone chart.*

Conditions and scope.

Base and premises

Classical real analysis on inner product spaces.

Conclusion

The physical causal order is not the round light cone in any chart, curved or not, and the obstruction does not need the continuum: the integer posting lattice already fails. This agrees with the theorem of Felsner, Fishburn and Trotter that the grids $n \times n \times n$ are not sphere orders for large n [201], the record-cone order on finite sets being containment of balls with time as radius; the proofs here do not use it.

Not claimed

The smallest finite piece without a chart; whether one exists inside $2 \times 3 \times \mathbb{N}$ is the sphere-order form of a question of Felsner, Fishburn and Trotter, and it is open.

Proof. (a) Along each line $t \mapsto (i, j, t)$ the chart's time is monotone, hence continuous off a countable set; take a common point t of continuity of the four lines. There every comparable pair of the four points (i, j, t) is null-separated: a positive margin would let (i, j, s), s slightly above t, still precede (i', j', t). Then $(1, 0, t)$ and $(0, 1, t)$ lie on the null segment from $(0, 0, t)$ to $(1, 1, t)$, by equality in the triangle inequality, and so are comparable, but they are not. The argument needs the real line. (b) Each chain $k \mapsto (i, j, k)$ decreases in time and is bounded below, so its space part is Cauchy, since $\|x(k) - x(k')\| \le t(k) - t(k')$, and it converges. Write L_c for the limit of the chain $c = (i, j)$; it precedes every point of its chain. Four facts are used. (i) If $c \le c'$ then $L_c \preceq L_{c'}$ and the pair is null: $(c, k) \preceq (c', k)$ for every k passes to the limit, and a positive margin $t(L_{c'}) - t(L_c) - \|x(L_{c'}) - x(L_c)\|$ would give $(c, k) \preceq (c', k')$ for some large $k < k'$, which the reversed order forbids. (ii) If the chains c, c' are incomparable and $L_c \preceq L_{c'}$, every point P of chain c' is null from L_c: P lies above $L_{c'}$, hence above L_c, and a positive margin would put P above the points of chain c near L_c, none of which it follows. (iii) If $a \preceq b \preceq d$ and the pair (a, d) is null, then b lies on the null segment from a to d: the triangle inequality $\|x(d) - x(a)\| \le \|x(d) - x(b)\| + \|x(b) - x(a)\| \le t(d) - t(a)$ is an equality, and in an inner product space that forces parallel steps. Any two points of one null line are comparable. (iv) By (i) and (iii), the limits of the chains $(0, 0) \le (0, 1) \le (0, 2) \le (1, 2)$ and $(0, 0) \le (1, 0) \le (1, 1) \le (1, 2)$ all lie on the null segment from L_{00} to L_{12}, so any two of the six limits are comparable. Now there are three cases. *Case 1:* $L_{10} \preceq L_{01}$. Then also $L_{10} \preceq L_{02}$, and by (ii) every point of the chains $(0, 1)$ and $(0, 2)$ is null from L_{10}. The points $(0, 1, 0)$ and $(0, 2, 1)$ both precede $(0, 2, 0)$, so by (iii) both lie on the null segment from L_{10} to $(0, 2, 0)$ and are comparable, but they are incomparable in the order. *Case 2:* $L_{02} \preceq L_{10}$. Then also $L_{02} \preceq L_{11}$, every point of the chains $(1, 0)$ and $(1, 1)$ is null from L_{02}, and the incomparable points $(1, 0, 0)$ and $(1, 1, 1)$, both below $(1, 1, 0)$, are comparable by (iii). *Case 3:* neither. By (iv), $L_{01} \preceq L_{10} \preceq L_{02}$ with strictly increasing times, on one null line. By (ii) the point $(1, 0, 0)$ is null from L_{01} and lies above L_{10}, so by (iii) L_{10} lies on the null segment from L_{01} to $(1, 0, 0)$, which therefore lies on that line; likewise $(0, 2, 0)$ is null from L_{10} and lies above L_{02}, so it lies on the same line. Then $(1, 0, 0)$ and $(0, 2, 0)$ are comparable, but they are not. (c) Minkowski inversion, $u \mapsto u/(t^2 - \|x\|^2)$ on the open future cone, reverses the cone order there. A chart of $2 \times 3 \times \mathbb{N}$, moved so that its least point lies one time unit above the origin, inverted, and relabelled by reversing the two finite coordinates, is a chart of the reversed order with positive times, which (b) excludes. The record cone is the case $E = \mathbb{R}^3$. □

How fast do charts of long runs degrade? A pair of events is at *angular margin* $\theta \in (0, 1]$ when $\theta(\|\Delta x\| + |\Delta t|) \le \|\Delta x\| - |\Delta t|$: it is spacelike by a definite angle, independent of scale. Two chains $A_0 \preceq \cdots \preceq A_{n-1}$ and $B_0 \preceq \cdots \preceq B_{n-1}$ with $A_k \preceq B_k$, where every A_k is incomparable with every earlier B_j, $j < k$, are a *ladder of length n*.

Theorem 24.85 (Long runs crowd every chart)**.** *In classical mathematics:*

(a) in every map of $2\times[n]$, $n\ge 2$, into $\mathbb{R}\times E$, E a real inner product space, that sends comparable pairs into the cone, some incomparable pair has $\|\Delta x\|-|\Delta t|\le 2\,\mathrm{span}/(n-1)$, where span *is the time from the least to the greatest point; so the same holds for every map of $2\times 3\times[n]$, through its subgrid $2\times 1\times[n]$, and for the record cone;*

(b) in a ladder of length n in $\mathbb{R}\times E$, E any real normed space, whose incomparable pairs (A_k,B_j), $j<k$, all have angular margin at least $\theta>0$, $\theta^2(n-1)\le 2$;

(c) in one space dimension the bound is $\theta^2(n-1)\le 1$, and it is sharp: a ladder of length 5 with every margin at least $\frac{1}{2}$ attains it.

Proof. (a) Write the points of $2\times[n]$ as $(0,0,k)$ and $(1,0,k)$, as in the subgrid $2\times 1\times[n]$; only these two chains are used. The pair $(0,0,k+1)$, $(1,0,k)$ is incomparable for every k. At a level k where the time step of the chain $(0,0,\cdot)$ is at most its average, at most $\mathrm{span}/(n-1)$, both points lie within that step of $(0,0,k)$ along cone relations, and the triangle inequality bounds the pair's spacelike margin $\|\Delta x\|-|\Delta t|$ by twice the step. (b) Only the triangle inequality is used; let $n\ge 2$. For a pair (A_k,B_j) put $G=\|x(A_k)-x(B_j)\|$, $\tau=t(A_k)-t(B_j)$ and the two null gaps $p(k,j)=G+\tau$, $q(k,j)=G-\tau$. For $j<k$ the margin $\theta(G+|\tau|)\le G-|\tau|$ gives $\theta q\le p$ and $\theta p\le q$, since $|\tau|\ge\pm\tau$. Put $a_k=q(k,0)$, $b_k=p(k,0)$ and $s_k=t(A_{k+1})-t(A_k)$, so that $\|x(A_{k+1})-x(A_k)\|\le s_k$. Five facts follow. (1) $a_{k+1}\le a_k$ and $b_{k+1}\ge b_k$: the distance to B_0 changes by at most s_k while τ grows by exactly s_k. (2) $(b_{k+1}-b_k)+(a_k-a_{k+1})=2s_k$, since $p-q=2\tau$. (3) $p(k+1,k)\le 2s_k$: from $A_k\preceq B_k$, $\|x(A_{k+1})-x(B_k)\|\le s_k+t(B_k)-t(A_k)$; add $t(A_{k+1})-t(B_k)$. (4) $q(k+1,k)\ge a_{k+1}$: from $B_0\preceq B_k$, $\|x(A_{k+1})-x(B_0)\|\le\|x(A_{k+1})-x(B_k)\|+t(B_k)-t(B_0)$; subtract $t(A_{k+1})-t(B_0)$. (5) $g=a_{n-1}>0$: if $q(n-1,0)=0$ the margin gives $p(n-1,0)=0$, so A_{n-1} and B_0 coincide and are comparable. By (3), the margin of the incomparable pair (A_{k+1},B_k) and (4), $\theta a_{k+1}\le\theta q(k+1,k)\le p(k+1,k)\le 2s_k$, so by (2)

$$\theta a_{k+1}\le(b_{k+1}-b_k)+(a_k-a_{k+1})\qquad(0\le k\le n-2).$$

Twice the step, not the step, is at least θa_{k+1}. Now take square roots $r=\sqrt{g}\le\sigma=\sqrt{a_{k+1}}\le\sigma'=\sqrt{a_k}$, by (1) and (5), and put $\Delta=b_{k+1}-b_k\ge 0$; the claim is $\theta g\le\Delta+2(1+\theta)r(\sigma'-\sigma)$. If $a_k\ge(1+\theta)a_{k+1}$, then $4(1+\theta)^2\sigma^2\le 4(1+\theta)\sigma'^2\le(2+\theta)^2\sigma'^2$, so $(2+2\theta)\sigma\le(2+\theta)\sigma'$, that is $\theta\sigma'\le 2(1+\theta)(\sigma'-\sigma)$, and $\theta g\le\theta r\sigma'\le 2(1+\theta)r(\sigma'-\sigma)$. Otherwise $\sigma'^2<(1+\theta)\sigma^2$, so $\sigma'+\sigma\le 2(1+\theta)\sigma$; multiplying the displayed inequality $\theta\sigma^2\le\Delta+(\sigma'-\sigma)(\sigma'+\sigma)$ by $r^2/\sigma^2\le 1$ gives $\theta g\le\Delta+(\sigma'-\sigma)\,r(r/\sigma)\,2(1+\theta)\le\Delta+2(1+\theta)r(\sigma'-\sigma)$. Adding the $n-2$ steps $k=1,\dots,n-2$, the sums telescope:

$$\theta g(n-2)\le b_{n-1}-b_1+2(1+\theta)\sqrt{g}\,(\sqrt{a_1}-\sqrt{g}).$$

The margins of the pairs (A_{n-1},B_0) and (A_1,B_0) give $b_{n-1}\le g/\theta$ and $b_1\ge\theta a_1$, and the inequality of arithmetic and geometric means gives $2(1+\theta)\sqrt{g}\sqrt{a_1}\le\theta a_1+(1+\theta)^2 g/\theta$. So $\theta g(n-2)\le g/\theta+(1+\theta)^2 g/\theta-2(1+\theta)g=g(2/\theta-\theta)$; dividing by $g/\theta>0$ gives $\theta^2(n-2)\le 2-\theta^2$, that is $\theta^2(n-1)\le 2$. (c) In light-cone coordinates $u=t+x$, $v=t-x$ the cone order of one space dimension is componentwise, and the margin of a spacelike pair is $\min(|\Delta u|,|\Delta v|)/\max(|\Delta u|,|\Delta v|)$. The pair (A_1,B_0) fixes an orientation for all pairs; each pair (A_k,B_{k-1}) has v-gap at least $g=v(B_0)-v(A_{n-1})$, so its u-gap is at least θg; the u-gaps add up

to at least $(n-1)\theta g$ on the pair (A_{n-1}, B_0), whose v-gap is g, so $\theta \cdot (n-1)\theta g \le g$. The ladder $A_k = (k, 0)$, $B_j = (j, 2)$ in light-cone coordinates, $n = 5$, meets every hypothesis with $\theta = \frac{1}{2}$ and equality. □

So no chart of a long run keeps a fixed angular distance from the light cone: the exponent two of one space dimension holds in every dimension, and extra dimensions buy at most a factor $\sqrt{2}$ in θ. The crowding bound does not explain the much faster fall of the margins observed in the numerical charts above.

Remark 24.86 (What is open, exactly)**.** Four statements are open, neither proved nor refuted. (i) The grid $2 \times 3 \times 3 \times 3$ has a record-cone chart read on its stage events. (ii) So does $3 \times 3 \times 3 \times 3$. (iii) Every truncation $2 \times 3 \times [n]$ has one; every $n > 20$ is open. (iv) In every real normed space, a ladder of length n with all angular margins at least $\theta > 0$ has $\theta^2(n-1) \le 1$. Searches found no chart in (i)–(iii) and no ladder above the bound $1/\sqrt{n-1}$ in small cases of (iv); a search that finds nothing proves nothing.

Questions to work through

1. (Theorem 24.5 and Proposition 24.6.) Split the history *dcddcdcd* of the opening into the three legs *dc*, *ddc* and *dcd*. Compute the three proper times, check that their sum is less than $2\sqrt{15}$, and verify the deficit formula of the proposition term by term. Which pair of legs contributes nothing, and why?

2. (Proposition 24.3 and Theorem 24.14(f).) Show that $(D, C) \mapsto (2D, C)$ preserves the componentwise order of $\mathbb{N}\times\mathbb{N}$ but is not an order bijection, and that $(D, C) \mapsto (kD, C/k)$ maps $\mathbb{N} \times \mathbb{N}$ into itself only for $k = 1$. Why is this consistent with the Doppler rescaling being a coherent change of determinant 1?

3. (Theorem 24.12.) With two accounts, which of the pairs of total post count and potentials $(5, (2, -1))$, $(4, (2, -1))$ and $(6, (3, 3))$ are reachable from the empty ledger? Give a posting for each reachable one.

4. (Theorems 24.17 and 24.19(f).) For the quaternionic carrier, $k = 4$, compute $P_4(n)$ for $n = 2, 3, 4, 6$, and show that record counts fail to multiply both at $2 \cdot 2$ and at $2 \cdot 3$.

5. (Theorem 24.31.) Show that agreement at the four times τ_0, $\frac{8}{3}\tau_0$, $\frac{8}{5}\tau_0$ and $\frac{8}{7}\tau_0$ already forces the band 105, and that the other four times of the theorem add nothing.

6. (Theorem 24.39 and Theorem 24.43(d).) Write the first eight posts and balances of the closing coder of $\alpha = (0, 1, 0, 0, \ldots)$, and find where it closes. Then consider the recorder with states $\{0, 1, 2\}$ that starts in 0, moves to state 1 after reading a 0 and to state 2 after reading a 1 (from any state), answers *yes* in state 2 and reads on otherwise. Does it always answer? Follow the proof of Theorem 24.43(d) on the run of zeros and say what it finds.

7. (Theorem 24.53 and Proposition 24.55.) For the core states $f = e_0 + 2e_2 - e_4 - 2e_6$ and $g = e_0 + e_1 - e_4 - e_5$, check that P keeps $\sum_t f(t)^2$ but not $\sum_t |f(t)|$, compute $\kappa(g, \{t\})$ and $\kappa(Pg, \{t\})$ with their totals, and find two positions of g showing that κ is not a function of the amplitude.

Part VII

Classical physics on the line

Part VII asks whether classical physics survives on a line where every number is a construction. It does, and each result says what it uses: some hold on the line with no omniscience principle and no choice, decisions that classical mechanics makes without comment carry a price, exact or between two named principles, and the many results proved only in classical mathematics say so. Chapter 25 moves the mechanics of Kepler and Newton onto $\mathbb{R}_\delta$: bound non-radial orbits return, N bodies keep ten integrals, the perihelion of a relativistic test orbit in a weak-field window advances by $6\pi m/p + \frac{3\pi}{2}(18 + e^2)(m/p)^2$ up to an explicitly bounded remainder, the pulsar-timing observables of such an orbit follow in a distant observer's time in the test-mass limit, every long-wave solution of the lattice's own field equations, in the weak sense of Section 25.12, with the jets of a point mass has $\beta = \gamma = 1$, and deciding, for every body, whether a given principal axis is its axis of largest moment costs exactly LPO. Chapter 26 treats lattice fields, entropy and the second law. It proves that the tick of Recognition Science exists and is unique, and gives the rate at which it approaches equilibrium from five numerical inputs, (T1)–(T5), which the chapter states and does not prove. Chapter 27 summarizes what the comparison cost says about gravity: on transverse-traceless strains its long-wave form is the Fierz–Pauli form of linearized gravity, the locality of a lattice cost selects the Fierz–Pauli completion, the cost built from J agrees with Regge's action, read as the gravitational action, to second order only, and at the Euclidean background its cubic term breaks gauge invariance, so it has no post-Newtonian parameter β of its own, and the lattice parameter $\kappa = 1$ is equivalent to a named premise about records and is not derived. Regge's own long-wave vertices are one half of Einstein's through quartic order on every Euclidean background of the Kuhn family; among hinge charges built from one function of the area, gauge consistency selects Regge's action through cubic order, and for shape costs it fixes Regge's action up to its coupling; four gravitons scatter at tree level as in general relativity on every flat background g_κ of the lattice family off its poles, at long wavelength; and at order K^4 every background with $\kappa > \frac{1}{2}$, $\kappa = 1$ included, is birefringent. The full treatments are the preprints (Zenodo, 2026) [95, 196, 197]. The chapter proves its results on its own pages; where a proof gives a route, or ends in a long finite computation that it describes, the result's scope box says so.

Chapter 25

Orbits and bodies

A planet moves on an ellipse about the Sun and comes back to where it was after one period. On $\mathbb{R}_\delta$ every number is a construction: a position is a regular sequence of ratios, a time is another one, and no comparison of two points is decided unless a rule decides it. The classical proof that the planet returns uses more than that. It solves Kepler's equation by an intermediate value argument, it integrates the time along the orbit, it names the direction of the perihelion, and it extends a local solution of a differential equation to all times. Each of these steps can carry a price on $\mathbb{R}_\delta$. Does a planet on $\mathbb{R}_\delta$, where nothing is decided for free, still return to where it was? And when the force law carries the first relativistic correction, by how much does its orbit turn per revolution?

Here is a small case. Put the gravitational parameter at $m = 1$ and start a body at $x = (1, 0, 0)$ with velocity $v = (0, \frac{6}{5}, 0)$. The energy, the angular momentum and the Laplace–Runge–Lenz vector are

$$E = \tfrac{1}{2}|v|^2 - \frac{m}{|x|} = -\frac{7}{25}, \qquad L = x \times v = \big(0, 0, \tfrac{6}{5}\big), \qquad A = v \times L - m\frac{x}{|x|} = \big(\tfrac{11}{25}, 0, 0\big),$$

and they satisfy $|A|^2 = 2E|L|^2 + m^2$: indeed $\frac{121}{625} = -\frac{504}{625} + 1$. The orbit is the conic $r(m + |A|\cos\theta) = |L|^2$, here $r(1 + \frac{11}{25}\cos\theta) = \frac{36}{25}$, with θ the angle from A: the body is at its perihelion $r = 1$ now and reaches its aphelion $r = \frac{18}{7}$ half a turn later. The semi-major axis is $a = \frac{1}{2}(1 + \frac{18}{7}) = \frac{25}{14} = m/(-2E)$, and Kepler's third law gives the period T by $T^2(-2E)^3 = (2\pi_\delta)^2 m^2$, so $T = 2\pi_\delta(\frac{25}{14})^{3/2} \approx 14.99$. Every number here is a ratio or is computed from ratios, so nothing needs deciding. The questions of this chapter begin when the initial state is a general point of $\mathbb{R}_\delta^6$. Then A may be so small that no finite stage of its regular sequences tells which way the perihelion points, and the classical inverse of Kepler's time map is an intermediate value search.

We prove that none of this stops the planet. Every bound, non-radial motion of Newton's inverse-square field on $\mathbb{R}_\delta$ is in the same state one period later, at every time, and the proof uses no omniscience principle and no choice principle (Theorems 25.20 and 25.21). Kepler's equation is solved with no choice (Theorem 25.10). The perihelion direction is where a price appears: assigning one to every planar state implies LLPO, and LLPO with countable choice provides it (Theorem 25.13).

The relativistic question has a sharp answer too. For the motion of a test body in proper time under the field $\ddot{x} = -mx/|x|^3 - 3mL^2x/|x|^5$, in a weak-field window, the polar angle advances per radial period by

$$\Phi = 2\pi_\delta + 6\pi_\delta\frac{m}{p} + \frac{3\pi_\delta}{2}\,(18 + e^2)\Big(\frac{m}{p}\Big)^2 + R, \qquad 0 \le R \le 160\,\pi_\delta\Big(\frac{m}{p}\Big)^3,$$

where p and e are read off the orbit's own two apsidal radii (Theorem 25.42). This, the proper-time form of Kepler's third law and the period seen by a far observer are proved for the

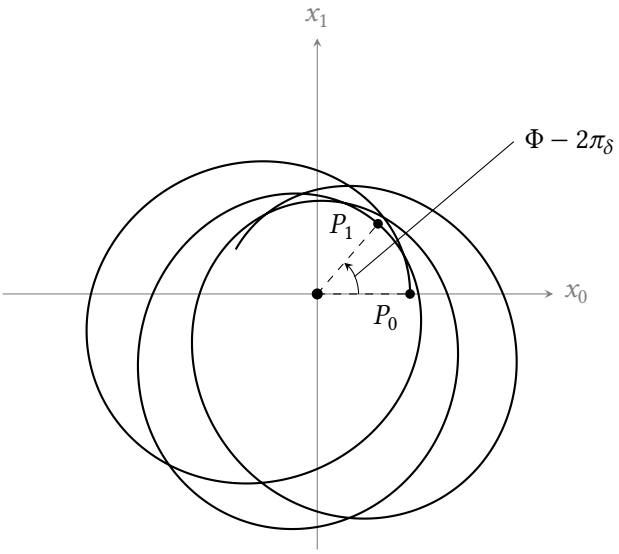

Figure 25.1. An orbit whose inverse radius oscillates in the polar angle with frequency $\kappa = 0.88$: after one radial period the polar angle has advanced by $\Phi = 2\pi_\delta/\kappa$, so the pericentre moves from P_0 to P_1. Newton's field has $\kappa = 1$ and closes; an inverse-cube term gives $\kappa = \sqrt{1 - \epsilon/L^2}$ (Theorem 25.23), and the relativistic field gives the advance of Theorem 25.42. The advance drawn is more than ten times the largest one the weak-field window of Section 25.6 allows.

actual motion, with explicit constants, and again with no omniscience and no choice. As a numerical illustration of the window: the orbit equation $u'' + u = 1 + u^2/100$ of Section 25.6, started at an apside $u = 1$ with $u' = 0$, has an apsidal period Φ with $2.02\,\pi_\delta \le \Phi \le 2.0208\,\pi_\delta$ (Theorem 25.35): after the polar angle turns by Φ, the inverse radius and its rate are back at their starting values. So the apsides advance by between 3.6 and 3.75 degrees per revolution. Figure 25.1 shows such an advancing orbit, with the correction made large enough to see.

Table 25.1 collects the prices. Most entries are free, which is the point: the classical mechanics of orbits and bodies holds on $\mathbb{R}_\delta$ as it stands, and the prices sit exactly at the decisions classical mechanics makes without comment, such as which way the perihelion points, whether an orbit is bound, or which axis of a body has the largest moment of inertia.

The chapter opens Part VII. It uses the line and its prices from Chapter 12, the certified solver of Chapter 15, and the circle functions and π_δ of Section 21.2. Maps are read as in Section 21.1: a map is a rule given as data, computed from regular sequences naming its arguments. Section 25.1 defines motions of polynomial fields and proves that they are determined by their initial states. Sections 25.2 to 25.5 treat Newton's mechanics of orbits: Kepler's laws, other central forces, the return of bound orbits, and N bodies. Sections 25.6 and 25.7 treat the relativistic orbit, first in the polar angle and then in proper time, and Section 25.8 says which of its inputs Recognition Science derives. Section 25.9 shows that the certified solver of Chapter 15 produces motions, and Section 25.10 treats the rigid body.

Two conventions hold throughout. The cosine, the sine and π_δ are those of Definition 21.6. A *quarter period* is a point q with $0 \le q \le 2$ and $\cos q = 0$; by Theorem 21.8 there is exactly one, $q = \pi_\delta/2$, so $4q = 2\pi_\delta$, $\cos q = 0$ and $\sin q = 1$, and the addition formulas of Section 21.2 give $\cos 2q = -1$, $\sin 2q = 0$ and period $4q$ for both functions. Physical readings are identifications: reading x as a position, m as GM and t as a time is classical physics laid over the mathematics,

and no theorem below supplies it.

25.1 Motions on the line

Every force law of this chapter is a polynomial in the state, once the inverse distance is carried as a coordinate of its own. That makes the laws exact objects with ratio coefficients and their derivatives formal.

Definition 25.1 (Polynomial fields and first integrals)**.** A *polynomial field* p on d coordinates gives each coordinate $i < d$ a polynomial p_i in $x_0, \dots, x_{d-1}$ with coefficients in $\mathbb{Q}_\delta$, as in Definition 15.27; we evaluate it at points of $\mathbb{R}_\delta^d$. For a polynomial F with coefficients in $\mathbb{Q}_\delta$ the *Lie derivative* is the polynomial

$$\mathscr{L}_p F = \sum_{i<d} \frac{\partial F}{\partial x_i}\, p_i,$$

formed formally. F is a *first integral* of p when $(\mathscr{L}_p F)(x) = 0$ for every $x \in \mathbb{R}_\delta^d$. A polynomial D is *invariant with rate* G when $\mathscr{L}_p D = G\,D$ at every point.

Definition 25.2 (Motions)**.** A *motion* of a polynomial field p is a map x from $\mathbb{R}_\delta$ to $\mathbb{R}_\delta^d$ such that for every natural number T and every k there is a j with

$$\bigl|x_i(t) - x_i(s) - p_i\bigl(x(s)\bigr)(t-s)\bigr| \le \frac{|t-s|}{k+1}$$

for every $i < d$ and all $s, t \in [-T, T]$ within $1/(j+1)$ of each other. A *motion on* $[0, T]$, for a natural number T, satisfies the same with $s, t \in [0, T]$.

So $p(x(s))$ is a uniform derivative of x in the sense of Definition 12.80 on every bounded interval, with one modulus for all its points, and x has derivative $p(x(s))$ at each s. This is Bishop's notion of a solution [38]. It asks for a modulus, not for a limit of approximations, so a motion carries its own evidence that it solves the equation.

Theorem 25.3 (A motion is determined by its initial state)**.** *Let p be a polynomial field on d coordinates.*

(a) If x and y are motions of p on $[0, T]$ with $x(0) = y(0)$, then $x(t) = y(t)$ for every $t \in [0, T]$.

(b) If x and y are motions of p with $x(0) = y(0)$, then $x(t) = y(t)$ for every $t \in \mathbb{R}_\delta$.

No omniscience principle and no choice principle is used.

Proof. (a) *A motion is bounded.* Take the modulus j_0 of x at $k = 0$ and $h = 1/(j_0 + 1)$. For a natural bound B let $P(B)$ be the sum of the absolute values of the coefficients of all p_i times $(B+1)^{\deg p}$, so that $|p_i(z)| \le P(B)$ when every $|z_i| \le B$. If $|x_i(nh)| \le B_n$ for all i, then $|x_i(t)| \le B_n + h(P(B_n) + 1) =: B_{n+1}$ for $nh \le t \le (n+1)h$. After $(j_0 + 1)T$ steps this bounds x on $[0, T]$ by a natural number, and likewise y; let B bound both.

Table 25.1. What the mechanics of this chapter costs on $\mathbb{R}_\delta$. "Free" means no omniscience principle and no choice principle; "classical" means proved with excluded middle and choice.

Statement	Price
Two motions with one initial state agree; first integrals are constant along motions	free
Kepler's first integrals, the vector A, the conic; Kepler's equation; the third law	free
Every bound, non-radial Kepler motion returns after one period, at every time	free
Every planar physical state has a perihelion direction	implies LLPO; LLPO with AC_ω gives it
Bound, parabolic or unbound, decided for every state	LPO
A vector $v \times L - g\,x$ is conserved only for the inverse square; Fradkin's tensor	free
"No precession" decided for every real frequency $\kappa > 0$	WLPO
Binet's clock for an inverse-cube correction; precession exactly when $\epsilon \neq 0$	free
Ten integrals of N bodies; two bodies; Lagrange's rotating triangle is the motion	free
The physical state $u_{ab} = 1/\lvert x_a - x_b\rvert$ from non-collision	$\mathrm{MP}_{\mathrm{bin}}$
Post-Newtonian advance, second order, proper-time Kepler law, far observer's period	free
Certified runs are motions; schedule independence; Lipschitz data; short times	free
Exact conservation along certified runs; invariant families preserved	free
Completeness of the region check; one fixed machine for short times	classical
One conversion certificate for a whole polynomial theory	classical (one clause)
Rigid body: integrals, stability, Chetaev's escape from the middle axis	free
Deciding whether an axis is a body's axis of largest moment	LPO

The field is Lipschitz on the ball. Expanding monomials, $|p_i(z) - p_i(z')| \le K \max_l |z_l - z'_l|$ for $|z_l|, |z'_l| \le B$, with an explicit natural number K.

The two motions stay together. Fix k, let j serve both motions at the tolerance k, fix $t \in [0,T]$, take a natural number $N \ge (j+1)T$ and put $t_n = nt/N$, so that consecutive points are within $1/(j+1)$. With $e_n = \max_i |x_i(t_n) - y_i(t_n)|$ and $h = t/N$,

$$x(t_{n+1}) = x(t_n) + p\big(x(t_n)\big)h + \rho_n, \qquad y(t_{n+1}) = y(t_n) + p\big(y(t_n)\big)h + \rho'_n,$$

with $|\rho_n|, |\rho'_n| \le h/(k+1)$. Hence $e_{n+1} \le (1 + Kh)e_n + 2h/(k+1)$ and, since $e_0 = 0$,

$$e_N \le (1+Kh)^N \frac{2Nh}{k+1} \le \frac{2Te^{KT}}{k+1},$$

using $1 + u \le e^u$ (Section 21.2). This holds for every k, so $x(t) = y(t)$.

(b) An equation between points of $\mathbb{R}_\delta$ is the negation of apartness, so it may be proved by cases that hold only under double negation. Under $t \ge 0$, restrict both motions to $[0,T]$ with $T \ge t$ natural and apply (a). Under $t \le 0$, the curves $s \mapsto x(-s)$ and $s \mapsto y(-s)$ are motions of the field $-p$ on $[0,T]$ with $T \ge -t$, and (a) applies again. Since $\neg\neg(t \le 0 \vee t \ge 0)$ holds, $x(t) = y(t)$. □

The discrete Gronwall step is the one of Chapter 15 (Theorem 15.8) and goes back to Gronwall [159]. Uniqueness costs nothing; what the classical theory adds is existence, and on $\mathbb{R}_\delta$ each existence statement below comes with a construction.

Lemma 25.4 (Calculus along motions)**.** *Let x be a motion of p and F a polynomial.*

(a) For every point c the curve $s \mapsto x(s + c)$ is a motion of p.

(b) The function $t \mapsto F(x(t))$ has the uniform derivative $(\mathscr{L}_p F)(x(t))$ on every bounded interval.

(c) A function with uniform derivative c, a constant, on every bounded interval satisfies $f(t) = f(0) + ct$ for every t.

The same holds for motions on $[0,T]$, with $[0,T]$ in place of the line. No omniscience principle and no choice principle is used.

Proof. (a) If $|s| \le T$ then $|s + c| \le T + C$ for a natural $C \ge |c|$; use the modulus of x on $[-T-C, T+C]$. (b) On a ball bounding x over the interval, Taylor's formula for the polynomial F gives $|F(z') - F(z) - \nabla F(z)\cdot(z'-z)| \le C|z'-z|^2$, and $|x(t) - x(s)| \le (P+1)|t-s|$ once $|t-s|$ is within the modulus at $k=0$; the derivative of x is $p(x)$, and $\nabla F \cdot p = \mathscr{L}_p F$. (c) Divide $[0,t]$ into N steps within the modulus at tolerance k; the errors add up to at most $|t|/(k+1)$, for every k. □

Proposition 25.5 (First integrals are constant along motions)**.** *If F is a first integral of p, then $F(x(t)) = F(x(0))$ for every motion x of p and every t, and for every motion on $[0,T]$ and every $t \in [0,T]$. No omniscience principle and no choice principle is used.*

Proof. By Lemma 25.4(b) the derivative of $F(x(t))$ is $(\mathscr{L}_p F)(x(t)) = 0$, and (c) with $c = 0$ gives the claim. □

Two constructions recur in the relativistic sections, where a time must be computed from an angle and an angle from a time. Proposition 12.85 forms the integral of a uniformly continuous function with countable choice, for the limit. When the integrand is a map with a Lipschitz constant, the limit has an explicit rate and no choice is needed.

Lemma 25.6 (Antiderivatives of Lipschitz maps)**.** *Let g be a map on $\mathbb{R}_\delta$ and K a natural number with $|g(t) - g(s)| \le K|t - s|$ for all s, t. There is a map G with $G(0) = 0$ and*

$$\big|G(t) - G(s) - g(s)(t - s)\big| \le K|t - s|^2 \qquad \text{for all } s, t,$$

so G has the uniform derivative g on every bounded interval. No omniscience principle and no choice principle is used.

Proof. For a natural number N take the grid $a_i = i/(N+1) - N$, $0 \le i \le 2N(N+1)$, of step $1/(N+1)$ from $-N$ to N. The clamp $c(t;\alpha,\beta) = \frac{1}{2}(\alpha + \beta + |t - \alpha| - |t - \beta|)$ equals α left of α, t between and β right of β, so $\ell_i(s,t) = c(t;a_i,a_{i+1}) - c(s;a_i,a_{i+1})$ is the signed length of the part of $[s,t]$ in the i-th cell. Put $G_N(t) = \sum_{i<2N(N+1)} g(a_i)\,\ell_i(0,t)$: a map with $G_N(0) = 0$ which, for $|t| \le N$ and t of either sign, is the integral from 0 to t of the step function equal to $g(a_i)$ on the i-th cell. The identity $c(t;\alpha,\beta) + c(t;\beta,\gamma) = c(t;\alpha,\gamma) + \beta$ is a ring identity, so for $|s|, |t| \le N$ the $\ell_i(s,t)$ add up to $t - s$; the clamp is nondecreasing, so they are all ≥ 0 if $s \le t$ and all ≤ 0 if $t \le s$, and either way their absolute values add up to $|t - s|$. Hence $G_N(t) - G_N(s) - g(s)(t - s) = \sum_i (g(a_i) - g(s))\,\ell_i(s,t)$, and $\ell_i(s,t)$ is 0 unless the cell meets $[s,t]$, where $|a_i - s| \le \frac{1}{N+1} + |t - s|$. Each case split here concludes an equation or an inequality, which holds once it holds up to double negation, so nothing is decided, and

$$\big|G_N(t) - G_N(s) - g(s)(t - s)\big| \le K\Big(\frac{1}{N+1} + |t - s|\Big)|t - s| \qquad \text{for } |s|, |t| \le N.$$

For $|t| \le R \le N, M$, the difference $D = G_N - G_M$ therefore changes by at most $K(\frac{1}{N+1} + \frac{1}{M+1} + 2|t' - s'|)|t' - s'|$ between points $s', t' \in [-R, R]$; adding this over n equal steps from 0 to t, with $D(0) = 0$, gives $|D(t)| \le K(\frac{1}{N+1} + \frac{1}{M+1})|t| + 2K|t|^2/n$ for every n, so $|G_N(t) - G_M(t)| \le K(\frac{1}{N+1} + \frac{1}{M+1})|t|$. A regular sequence naming t gives a natural number $B \ge |t|$, and then the points $G_{\mu(k)}(t)$, $\mu(k) = 2KB(k+1) + B$, form a Cauchy family. Theorem 12.25 gives its limit $G(t)$ with no choice; $G_N(t)$ tends to it, and limits are unique (Theorem 12.26), so $G(t)$ does not depend on the sequence naming t: G is a map, and $G(0) = 0$. For N at least natural bounds of $|s|$ and $|t|$ the remainder of G_N is at most $K|t - s|^2 + K|t - s|/(N+1)$, and the last term tends to 0, which gives the inequality for G. □

Lemma 25.7 (Inverting a clock)**.** *Let θ be a map on $\mathbb{R}_\delta$ with $\theta(0) = 0$ and a natural number K with $t - s \le \theta(t) - \theta(s) \le K(t - s)$ whenever $s \le t$. There is a map ψ with $\theta(\psi(y)) = y$ and $\psi(\theta(t)) = t$ for all y and t. If θ has the uniform derivative H on every bounded interval, and $HG = 1$ with $|G| \le 1$, then ψ has the uniform derivative $G \circ \psi$ on every bounded interval. No omniscience principle and no choice principle is used.*

Proof. Given y, a regular sequence naming it gives a natural $B \ge |y|$, and the root of $t \mapsto \theta(t) - y$ lies in $[-B, B]$ because $|\theta(t)| \ge |t|$. On $[-B, B]$ the function is uniformly continuous with modulus from K, it has the modulus of uniqueness $\mu(k) = k$ (two near-roots t, t' satisfy $|t - t'| \le |\theta(t) - \theta(t')|$), and its values at grid points are computed from those of θ. Theorem 12.92, after rescaling $[-B, B]$ to $[0, 1]$, computes the root. Two names of y give roots with the same image, and θ is injective, so ψ is a map. For the derivative, with $\xi = \psi(s)$ and $\xi' = \psi(t)$, $\psi(t) - \psi(s) - G(\xi)(t - s) = -G(\xi)\big(\theta(\xi') - \theta(\xi) - H(\xi)(\xi' - \xi)\big)$, and $|\xi' - \xi| \le |t - s|$. □

25.2 Kepler from Newton

Newton's inverse-square force $\ddot{x} = -mx/|x|^3$ is not a polynomial in the position. It becomes one when the inverse distance is carried as a coordinate u with its own equation of motion, and the gravitational parameter m as a coordinate that does not move.

Definition 25.8 (The Kepler field)**.** The *Kepler field* acts on states $(x, v, u, m) \in \mathbb{R}^8_\delta$, with $x, v \in \mathbb{R}^3_\delta$:

$$\dot{x} = v, \qquad \dot{v} = -m\,u^3 x, \qquad \dot{u} = -u^3\,(x \cdot v), \qquad \dot{m} = 0.$$

Its quantities are the energy $E = \frac{1}{2}|v|^2 - mu$, the angular momentum $L = x \times v$, the Laplace–Runge–Lenz vector $A = v \times L - mu\,x$ and the invariant $I = u^2|x|^2$. A state is *physical* when $I = 1$, $u > 0$ and $m \ge 0$; then $u = 1/|x|$, and the field is Newton's.

The coordinate u obeys the equation that $1/|x|$ obeys: $\frac{d}{dt}|x|^{-1} = -|x|^{-3}(x \cdot v)$. On physical states the two agree, and the next theorem shows that the field keeps $I - 1$ at zero at the rate $I - 1$ itself.

Theorem 25.9 (Kepler's integrals, the vector A and the conic)**.** *For the Kepler field p and every state of $\mathbb{R}^8_\delta$:*

(a) E and the three components of L are first integrals;

(b) $\mathscr{L}_p A_k = m\,u\,v_k\,(I - 1)$ for $k = 0, 1, 2$, and $\mathscr{L}_p(I - 1) = -2u^2(x \cdot v)(I - 1)$;

(c) $u\,(A \cdot x) - u|L|^2 + mI = 0$ and $|A|^2 = 2E|L|^2 + m^2 I$.

In particular, on states with $I = 1$ the rate of A vanishes, and with $r = 1/u$,

$$A \cdot x + m\,r = |L|^2, \qquad |A|^2 = 2E|L|^2 + m^2.$$

No omniscience principle and no choice principle is used.

Proof. All three parts are identities of polynomials with ratio coefficients, and $\mathbb{R}_\delta$ is a commutative ring (Proposition 12.19), so ordinary vector algebra proves them.

(a) $\mathscr{L}_p E = v\cdot\dot v - m\dot u = -mu^3(x\cdot v) + mu^3(x\cdot v) = 0$, and $\mathscr{L}_p L = v\times v + x\times(-mu^3 x) = 0$.

(b) With $x\times(x\times v) = x(x\cdot v) - v|x|^2$ and $\dot L = 0$,

$$\begin{aligned}\dot A &= \dot v\times L - m\dot u\, x - mu\, v = -mu^3 x\times(x\times v) + mu^3(x\cdot v)x - mu\, v\\ &= mu^3|x|^2 v - mu\, v = mu\, v(I-1).\end{aligned}$$

And $\dot I = 2u\dot u|x|^2 + 2u^2(x\cdot v) = -2u^4|x|^2(x\cdot v) + 2u^2(x\cdot v) = -2u^2(x\cdot v)(I-1)$.

(c) $A\cdot x = (v\times L)\cdot x - mu|x|^2 = L\cdot(x\times v) - mu|x|^2 = |L|^2 - mu|x|^2$; multiplying by u gives the first identity. Since v is orthogonal to L and $x\cdot(v\times L) = |L|^2$,

$$|A|^2 = |v|^2|L|^2 - 2mu\,|L|^2 + m^2u^2|x|^2 = 2E|L|^2 + m^2 I.$$

On $I = 1$ divide the first identity by u. □

When A has a direction n, so that $A = |A|n$, and θ is the angle from n to x, the identity $A\cdot x + mr = |L|^2$ is the conic $r(m + |A|\cos\theta) = |L|^2$ with eccentricity $e = |A|/m$, which is an ellipse when $E < 0$. Kepler found the ellipse and the equal areas [160] and the third law [161]; Newton derived them from the inverse-square force [166]. The vector A goes back to Laplace and was used by Runge and by Lenz [164, 167, 165]; Goldstein traces its history [158].

The classical step from position to time is Kepler's equation $M = \eta - e\sin\eta$ between the mean anomaly M, which grows uniformly in time, and the eccentric anomaly η. Its inverse is classically an intermediate value argument, and on $\mathbb{R}_\delta$ the intermediate value theorem costs LLPO with countable choice (Theorem 12.54). The map $\eta \mapsto \eta - e\sin\eta$ increases at rate at least $1-e$, and that rate removes the price.

Theorem 25.10 (Kepler's equation is solved with no choice)**.** *Let h be a map on $\mathbb{R}_\delta$ with $|h(\theta)| \le 1$ and $|h(\alpha) - h(\beta)| \le |\alpha - \beta|$ for all points. For all points e and M with $0 \le e < 1$ there is exactly one η with $\eta - e\,h(\eta) = M$. In particular Kepler's equation $\eta - e\sin\eta = M$ has exactly one solution. No omniscience principle and no choice principle is used.*

Proof. Put $k(\eta) = \eta - e\,h(\eta)$. For $\alpha \le \beta$, $k(\beta) - k(\alpha) \ge (\beta-\alpha) - e|h(\beta) - h(\alpha)| \ge (1-e)(\beta-\alpha)$.

Uniqueness. If $k(\eta) = k(\eta') = M$ and $\eta < \eta'$, then $k(\eta') - k(\eta) \ge (1-e)(\eta'-\eta) > 0$, which is false; so $\eta' \le \eta$, and likewise $\eta \le \eta'$. Hence $\eta = \eta'$.

Existence. On $[0,1]$ put $f(t) = k(M + 2t - 1) - M$. Then $f(0) = -1 - e\,h(M-1) \le -1 + e \le 0$ and $f(1) = 1 - e\,h(M+1) \ge 1 - e \ge 0$, and $|f(t) - f(t')| \le 4|t - t'|$, a modulus of uniform continuity given as a function. Since $1 - e > 0$, a positive stage gives a natural N with $1 - e \ge 1/(N+1)$ (Lemma 12.16). The inequality $|t - t'| \le \frac{N+1}{2}|f(t) - f(t')|$ may be proved by cases on the order of t and t', and each case follows from the rate of k; so $\mu(k) = (N+1)(k+1)$ is a modulus of uniqueness. Finally h is a map in the sense of Section 21.1: its value at each grid point $M + 2j/3^n - 1$ is named by a regular sequence computed from n, j and the sequences naming M and e. Theorem 12.92 computes a root t^* of f, and $\eta = M + 2t^* - 1$ solves the equation.

The sine qualifies. $|\sin| \le 1$ by Section 21.2. For the Lipschitz bound, $\sin\alpha - \sin\beta = 2\cos\frac{\alpha+\beta}{2}\sin\frac{\alpha-\beta}{2}$ by the addition formulas, so it suffices that $|\sin\theta| \le |\theta|$. By cotransitivity $|\theta| > 1$ or $|\theta| < 2$. In the first case $|\sin\theta| \le 1 < |\theta|$. In the second $\sin\theta = \theta\,\mathrm{S}(\theta^2)$ with $0 \le \theta^2 \le 4$, and $\mathrm{S}(s) - 1 = \sum_{i\ge 0}\big(-s^{2i+1}/(4i+3)! + s^{2i+2}/(4i+5)!\big)$ has nonpositive brackets for $s \le 20$, while $\mathrm{S}(s) \ge 1 - s/6 \ge 0$ for $s \le 4$; so $0 \le \mathrm{S}(\theta^2) \le 1$. □

Without the rate the same root would need the presented intermediate value theorem of Theorem 12.92 with a modulus of uniqueness from elsewhere, or LLPO with countable choice. Kepler's map supplies the modulus itself: two near-solutions are near each other because the map increases at rate $1 - e$.

The ellipse of Kepler's first law, run in the eccentric anomaly, solves the field exactly, and its period is $2\pi_\delta$ in η.

Theorem 25.11 (Kepler's third law, with no choice)**.** *Let m, a, b, n, e be points with $a > 0$, $0 \le e < 1$, $b \ge 0$, $b^2 = a^2(1-e^2)$, $n > 0$ and $n^2a^3 = m$. Put $\rho(\eta) = 1 - e\cos\eta$,*

$$X(\eta) = \Big(a(\cos\eta - e),\ b\sin\eta,\ 0,\ -\frac{na\sin\eta}{\rho},\ \frac{nb\cos\eta}{\rho},\ 0,\ \frac{1}{a\rho},\ m\Big), \qquad t(\eta) = \frac{\eta - e\sin\eta}{n}.$$

Then for every η:

(a) $X(\eta)$ is a physical state with $I = 1$ and $2a\,E = -m$;

(b) t has derivative $\rho(\eta)/n$ at η, and each coordinate X_i has derivative $\frac{\rho(\eta)}{n}\,p_i(X(\eta))$ at η, where p is the Kepler field;

(c) $X(\eta + 2\pi_\delta) = X(\eta)$ and $t(\eta + 2\pi_\delta) = t(\eta) + 2\pi_\delta/n$;

(d) the period $T = 2\pi_\delta/n$ satisfies $T^2 m = (2\pi_\delta)^2 a^3$.

No omniscience principle and no choice principle is used.

Proof. $\rho \ge 1 - e > 0$, so $1/\rho$ exists. Write $c = \cos\eta$ and $s = \sin\eta$.

(a) $|x|^2 = a^2(c-e)^2 + b^2s^2 = a^2(c-e)^2 + a^2(1-e^2)(1-c^2) = a^2(1-ec)^2 = a^2\rho^2$, so $u = 1/(a\rho)$ gives $I = 1$. Next $a^2s^2 + b^2c^2 = a^2(1-e^2c^2) = a^2\rho(1+ec)$, so $|v|^2 = n^2a^2(1+ec)/\rho$ and

$$E = \frac{n^2a^2(1+ec)}{2\rho} - \frac{m}{a\rho} = \frac{n^2a^2\big((1+ec)-2\big)}{2\rho} = -\frac{n^2a^2}{2} = -\frac{m}{2a},$$

using $m = n^2a^3$ and $(1+ec) - 2 = -\rho$.

(b) The sine and cosine have derivatives cos and $-\sin$ at every point, with no choice: by the addition formulas, $\sin(\eta+h) - \sin\eta - h\cos\eta = \sin\eta(\cos h - 1) + \cos\eta(\sin h - h)$, which is at most $h^2 + |h|^3$ in absolute value for $|h| \le 1$ (Section 21.2), and likewise for the cosine. Sums, products and quotients by the positive ρ follow the usual rules, with the usual proofs. Then $t' = (1-ec)/n = \rho/n$, and the coordinates check one by one. For instance $\frac{d}{d\eta}a(c-e) = -as = \frac{\rho}{n}\cdot v_0$ with $v_0 = -nas/\rho$. With $\rho' = es$,

$$\frac{dv_0}{d\eta} = -na\,\frac{c\rho - s\cdot es}{\rho^2} = -na\,\frac{c-e}{\rho^2},$$

because $c(1-ec)-es^2 = c-e$; and $\frac{\rho}{n}(-mu^3x_0) = \frac{\rho}{n}\cdot(-n^2a^3)\frac{a(c-e)}{a^3\rho^3} = -na\frac{c-e}{\rho^2}$. For u: $\frac{d}{d\eta}\frac{1}{a\rho} = -\frac{es}{a\rho^2}$, and $x\cdot v = \big(-na^2s(c-e)+nb^2sc\big)/\rho = na^2es(1-ec)/\rho = na^2es$, so $\frac{\rho}{n}(-u^3x\cdot v) = -\frac{\rho}{n}\cdot\frac{na^2es}{a^3\rho^3} = -\frac{es}{a\rho^2}$. The coordinates x_1, v_1 are similar, and x_2, v_2, m are constant.

(c) The sine and cosine have period $4q = 2\pi_\delta$.

(d) $T^2m = (2\pi_\delta)^2m/n^2 = (2\pi_\delta)^2a^3$. □

Conditions and scope.

Base and premises

The line $\mathbb{R}_\delta$, its circle functions and π_δ, and the Kepler field. Nothing is decided and nothing is chosen.

Conclusion

Kepler's ellipse, run in the eccentric anomaly, is a solution of Newton's field whose period obeys $T^2m = (2\pi_\delta)^2a^3$, and every mean anomaly has exactly one eccentric anomaly.

Identification

Reading (x, v) as a body's position and velocity, m as GM, and t as time is classical physics; the theorem does not supply it. Under the classical reading π_δ is π.

Not claimed

That every motion of the field lies on such an ellipse; that is Theorem 25.20.

The first price in classical mechanics appears at the direction of the perihelion. On a circular orbit $A = 0$, and near one A is a vector whose regular sequences may stay near 0 for as long as one cares to read them.

Definition 25.12 (Directions and perihelion directions)**.** *Every plane vector has a direction* when for all points a, b there are points n_0, n_1, l with $n_0^2 + n_1^2 = 1$, $l \geq 0$, $a = ln_0$ and $b = ln_1$. *Every planar physical state has a perihelion direction* when every physical Kepler state with $x_2 = v_2 = 0$ has a unit vector (n_0, n_1) and $l \geq 0$ with $(A_0, A_1) = l(n_0, n_1)$. *Every physical state has a perihelion direction* when every physical Kepler state has a unit vector n with $n \cdot L = 0$ and $l \geq 0$ with $A = ln$.

Theorem 25.13 (The perihelion direction lies between LLPO and LLPO with countable choice)**.**

(a) Every planar physical state has a perihelion direction if and only if every plane vector has a direction, and if and only if every physical state has a perihelion direction.

(b) If every plane vector has a direction, then LLPO holds.

(c) Assuming AC_ω*, LLPO implies that every plane vector has a direction.*

Apart from the countable choice named in (c), no choice principle is used.

Proof. (a) Every plane vector (a, b) is the vector A of a planar physical state: take $x = (1, 0, 0)$, $u = 1$, $t = a^2 + 1$, $v = (-b/t,\ t,\ 0)$ and $m = t^2 - a$. Then $L = (0, 0, t)$, $v \times L = (t^2,\ b,\ 0)$ and $A = (t^2, b, 0) - m(1, 0, 0) = (a, b, 0)$; and $m \geq 0$ because $2m = 2a^4 + 3a^2 + (a - 1)^2 + 1$. So perihelion directions for planar states give directions for plane vectors. Conversely a direction of (A_0, A_1) is a perihelion direction.

For the spatial form, the state just built has $L = (0, 0, t)$ with $t \geq 1$, so a unit n with $n \cdot L = 0$ has $n_2 = 0$, and (n_0, n_1) is a direction of (a, b). Conversely, assume that plane vectors have directions. Then space vectors have directions: write $(a, b) = l_1(m_0, m_1)$ and $(l_1, c) = l(k_0, k_1)$; then $(k_0 m_0, k_0 m_1, k_1)$ is a unit vector and $(a, b, c) = l(k_0 m_0, k_0 m_1, k_1)$. By (b) LLPO holds, and with it $yz = 0$ implies $y = 0$ or $z = 0$: LLPO decides $|y| \leq |z|$ or $|z| \leq |y|$, and in the first case $y^2 \leq |yz| = 0$. Now let a physical state be given, and let $A = ln$ with n a unit vector. The identities of Theorem 25.9 give $A \cdot L = (v \times L) \cdot L - mu\, x \cdot (x \times v) = 0$, so $l(n \cdot L) = 0$. If $n \cdot L = 0$ we are done. If $l = 0$, then $A = 0$, and any unit vector orthogonal to L serves: write $L = \lambda k$ with k a unit vector; by cotransitivity $k_0^2 < \frac{1}{2}$ or $k_0^2 > \frac{1}{4}$, so $k \times (1, 0, 0)$ or $k \times (0, 1, 0)$ has squared length above $\frac{1}{4}$, and its direction p satisfies $p \cdot L = \lambda\,(p \cdot k) = 0$.

(b) Let α be a binary sequence with at most one entry 1. Put $a = \sum_{n\ \mathrm{even}} \alpha(n) 2^{-n}$ and $b = \sum_{n\ \mathrm{odd}} \alpha(n) 2^{-n}$, and let $(a, b) = l(n_0, n_1)$ with $n_0^2 + n_1^2 = 1$. By cotransitivity $n_0^2 > \frac{1}{3}$ or $n_0^2 < \frac{1}{2}$, and in the second case $n_1^2 > \frac{1}{2}$. Suppose $n_0^2 > \frac{1}{3}$. If $\alpha(n) = 1$ for an odd n, then $a = 0$, so $l n_0 = 0$ with n_0 apart from 0; hence $l = 0$ and $b = 0$, although $b = 2^{-n}$. So α vanishes at every odd place. If $n_1^2 > \frac{1}{3}$ the same argument shows that α vanishes at every even place. That is LLPO.

(c) Let (a, b) be given. On $[0, 1]$ the path $P(t) = 1 - |2t - 1|$, $Q(t) = 2t - 1$ runs from $(0, -1)$ through $(1, 0)$ to $(0, 1)$, and $P(t)^2 + Q(t)^2 \geq \frac{1}{2}$. The cross product $f(t) = P(t)\, b - Q(t)\, a$ is uniformly continuous with $f(0) = a$ and $f(1) = -a$. LLPO decides $a \geq 0$ or $a \leq 0$ (Corollary 12.18); in the first case use $f(1 - t)$, in the second $f(t)$, so that the values at the ends have the order the intermediate value theorem asks. With countable choice, LLPO gives that theorem (Theorem 12.54), hence a t^* with $f(t^*) = 0$. Put $(P, Q) = (P(t^*), Q(t^*))$, $N = \sqrt{P^2 + Q^2} > 0$ and $D = aP + bQ$. Since the cross product vanishes, $(a, b) = (D/N^2)(P, Q)$. LLPO decides $D \geq 0$ or $D \leq 0$: in the first case $n = (P, Q)/N$ and $l = D/N$, in the second $n = -(P, Q)/N$ and $l = -D/N$. □

Near a circular orbit the vector A is nearly 0, and no finite reading of the state tells which way the perihelion points. The theorem makes that precise: the direction is not merely hard to compute, it is equivalent to a decision about a binary sequence. Everything the orbit does in time, as the next sections show, needs no such decision.

The type of an orbit is the sign of its energy, and the four prices of signs on the line (Corollary 12.18) reappear exactly.

Theorem 25.14 (What deciding the orbit type costs)**.** *Every point of $\mathbb{R}_\delta$ is the energy of a physical Kepler state. Consequently, made for every physical state, the assertion $E < 0 \vee E = 0 \vee E > 0$ is equivalent to LPO; the assertion $E = 0 \vee E \neq 0$ to WLPO; the assertion $E \leq 0 \vee E \geq 0$ to LLPO; and the assertion $E \neq 0 \to E < 0 \vee E > 0$ to $\mathrm{MP}_{\mathrm{bin}}$. No choice principle is used.*

Proof. Given a point z, take $x = (1, 0, 0)$, $u = 1$, $m = |z| + 1$ and $v = (0, \sqrt{2(z + m)}, 0)$, using the free square root of the nonnegative point $2(z + m) \geq 2$ (Proposition 12.19). Then the state is

physical and $E = (z + m) - m = z$. Each assertion for all physical states is therefore the same assertion for all points, and Corollary 12.18 names its price. □

25.3 Other central forces

Newton's force is one member of a family. Replace u^3 in the force by u^k: on physical states the acceleration becomes $-m\,x/|x|^k$, a central force of strength m/r^{k-1}. Which of the Kepler identities survive?

Definition 25.15 (Central fields)**.** For a natural number k the *central field* c_k acts on states $(x, v, u, m) \in \mathbb{R}^8_\delta$ by

$$\dot{x} = v, \qquad \dot{v} = -m\,u^k x, \qquad \dot{u} = -u^3(x \cdot v), \qquad \dot{m} = 0.$$

So c_3 is the Kepler field, c_{n+3} has the force m/r^{n+2} on physical states, and c_0 is the harmonic force $\ddot{x} = -mx$. For a polynomial g in u and m alone, the *vector* $A_g = v \times L - g\,x$; the Kepler vector is A_{mu}. The *Fradkin tensor* is $F_{ij} = v_i v_j + m\,x_i x_j$ for $i, j < 3$.

Theorem 25.16 (Integrals of central forces)**.**

(a) For every k the three components of $L = x \times v$ are first integrals of c_k.

(b) For every n, the energy $\tfrac{1}{2}|v|^2 - m\,u^{n+1}/(n+1)$ is a first integral of c_{n+3}.

(c) $\tfrac{1}{2}|v|^2 + \tfrac{1}{2}m|x|^2$ is a first integral of c_0, and so is every component F_{ij} of the Fradkin tensor.

No omniscience principle and no choice principle is used.

Proof. (a) $\dot{L} = x \times (-mu^k x) = 0$. (b) The derivative is $-mu^{n+3}(x \cdot v) - mu^n \dot{u} = -mu^{n+3}(x \cdot v) + mu^{n+3}(x \cdot v) = 0$. (c) $v \cdot (-mx) + m\,x \cdot v = 0$, and $\dot{F}_{ij} = -mx_i v_j - m v_i x_j + m(v_i x_j + x_i v_j) = 0$. □

The harmonic oscillator's tensor is due to Fradkin [157]; its eigenvectors are the axes of the ellipse that every harmonic orbit traces. For the vector A_g the answer is the opposite of generous.

Theorem 25.17 (A conserved vector only for the inverse square)**.** *Let k be a natural number. There is a polynomial g in u and m alone such that every component of $A_g = v \times L - g\,x$ has Lie derivative 0 along c_k at every state with $I = 1$ if and only if $k = 3$. For $k = 3$, every such g satisfies $g = mu$ at every state with $u > 0$. No omniscience principle and no choice principle is used.*

Proof. The rate. Since L is conserved, $\frac{d}{dt}(v \times L) = -mu^k x \times (x \times v) = -mu^k\big((x \cdot v)x - |x|^2 v\big)$ and $\frac{d}{dt}(gx) = \partial_u g\,\dot{u}\,x + g\,v = -\partial_u g\,u^3(x \cdot v)x + g\,v$, so for each component l

$$\mathscr{L}_{c_k}(A_g)_l = (x \cdot v)\,x_l\big(u^3 \partial_u g - mu^k\big) + v_l\big(mu^k|x|^2 - g\big). \tag{25.1}$$

If $k = 3$. With $g = mu$ the first bracket is $mu^3 - mu^3 = 0$ and the second is $mu(u^2|x|^2 - 1) = mu(I - 1)$, which vanishes when $I = 1$.

Only if. For natural numbers $N \geq 1$ and M take the states $x = (1/N, 0, 0)$, $u = N$, $m = M$, which have $I = 1$. With $v = (0, 1, 0)$ and $l = 1$, (25.1) gives $MN^{k-2} - g(N, M) = 0$; with $v = (1, 0, 0)$ and $l = 0$ it gives $N^{-2}\big(N^3 \partial_u g(N, M) - MN^k\big) + MN^{k-2} - g(N, M) = 0$, that is $N\partial_u g(N, M) = g(N, M)$. So the polynomials $u^2 g - mu^k$ and $u\,\partial_u g - g$, which have ratio coefficients, vanish at every point of $\{1, 2, \dots\} \times \{0, 1, \dots\}$. Such a polynomial is zero: written as $\sum_j P_j(u) m^j$, for each fixed N it has infinitely many roots in m, so every $P_j(N) = 0$, and then every P_j has infinitely many roots. Hence $u^2 g = mu^k$ as polynomials. For $k \leq 1$ the right side has no factor u^2, which is impossible; so $k \geq 2$ and $g = mu^{k-2}$. Then $u\,\partial_u g = (k - 2)mu^{k-2}$ equals $g = mu^{k-2}$, so $k - 2 = 1$.

Uniqueness. For $k = 3$ the same rows give $u^2 g = mu^3$ as polynomials, so $g = mu$ as polynomials, and $g(u, m) = mu$ at every state. □

Bertrand proved that among central forces only the inverse square and the harmonic force have all bounded orbits closed [152]. The theorem is the algebraic core of that statement on $\mathbb{R}_\delta$: a conserved vector pointing at the pericentre, built from the state with a coefficient depending only on the distance, exists only for the inverse square. The harmonic force has a tensor instead of a vector, because its orbits are centred ellipses with two pericentres.

What happens when Newton's force is perturbed? The simplest perturbation that keeps the orbit equation linear is an inverse-cube term.

Definition 25.18 (The inverse-cube correction)**.** For a ratio ϵ, the field c^ϵ is $\dot{x} = v$, $\dot{v} = -mu^3 x - \epsilon u^4 x$, $\dot{u} = -u^3(x \cdot v)$, $\dot{m} = 0$; on physical states the force is $m/r^2 + \epsilon/r^3$. Write $P = -(x \cdot v)\,u$ for the radial rate. A point Θ is a *first apsis* of frequency κ when $\Theta > 0$, $\sin \kappa\Theta = 0$ and $\sin \kappa\theta > 0$ for every θ with $0 < \theta < \Theta$. The oscillator has *no precession* when $2q$ is a first apsis, that is, when the inverse radius returns to its extreme after a polar half-turn.

Theorem 25.19 (Binet's oscillator for an inverse-cube correction)**.**

(a) The angular momentum and $\frac{1}{2}|v|^2 - mu - \frac{1}{2}\epsilon u^2$ *are first integrals of* c^ϵ*. On states with* $I = 1$, $\mathscr{L} u = u^2 P$ *and* $\mathscr{L} P = u^2\big(m - (|L|^2 - \epsilon)u\big)$.

(b) Let $m, \epsilon, L, \kappa, w_0, C$ *be points with* $\kappa^2 L^2 = L^2 - \epsilon$ *and* $w_0 \kappa^2 L^2 = m$*, and put* $W(\theta) = w_0 + C\cos\kappa\theta$*. Then* W *has derivative* $W'(\theta) = -C\kappa \sin\kappa\theta$*, the function* LW' *has derivative* $-L\kappa^2(W - w_0)$*, and* $L^2\big(-\kappa^2(W - w_0)\big) = m - (L^2 - \epsilon)W$.

(c) For $\kappa > 0$, Θ *is a first apsis of frequency* κ *if and only if* $\Theta > 0$ *and* $\kappa\Theta = 2q$.

(d) For $\kappa > 0$ *there is no precession if and only if* $\kappa = 1$*; when* L *is apart from* 0 *and* $\kappa^2 L^2 = L^2 - \epsilon$*, this holds if and only if* $\epsilon = 0$.

(e) The assertion that for every point $\kappa > 0$ *there is no precession or there is, is equivalent to WLPO.*

Parts (a) to (d) use no omniscience principle and no choice principle; (e) uses no choice principle.

Proof. (a) As in Theorem 25.16, the energy has derivative $-(mu^3+\epsilon u^4)(x\cdot v)+(m+\epsilon u)u^3(x\cdot v) = 0$. Next $\mathscr{L}u = -u^3(x\cdot v) = u^2 P$. For P,

$$\mathscr{L}P = -|v|^2 u + (mu^3 + \epsilon u^4)|x|^2 u + (x\cdot v)^2 u^3.$$

On $I = 1$ the middle term is $mu^2 + \epsilon u^3$, and Lagrange's identity $|L|^2 = |x|^2|v|^2 - (x\cdot v)^2$ gives $|v|^2 = |L|^2u^2 + (x\cdot v)^2u^2$; substituting, $\mathscr{L}P = u^2(m - (|L|^2 - \epsilon)u)$.

(b) The derivatives of the cosine and sine (Theorem 25.11) and the chain rule for $\theta \mapsto \kappa\theta$ give W' and $(LW')' = -L\kappa^2 C\cos\kappa\theta = -L\kappa^2(W - w_0)$. Finally $-L^2\kappa^2(W - w_0) = -\kappa^2L^2W + w_0\kappa^2L^2 = -(L^2 - \epsilon)W + m$.

(c) The sine is positive on $(0, 2q)$: for $0 < \theta \le 2$, $\sin\theta \ge \theta/3 > 0$ (Section 21.2), and $\sin(2q - \theta) = \sin\theta$ by the addition formulas; since $2q - 2 < 2$, cotransitivity places every $\theta \in (0, 2q)$ in $(0, 2)$ or in $(2q - 2, 2q)$. And $\sin 2q = 0$. So $\Theta = 2q/\kappa$ is a first apsis. Conversely, let Θ be a first apsis. If $\kappa\Theta < 2q$, then $\sin\kappa\Theta > 0$; if $\kappa\Theta > 2q$, then $\theta = 2q/\kappa$ lies in $(0, \Theta)$ with $\sin\kappa\theta = 0$. Both are refuted, so $\kappa\Theta = 2q$.

(d) By (c), $2q$ is a first apsis exactly when $2q\kappa = 2q$, that is $\kappa = 1$, since $q > 0$. If $\kappa = 1$ then $\epsilon = L^2 - \kappa^2L^2 = 0$. If $\epsilon = 0$ then $(\kappa^2 - 1)L^2 = 0$ with L^2 invertible, so $\kappa^2 = 1$ and $\kappa = 1$.

(e) By (d) the assertion is: $\kappa = 1$ or $\kappa \ne 1$, for every $\kappa > 0$. Given any point z, apply it to $\kappa = 1 + |z|$: this decides $z = 0$ or $z \ne 0$, which for every z is WLPO (Corollary 12.18). Conversely WLPO decides $\kappa - 1 = 0$ or not. □

For a ratio ϵ the test $\epsilon = 0$ is integer arithmetic, so the price in (e) belongs to frequencies given only as points. The theorem is still about the oscillator, a function of the polar angle. That the actual motion in time is this oscillator, read in a polar angle constructed along the motion, is Theorem 25.23 below.

25.4 Bound orbits return

Theorem 25.11 shows that Kepler's ellipse is a solution. The question of the opening is the converse: does every motion with a bound state return? Classically one fits the ellipse to the initial state, inverts Kepler's time map and invokes uniqueness. On $\mathbb{R}_\delta$ the inversion is avoided by running both curves in the eccentric anomaly.

Theorem 25.20 (Every bound Kepler motion returns)**.** *Let x be a motion of the Kepler field whose state at time 0 has $I = 1$, $u > 0$, $E < 0$ and $|L|^2 > 0$, and let $T \ge 0$ satisfy $T^2(-2E)^3 = (2\pi_\delta)^2m^2$, with E and m taken at time 0. Then $x(T) = x(0)$. No omniscience principle and no choice principle is used.*

Proof. A larger field. On $\mathbb{R}^{12}_\delta$, with a Kepler state z and four more coordinates C, S, e, ι, let

$$z' = \iota(1 - eC)\,p(z), \qquad C' = -S, \qquad S' = C, \qquad e' = 0, \qquad \iota' = 0,$$

with p the Kepler field. This is a polynomial field, so Theorem 25.3 applies to it.

The fit. Let $s = x(0) = (x, v, u, m)$. Since $2mu = |v|^2 - 2E > 0$ and $u > 0$, $m > 0$; by Theorem 25.9, $m^2 - |A|^2 = -2E|L|^2 > 0$. Put $\kappa = \sqrt{-2E}$, $\alpha = |A|$ and $\lambda = |L|$, free square roots, and

$$a = \frac{m}{\kappa^2}, \quad e = \frac{\alpha}{m} < 1, \quad b = \frac{\lambda}{\kappa}, \quad n = \frac{\kappa^3}{m},$$

so that $b^2 = a^2(1-e^2)$ and $n^2a^3 = m$. The equation $x(T) = x(0)$ may be proved under double negation, and $\neg\neg(|A|^2 > 0 \vee |A|^2 = 0)$ holds. If $|A|^2 > 0$, put $C_0 = (m-\kappa^2/u)/\alpha$, $S_0 = (x\cdot v)\kappa/\alpha$ and take the frame $f_1 = A/\alpha$, $f_2 = (L\times A)/(\lambda\alpha)$, $f_3 = L/\lambda$. If $|A|^2 = 0$, put $e = 0$, $b = a$, $(C_0, S_0) = (1, 0)$ and take the frame $f_1 = ux$, $f_2 = u(L\times x)/\lambda$, $f_3 = L/\lambda$; here $x\cdot v = 0$, $|v|^2 = mu$ and $\kappa/u = \lambda$. In both cases $C_0^2 + S_0^2 = 1$, for instance $(m-\kappa^2 r)^2 + \kappa^2(x\cdot v)^2 = m^2 - \kappa^2\big(r^2|v|^2 - (x\cdot v)^2\big) = m^2 - \kappa^2|L|^2 = \alpha^2$ with $r = 1/u$, and expanding the definitions shows

$$x = a(C_0 - e)f_1 + bS_0 f_2, \qquad v = \frac{-naS_0}{1-eC_0}f_1 + \frac{nbC_0}{1-eC_0}f_2, \qquad u = \frac{1}{a(1-eC_0)}.$$

The orbit as a motion. Put $C(\eta) = C_0\cos\eta - S_0\sin\eta$ and $S(\eta) = S_0\cos\eta + C_0\sin\eta$, and let $o(\eta)$ be the state of Theorem 25.11 with $\cos\eta, \sin\eta$ replaced by $C(\eta), S(\eta)$, its position and velocity written in the frame f_1, f_2, f_3. The computation of that theorem, with uniform remainders on bounded intervals, and $p(Rz) = Rp(z)$ for the orthonormal frame R, show that $V(\eta) = (o(\eta), C(\eta), S(\eta), e, 1/n)$ is a motion of the larger field. By the fit, $V(0) = (s, C_0, S_0, e, 1/n)$.

The given motion in anomaly time. Put $\tau(\eta) = \big(\eta - e(S(\eta) - S_0)\big)/n$, so that $\tau' = (1-eC)/n$ and $\tau(0) = 0$. By the chain rule $W(\eta) = \big(x(\tau(\eta)), C(\eta), S(\eta), e, 1/n\big)$ is a motion of the larger field, and $W(0) = V(0)$.

Return. By Theorem 25.3, $W = V$. At $\eta = 4q$ the functions C, S are back at C_0, S_0, so $o(4q) = s$ and $x(\tau(4q)) = x(0)$, with $\tau(4q) = 4q/n = 2\pi_\delta/n$. Finally $(1/n)^2(-2E)^3 = m^2/\kappa^6\cdot\kappa^6 = m^2$, so $(2\pi_\delta/n)^2(-2E)^3 = (2\pi_\delta)^2m^2 = T^2(-2E)^3$; both T and $2\pi_\delta/n$ are nonnegative and $(-2E)^3 > 0$, hence $T = 2\pi_\delta/n$. □

No inverse of Kepler's equation and no polar angle enter the proof: the eccentric anomaly is the clock of both curves, and uniqueness compares them. The perihelion direction appears only through the frame, inside a case split that a goal of the form $x(T) = x(0)$ permits.

Theorem 25.21 (Kepler motion is periodic at every time)**.** *Under the hypotheses of Theorem 25.20, $x(t+T) = x(t)$ for every $t \in \mathbb{R}_\delta$. No omniscience principle and no choice principle is used.*

Proof. By Lemma 25.4(a) the curve $t \mapsto x(t+T)$ is a motion, and its state at time 0 is $x(T) = x(0)$ by Theorem 25.20. Theorem 25.3(b) makes it equal to x. □

Conditions and scope.

Base and premises

A motion of the Kepler field on all of $\mathbb{R}_\delta$ whose initial state is physical, bound ($E < 0$) and not radial ($|L|^2 > 0$); T is given by its defining equation, which is Kepler's third law.

Conclusion

The motion repeats with period T at every time. No omniscience principle and no choice principle is used, although the perihelion direction of every such state requires LLPO (Theorem 25.13).

Identification

The coordinates are a body's position, velocity, inverse distance and GM (classical).

Not claimed

That a motion exists for every initial state. For the states of Theorem 25.11 one does (the ellipse in the time $t(\eta)$); the certified solver of Section 25.9 provides motions on bounded intervals of time.

Now the polar angle. Along a planar motion with $I = 1$ the unit vector $(x_0 u, x_1 u)$ turns at the rate Lu^2. Classically the polar angle is $\theta_0 + \int Lu^2\, dt$; on $\mathbb{R}_\delta$ a time integral of a given motion is a limit that in general costs countable choice (Proposition 12.85), and θ_0 itself is the direction of a vector. Both are avoided: the angle is built from finitely many small angles, each an arcsine.

Lemma 25.22 (A polar angle without choice)**.**

(a) Every unit vector (c, s) has an angle: a point θ with $\cos\theta = c$ and $\sin\theta = s$.

(b) Let $e = (e_0, e_1)$ be a map from $\mathbb{R}_\delta$ to the unit circle, and $h = 1/(p+1)$ with p natural, such that $|e_i(\alpha) - e_i(\beta)| \le \frac{1}{8}$ for $i = 0, 1$ whenever $|\alpha - \beta| \le h$. Let θ_0 be an angle of $e(0)$. There is a map θ with $\cos\theta(t) = e_0(t)$ and $\sin\theta(t) = e_1(t)$ for every t.

(c) If moreover, on $[-T, T]$, e_0 has the uniform derivative $-\omega e_1$ and e_1 the uniform derivative ωe_0, with $|\omega|$ bounded there, then θ has the uniform derivative ω on $[-T, T]$.

No omniscience principle and no choice principle is used.

Proof. Arcsine. On $[-1, 1]$ the sine increases with rate at least $\cos 1 > \frac{1}{2}$, so for $|y| \le \sin 1$ the root of $\sin\theta = y$ in $[-1, 1]$ is computed by Theorem 12.92, with modulus of uniqueness from the rate, as in Theorem 25.10. This is a map arcsin.

Small angles. For unit vectors a, b whose coordinates differ by at most $\frac{1}{8}$, $|a \times b| \le |a_0 - b_0| + |a_1 - b_1| \le \frac{1}{4} < \sin 1$ and $a \cdot b = 1 - \frac{1}{2}|a - b|^2 > 0$. Put $\angle(a, b) = \arcsin(a \times b)$. Then $\sin\angle(a, b) = a \times b$ and $\cos\angle(a, b) = a \cdot b$, since both cosines are positive with the same square. For three such vectors, the addition formula gives $\sin\big(\angle(a, b) + \angle(b, c)\big) = (a \times b)(b \cdot c) + (a \cdot b)(b \times c) = a \times c$, an identity for unit plane vectors, and so $\angle(a, b) + \angle(b, c) = \angle(a, c)$, the sine being injective on $[-1, 1]$.

(a) Note $\sin 1 \ge 1 - \frac{1}{6} > \frac{4}{5}$, and $\cos\vartheta > 0$ for $|\vartheta| \le 1$. By cotransitivity $|s| < \frac{7}{10}$ or $|s| > \frac{6}{10}$. In the first case $c^2 > \frac{1}{2}$, so c is apart from 0: if $c > 0$ take $\theta = \arcsin s$, whose cosine is the positive root of $1 - s^2$, namely c; if $c < 0$ take $\theta = 2q - \arcsin s$. In the second case s is apart from 0 and $|c| < \frac{4}{5}$: take $\theta = q - \arcsin c$ if $s > 0$ and $\theta = \arcsin c - q$ if $s < 0$. The addition formulas with $\cos q = 0$, $\sin q = 1$ check each case.

(b) For t read a natural N with $Nh \ge |t|$ off a regular sequence naming t, let $c_n(t)$ be t clamped into $[-nh, nh]$, and put

$$\theta(t) = \theta_0 + \sum_{n<N} \angle\big(e(c_n(t)), e(c_{n+1}(t))\big).$$

Consecutive clamped times are within h, so each angle is defined. Once $Nh \ge |t|$ the further terms are $\angle(e(t), e(t)) = 0$, so $\theta(t)$ does not depend on N or on the sequence: θ is a map. By additivity, $\theta(t) - \theta(s) = \angle(e(s), e(t))$ when $|t - s| \le h$, and induction on the number of steps from 0, with the addition formulas, gives $\cos\theta = e_0$ and $\sin\theta = e_1$.

(c) For $|t-s| \le h$, $\sin\big(\theta(t)-\theta(s)\big) = e(s)\times e(t) = \omega(s)(t-s) + o(|t-s|)$ uniformly on $[-T,T]$, and $|\alpha - \sin\alpha| \le |\alpha|^3$ for $|\alpha| \le 1$. □

Theorem 25.23 (Binet's clock: the motion is the oscillator)**.** *Let ϵ be a ratio and $y = (x, v, u, m)$ a motion of the field c^ϵ of Definition 25.18 such that for every t: $I = 1$, $u > 0$, $x_2 = v_2 = 0$, and $x_0 v_1 - x_1 v_0 = L$, a constant apart from 0 with $\epsilon < L^2$. Then there are a map θ and points w_0, A, B, κ with $\kappa > 0$ such that:*

(a) θ has derivative $Lu(t)^2$ at every t, and $x_0(t)u(t) = \cos\theta(t)$, $x_1(t)u(t) = \sin\theta(t)$ for every t;

(b) $\kappa^2 L^2 = L^2 - \epsilon$ and $w_0\kappa^2 L^2 = m$;

(c) $u(t) = w_0 + A\cos\kappa\theta(t) + B\sin\kappa\theta(t)$ for every t;

(d) whenever $\theta(t') = \theta(t) + 4q/\kappa$, $u(t') = u(t)$; whenever $\theta(t') = \theta(t) + 2q/\kappa$, $u(t') - w_0 = -(u(t) - w_0)$;

(e) $4q/\kappa = 4q$ if and only if $\epsilon = 0$.

No omniscience principle and no choice principle is used.

Proof. The polar angle. The energy $E_\epsilon = \frac{1}{2}|v|^2 - mu - \frac{1}{2}\epsilon u^2$ is constant (Theorem 25.19(a) and Proposition 25.5). On a planar state with $I = 1$, Lagrange's identity gives $|v|^2 = L^2u^2 + P^2 \ge L^2u^2$, so $(L^2-\epsilon)u^2 \le 2E_\epsilon + 2mu$, and since $L^2 - \epsilon > 0$ this bounds u by a natural number U for all times. The unit vector $e = (x_0u, x_1u)$ satisfies $\dot e_0 = -Lu^2 e_1$ and $\dot e_1 = Lu^2 e_0$: for instance $\frac{d}{dt}(x_0u) = u\big(v_0 - x_0u^2(x\cdot v)\big) = -u^3x_1(x_0v_1 - x_1v_0)$, using $u^2(x_0^2 + x_1^2) = 1$. Its speed is at most $|L|U^2$, so one step h serves for all times in Lemma 25.22(b). Part (a) of the lemma gives an angle of $e(0)$, parts (b) and (c) give θ with (a).

The oscillator. Put $\kappa = \sqrt{(L^2-\epsilon)/L^2} > 0$ and $w_0 = m/(L^2-\epsilon)$, so (b) holds. Let $\theta_0 = \theta(0)$, $C_0 = \cos\kappa\theta_0$, $S_0 = \sin\kappa\theta_0$, $u_0 = u(0)$, $P_0 = P(0)$, $D = P_0/(L\kappa)$, and

$$A = (u_0 - w_0)C_0 - DS_0, \qquad B = (u_0 - w_0)S_0 + DC_0.$$

Then $U(\vartheta) = w_0 + A\cos\kappa\vartheta + B\sin\kappa\vartheta$ has $U(\theta_0) = u_0$ and $U'(\theta_0) = \kappa(BC_0 - AS_0) = \kappa D = P_0/L$: the two conditions solved in closed form, with no search.

The motion is the oscillator. Put $\tilde u(t) = U(\theta(t))$ and $\tilde P(t) = LU'(\theta(t))$. The computation of Theorem 25.19(b) applies term by term to $B\sin\kappa\vartheta$, whose second derivative is $-\kappa^2 B\sin\kappa\vartheta$, so $U'' = -\kappa^2(U - w_0)$ and $L^2U'' = m - (L^2-\epsilon)U$. By the chain rule, $\dot{\tilde u} = u^2\tilde P$ and $\dot{\tilde P} = L^2u^2U''(\theta) = u^2\big(m - (L^2-\epsilon)\tilde u\big)$, while Theorem 25.19(a) gives $\dot u = u^2P$ and $\dot P = u^2(m - (L^2-\epsilon)u)$. So

$$Q = (L^2-\epsilon)(u-\tilde u)^2 + (P-\tilde P)^2$$

has derivative $2(L^2-\epsilon)(u-\tilde u)u^2(P-\tilde P) - 2(P-\tilde P)u^2(L^2-\epsilon)(u-\tilde u) = 0$ on every bounded interval and vanishes at 0; by Lemma 25.4(c) it vanishes everywhere, and $u = \tilde u$. That is (c).

(d) The cosine and sine have period $4q$ and change sign under a shift by $2q$. (e) $4q/\kappa = 4q$ exactly when $\kappa = 1$, which is $\epsilon = 0$ by Theorem 25.19(d). □

Conditions and scope.

Base and premises
A planar motion of Newton's field with an inverse-cube correction ϵ/r^3, ϵ a ratio below L^2, on all of $\mathbb{R}_\delta$.

Conclusion
In its own polar angle, the inverse radius of the motion is an oscillator of frequency $\kappa = \sqrt{1-\epsilon/L^2}$; the pericentre advances by $2\pi_\delta(1/\kappa - 1)$ per radial period, and the orbit closes after one turn exactly when $\epsilon = 0$.

Not claimed
The value of ϵ for any physical system. Section 25.6 treats the relativistic correction, whose orbit equation is not linear.

Two choices of form keep the proof free. The angle is a sum of small arcsines, not an integral. And the oscillator is written as $w_0 + A\cos\kappa\theta + B\sin\kappa\theta$, not as $w_0 + C\cos\kappa(\theta - \theta_1)$: the phase form needs the direction of the vector (A, B), which near a circular orbit requires LLPO, exactly as the perihelion direction does.

25.5 The N-body problem

With several bodies every pair needs its own inverse distance. Carrying one coordinate per pair keeps the field polynomial for every N.

Definition 25.24 (The N-body field)**.** For a natural number N, a state consists of positions and velocities $x_a, v_a \in \mathbb{R}^3_\delta$ and masses m_a for $a < N$, one slot u_{ab} for each pair $a < b$ (we write $u_{ba} = u_{ab}$), and a clock τ. The *N-body field* is

$$\dot{x}_a = v_a, \quad \dot{v}_a = \sum_{b \neq a} m_b\, u_{ab}^3\,(x_b - x_a), \quad \dot{u}_{ab} = -u_{ab}^3\,(x_a - x_b)\cdot(v_a - v_b), \quad \dot{m}_a = 0, \quad \dot{\tau} = 1.$$

Its quantities are the energy $\sum_a m_a|v_a|^2/2 - \sum_{a<b} m_a m_b u_{ab}$, the momentum $\mathscr{P} = \sum_a m_a v_a$, the angular momentum $\sum_a m_a\, x_a \times v_a$, the centre-of-mass integral $\sum_a m_a x_a - \tau\mathscr{P}$, and the pair defects $D_{ab} = u_{ab}^2|x_a - x_b|^2 - 1$. A state is *physical* when every $D_{ab} = 0$ and every $u_{ab} > 0$; then $u_{ab} = 1/|x_a - x_b|$ and the field is Newton's, with $m_a = GM_a$.

Theorem 25.25 (Ten integrals for every N)**.** *For every N:*

(a) the energy and the three components each of the momentum, the angular momentum and the centre-of-mass integral are first integrals of the N-body field;

(b) for every pair $a < b$, $\mathscr{L}\, D_{ab} = -2u_{ab}^2\,(x_a - x_b)\cdot(v_a - v_b)\, D_{ab}$.

These are identities in every commutative ring with the ratios, in particular on $\mathbb{R}_\delta$. No omniscience principle and no choice principle is used.

Proof. A double sum over $a \neq b$ is the sum over $a < b$ of the two terms (a,b) and (b,a), and three cancellations follow. *Momentum:* $\sum_a m_a \dot{v}_a = \sum_{a \neq b} m_a m_b u_{ab}^3 (x_b - x_a) = 0$, the summand being antisymmetric in (a,b); this is Newton's third law. *Centre of mass:* its derivative is $\mathscr{P} - \mathscr{P} - \tau \dot{\mathscr{P}} = 0$. *Angular momentum:* $\sum_a m_a\, x_a \times \dot{v}_a = \sum_{a<b} m_a m_b u_{ab}^3 \big(x_a \times (x_b - x_a) + x_b \times (x_a - x_b) \big) = \sum_{a<b} m_a m_b u_{ab}^3 (x_a - x_b) \times (x_b - x_a) = 0$. *Energy:* $\sum_a m_a v_a \cdot \dot{v}_a = \sum_{a<b} m_a m_b u_{ab}^3 (x_b - x_a) \cdot (v_a - v_b)$, while $-\sum_{a<b} m_a m_b \dot{u}_{ab} = \sum_{a<b} m_a m_b u_{ab}^3 (x_a - x_b) \cdot (v_a - v_b)$; the two cancel. (b) involves one pair: with $\Delta x = x_a - x_b$ and $\Delta v = v_a - v_b$, $\frac{d}{dt}(u^2 |\Delta x|^2 - 1) = 2u\dot{u}|\Delta x|^2 + 2u^2\, \Delta x \cdot \Delta v = -2u^2 (\Delta x \cdot \Delta v)(u^2 |\Delta x|^2 - 1)$. □

The ten classical integrals are due to Newton, Euler and Lagrange; Wintner's treatise collects them [170]. The identities are polynomial, so they hold for every N at once and need no physical state; the pair invariant says that the field keeps every D_{ab} at zero at a rate proportional to D_{ab} itself.

Theorem 25.26 (Two bodies are a Kepler problem with a drifting centre)**.**

(a) For $N = 2$ the relative coordinates $(x_0 - x_1,\ v_0 - v_1,\ u_{01},\ m_0 + m_1)$ have Lie derivatives equal to the Kepler field evaluated at them. So along every motion of the two-body field the relative coordinates form a motion of the Kepler field.

(b) Let x be a motion of the two-body field whose relative state at time 0 has $I = 1$, $u_{01} > 0$, relative energy $E = \frac{1}{2}|v_0 - v_1|^2 - (m_0 + m_1) u_{01} < 0$ and $|L|^2 > 0$ for $L = (x_0 - x_1) \times (v_0 - v_1)$, and let $T \geq 0$ satisfy $T^2 (-2E)^3 = (2\pi_\delta)^2 (m_0 + m_1)^2$. Then the relative position, the relative velocity and u_{01} at time T equal their values at 0, and for each body a,

$$(m_0 + m_1)\big(x_a(T) - x_a(0)\big) = T\big(m_0 v_0(0) + m_1 v_1(0)\big).$$

No omniscience principle and no choice principle is used.

Proof. (a) The relative accelerations are $\dot{v}_0 - \dot{v}_1 = m_1 u^3 (x_1 - x_0) - m_0 u^3 (x_0 - x_1) = -(m_0 + m_1) u^3 (x_0 - x_1)$, and $\dot{u}_{01} = -u^3 (x_0 - x_1) \cdot (v_0 - v_1)$: the Kepler field with $m = m_0 + m_1$. If polynomials F_j satisfy $\mathscr{L}_p F_j = q_j(F)$, then by Lemma 25.4(b) the curve $F(x(t))$ has the uniform derivative $q(F(x(t)))$, so it is a motion of q.

(b) By (a) and Theorem 25.20, the relative state returns at T. The masses are constant, $\tau(T) = \tau(0) + T$ by Lemma 25.4(c), and the momentum and the centre-of-mass integral are constant (Theorem 25.25 and Proposition 25.5). So $\sum_b m_b x_b(T) - \sum_b m_b x_b(0) = T\mathscr{P}(0)$. Since $x_0 - x_1$ has returned, both bodies are displaced by the same vector d, and $(m_0 + m_1) d = T\mathscr{P}(0)$. □

Lagrange found that three bodies at the corners of an equilateral triangle, rotating rigidly at the right rate, move exactly so for all time [162]. On $\mathbb{R}_\delta$ the rotation is constructed with no choice, and uniqueness says more: nothing else starts there.

Theorem 25.27 (Lagrange's triangle rotates rigidly, and no other motion starts there)**.**

(a) Let N be a natural number, $c_a \in \mathbb{R}^2_\delta$ and m_a points for $a < N$, and u, ω points with $\sum_a m_a c_a = 0$ and $\omega^2 = \big(\sum_a m_a\big)u^3$. Let $\ell(t)$ be the rotating state*: $x_a(t)$ is c_a turned by the angle ωt in the plane $x_2 = 0$, $v_a(t)$ is ω times $x_a(t)$ turned by a further quarter turn, every pair slot equals u, the masses are m_a and $\tau = t$. Then ℓ is a motion of the N-body field, and every motion x of the field with $x(0) = \ell(0)$ satisfies $x(t) = \ell(t)$ for every t.*

(b) Let m_0, m_1, m_2 have sum $M > 0$ and let $\ell_0 > 0$. There are planar points c_a and points u, ω with $u\ell_0 = 1$, $\omega \geq 0$ and $\omega^2 \ell_0^3 = M$, such that the rotating state is a motion of the three-body field, every pair defect vanishes along it, and every coordinate other than the clock returns after any T with $T\omega = 2\pi_\delta$.

No omniscience principle and no choice principle is used.

Proof. (a) Each coordinate of ℓ is of the form $\alpha \cos \omega t + \beta \sin \omega t$, a constant, or t, so it has uniform derivatives on bounded intervals. With every pair slot equal to u and $\sum_b m_b x_b = 0$, the field at the rotating state is

$$\dot{v}_a = u^3\Big(\sum_b m_b x_b - \big(\textstyle\sum_b m_b\big)x_a\Big) = -\Big(\textstyle\sum_b m_b\Big)u^3 x_a = -\omega^2 x_a,$$

which is the acceleration of the rotation, and $\dot{u}_{ab} = -u^3(x_a - x_b)\cdot(v_a - v_b) = 0$ because $v_a - v_b$ is $x_a - x_b$ turned by a quarter turn. So ℓ is a motion, and Theorem 25.3(b) gives the uniqueness.

(b) Put the corners at $(0,0)$, $(\ell_0, 0)$ and $(\ell_0/2, \ell_0\sqrt{3}/2)$ and subtract their centre of mass $\sum_a m_a c_a / M$; take $u = 1/\ell_0$ and $\omega = \sqrt{Mu^3}$, all by free square roots and inverses of points apart from 0. Each side has length ℓ_0, so every pair defect vanishes at time 0, and rotation keeps the distances. The return follows from the period $4q = 2\pi_\delta$ of the cosine and sine. □

For $N \geq 4$ no planar points are pairwise equidistant, so part (a) has its Newtonian reading, all pair slots equal to the inverse distance, only for $N \leq 3$. As a statement about the polynomial field it holds for every N.

A physical state needs $u_{ab} = 1/|x_a - x_b|$, and forming it from the knowledge that two bodies do not collide has a price.

Theorem 25.28 (The physical state from non-collision costs Markov's principle)**.** *The following are equivalent, with no choice principle: for every N, every state and every pair $a < b$ with $\neg\big(|x_a - x_b|^2 = 0\big)$ there is a point u with $u^2|x_a - x_b|^2 = 1$; and* $\mathrm{MP}_{\mathrm{bin}}$*. The same holds for a single pair of points of $\mathbb{R}^3_\delta$.*

Proof. If $u^2 r^2 = 1$ then r^2 is invertible, hence apart from 0, and being nonnegative it is positive. Every nonnegative point z is such an r^2, for $x_a = (\sqrt{z}, 0, 0)$ and $x_b = 0$. So the assertion gives $z > 0$ from $\neg(z = 0)$ for every $z \geq 0$, which applied to $|z|$ is $\mathrm{MP}_{\mathrm{bin}}$ (Corollary 12.18). Conversely $\mathrm{MP}_{\mathrm{bin}}$ gives $r^2 > 0$ and then $u = 1/\sqrt{r^2}$. □

For ratio data the test $|x_a - x_b|^2 = 0$ is decided by arithmetic, and the price does not arise. That matters for the certified solver of Chapter 15, which starts from ratio data. Its runs keep the physical manifold exactly, and more generally keep every family of polynomials that the field maps into combinations of itself. The proof follows the solver's trajectories of Chapter 15, and one more estimate about them comes first: they stay close to each other at every step, not only at the end, and close to the monomial surface on which the quadratized field moves as the original one does.

Lemma 25.29 (Level trajectories stay together and near the monomial surface)**.** *Let the quadratized problem of a polynomial field p on d coordinates, with initial point $x_0 \in \mathbb{Q}_\delta^d$, radius M and end time T, satisfy the region certificate at level n_0, with trajectories $y_k^{(n)}$, S steps and orders $N(n)$ (Definition 15.18). For a state y of the quadratized field write $x(y)$ for its coordinates w_{e_i} and $z(y) = W(x(y))$, where $W(x) = (x^\alpha)_{|\alpha|\le D}$: the point of the monomial surface $w_\alpha = x^\alpha$ above y.*

(a) If $n_0 \le n \le n'$, then $\|y_k^{(n')} - y_k^{(n)}\| \le 2^{-(n+2)}$ for every $k \le S$.

(b) There are natural numbers A and $n_1 \ge n_0$ such that $\|y_k^{(n)} - z(y_k^{(n)})\| \le A\,2^{-n}$ and $\|z(y_k^{(n)})\| \le M$ for every $n \ge n_1$ and every $k \le S$.

No omniscience principle and no choice principle is used.

Proof. (a) This is the proof of Theorem 15.21, read at every step: both trajectories stay in the ball of radius M (Theorem 15.20), the second form of Theorem 15.9, with $\Phi = \Phi_{N(n)}$ and the defects of Lemma 15.17(b), bounds their distance at step k by E_k, and Lemma 15.19 gives $E_k \le 2^{-(n+2)}$ for every $k \le S$.

(b) Write $h = 2^{-\sigma}$ for the step, so that $8Rh \le 1$.

A margin. For the levels $n_0 \le n$, the proof of Lemma 15.19 bounds E_k by $G(1+2S(M+2))2^{-N(n_0)}$, and the integer $G(1 + 2S(M + 2))$ is less than $2^{\kappa-2}$. So $E_k \le 2^{-(n_0+2)} - 2^{-N(n_0)}$, and the proof of Theorem 15.20 gives $\|y_k^{(n)}\| \le M - 2^{-N(n_0)}$ for $k \le S$.

Products of series. If power series $X_1, \dots, X_d$ have $|X_{i,j}| \le MR^j$, the coefficient of order j of a product of $r \ge 1$ of them is at most $M^r\binom{j+r-1}{r-1}R^j \le M^r 2^{j+r-1}R^j$. For a polynomial F write $|F|(c)$ for the value at $(c, \dots, c)$ of F with every coefficient replaced by its absolute value. Summing over the terms of F,

$$|F(X)_j|\,(4s)^j \le |F|(2M) \quad \text{when } 8Rs \le 1, \tag{25.2}$$

and at a point $\tau \ge 0$ with $8R\tau \le 1$ the terms of $F(X)$ of order at least $K \ge 1$ add up to at most $|F|(2M)\,2^{-K}$ in absolute value. Both hold as well when each X_i is cut off at some order.

One step from the surface. Let z be a point of the monomial surface with $\|z\| \le M$, and let X be the formal solution of $x' = p(x)$ from $x(z)$: $X_0 = x(z)$, and $(j+1)X_{j+1}$ is the coefficient of order j of $p(X)$. The identity $B(W(x), W(x))_\alpha = \sum_i \alpha_i x^{\alpha - e_i} p_i(x)$ in the proof of Corollary 15.30 holds for power series, so $W(X)$ solves the quadratized equation formally from z, and its coefficients are the exact coefficient table at z; by Lemma 15.14, $|X_{i,j}| \le MR^j$. Coordinate α of $\Phi_N(z)$ is the part of X^α of order at most N, at h; that of $z(\Phi_N(z))$ is the product of the parts

of order at most N of the X_i, at h. They differ by the terms of order above N of the latter, so $\|\Phi_N(z) - z(\Phi_N(z))\| \le (2M)^D 2^{-(N+1)}$; and $\|\Phi_N(z)\| \le M \sum_j 8^{-j} \le 2M$.

The induction. On points whose coordinates are at most $2M$, the monomials of degree at most D are Lipschitz with constant $K_W = D(2M)^{D-1}$. Put $a_0 = 1 + K_W$ and $a_{k+1} = (1 + K_W)(M + 2 + 2a_k) + (2M)^D$, an increasing sequence, and $n_1 = n_0 + a_S$. Let $n \ge n_1$, $N = N(n)$ and $y_k = y_k^{(n)}$; we show $\|y_k - z(y_k)\| \le a_k 2^{-N}$ for $k \le S$. At $k = 0$, $y_0 = [W(x_0)]_N$ and $z(y_0) = W([x_0]_N)$, which are within $(1 + K_W)2^{-(N+1)}$. If the bound holds at k, then $a_k 2^{-N} \le 2^{-N(n_0)}$, and the margin gives $\|z(y_k)\| \le M$. With $Y = \Phi_N(z(y_k))$, Lemma 15.17(a) and (b), with the bound $(M+2)2^{-N}$ of the proof of Lemma 15.19, give $\|y_{k+1} - Y\| \le (M + 2 + 2a_k)2^{-N}$; the step from the surface gives $\|Y - z(Y)\| \le (2M)^D 2^{-N}$; and $\|z(Y) - z(y_{k+1})\| \le K_W \|Y - y_{k+1}\|$. The three add up to $a_{k+1}2^{-N}$. So $A = a_S$ will do, and $\|z(y_k)\| \le M$ was shown on the way. □

Theorem 25.30 (Invariant families are kept exactly by certified runs)**.** *Let p be a polynomial field on d coordinates, $D_0, \dots, D_{n-1}$ polynomials and G_{ij} polynomials with $\mathscr{L}_p D_i = \sum_j G_{ij} D_j$ at every point of $\mathbb{R}^d_\delta$. Let $x_0 \in \mathbb{Q}^d_\delta$ have $D_j(x_0) = 0$ for every j, and let the quadratized problem of p with initial point x_0, radius M and end time T satisfy the region certificate at some level, so that the polynomial solution $\bar{x}$ at time T is defined (Definition 15.27). Then $D_i(\bar{x}) = 0$ for every i. In particular:*

- *(a) if $\mathscr{L}_p D = G D$, $\mathscr{L}_p F = A D$ and $D(x_0) = 0$, then $F(\bar{x}) = F(x_0)$: conservation modulo an invariant;*
- *(b) a certified run of the Kepler field started with $I = 1$ ends with $I = 1$ and with its initial vector A;*
- *(c) a certified run of the N-body field started with every pair defect 0 ends with every pair defect 0.*

No omniscience principle and no choice principle is used.

Proof. The idea is linearity: along a formal solution the family obeys a linear equation, which keeps it at 0 when it starts at 0 and multiplies a small start by a fixed factor. Let A, n_1, $x(y)$, $z(y)$ and $|F|(c)$ be as in Lemma 25.29 and its proof, $h = 2^{-\sigma}$ the step of the schedule, and μ a natural number with $|G_{ij}|(2M) \le \mu$ for all i, j.

A linear formal equation. Let power series $E_0, \dots, E_{n-1}$ and g_{ij} satisfy $E_i' = \sum_j g_{ij} E_j$, with $|g_{ij,l}|(4s)^l \le \mu$ for every l, $|E_{i,0}| \le \varepsilon$, and $sn\mu \le \Gamma$ for a natural number Γ. Then $\sum_{k \le K} |E_{i,k}| s^k \le 2\varepsilon(4\Gamma + 2)^{4\Gamma}$ for every K. Indeed, the weights $a_{i,k} = |E_{i,k}|(2s)^k$ satisfy $(k+1)a_{i,k+1} \le 2s\mu \sum_j \sum_{l \le k} 2^{-l} a_{j,k-l}$. With $P = 4\Gamma + 2$, induction on k gives $a_{i,k} \le \varepsilon P^k$, since the right side is then at most $4\Gamma\varepsilon P^k$. In particular $a_{i,k} \le \varepsilon P^{4\Gamma}$ for $k \le 4\Gamma$, and for $k \ge 4\Gamma$ the same inequality gives $a_{i,k+1} \le 4\Gamma\varepsilon P^{4\Gamma}/(k+1) \le \varepsilon P^{4\Gamma}$. So $\sum_k a_{i,k} 2^{-k} \le 2\varepsilon P^{4\Gamma}$.

One step. Fix a level $\ell \ge n_1$ of the solver (we keep n for the number of the D_i), and write $N = N(\ell)$ and $y_k = y_k^{(\ell)}$. Let z be a point of the monomial surface with $\|z\| \le M$ and $|D_i(x(z))| \le \varepsilon$ for every i. As in the proof of Lemma 25.29, $x(\Phi_N(z)) = \sum_{j \le N} h^j X_j$, where X is the formal solution of $x' = p(x)$ from $x(z)$ and $|X_{i,j}| \le MR^j$. The rate law holds at every ratio

point, so it is an identity of polynomials, and the series $E_i = D_i(X)$ satisfy $E_i' = \sum_j g_{ij}E_j$ with $g_{ij} = G_{ij}(X)$. By (25.2) with $s = h$, $|g_{ij,l}|(4h)^l \le \mu$; so for a natural number $\Gamma \ge hn\mu$ the linear equation gives $\sum_{k\le N}|E_{i,k}|h^k \le L\varepsilon$, with $L = 2(4\Gamma+2)^{4\Gamma}$. Now $D_i(x(\Phi_N(z)))$ is $\sum_{k\le N}E_{i,k}h^k$ plus the terms of order above N of D_i at the cut-off series, which add up to at most $|D_i|(2M)2^{-(N+1)}$. So $|D_i(x(\Phi_N(z)))| \le L\varepsilon + C2^{-(N+1)}$, with $C = \max_i |D_i|(2M)$.

Along the trajectory. Let L_D be a natural number with $|D_i(x) - D_i(x')| \le L_D\|x - x'\|$ for all i on points whose coordinates are at most $2M$, and put $b_0 = L_D$ and $b_{k+1} = Lb_k + C + L_D(M+2+2A)$. Then $|D_i(x(y_k))| \le b_k 2^{-\ell}$ for $k \le S$. At $k = 0$, $x(y_0) = [x_0]_N$ is within $2^{-(N+1)}$ of x_0, where every D_i vanishes. For the step take $z = z(y_k)$: $x(z) = x(y_k)$ and $\|z\| \le M$ by Lemma 25.29(b), so $|D_i(x(\Phi_N(z)))| \le (Lb_k + C)2^{-\ell}$; and, as in the proof of that lemma, $\|y_{k+1} - \Phi_N(z)\| \le (M + 2 + 2A)2^{-\ell}$. The numbers b_k depend only on p, the family, M and T, which fix the schedule.

The limit. By Theorem 15.22 the coordinates $x(y_S^{(\ell)})$ converge to $\bar{x}$ as ℓ grows, so $|D_i(\bar{x})| \le b_S 2^{-\ell} + L_D\|\bar{x} - x(y_S^{(\ell)})\|$ tends to 0, and $D_i(\bar{x}) = 0$. No uniqueness of solutions is used. For (a) take the family $(D, F - F(x_0))$ with rates (GD, AD); for (b) use Theorem 25.9(b); for (c) Theorem 25.25(b). □

The same argument bounds the family by a fixed multiple of its initial size when the initial point is near the invariant set rather than on it, and it holds at every certified dyadic time of the run. The conserved quantities of Theorem 25.25 are a family with all rates zero, so a certified N-body run keeps all ten integrals exactly (Theorem 25.52 below).

25.6 The relativistic orbit equation

In the polar angle θ the inverse radius $u = 1/r$ of a Newtonian orbit obeys $u'' + u = m/L^2$, whose solutions are the conics. The first relativistic correction adds a term $3mu^2$: for a test body about a mass m in Schwarzschild's geometry the orbit equation is $u'' + u = m/L^2 + 3mu^2$ [155, 168]. This section treats the equation with general coefficients, $u'' + u = a + bu^2$, in the polar angle; the next one treats the motion in proper time.

Definition 25.31 (The orbit equation)**.** For ratios a and b, the *orbit field* acts on pairs (u, w) of points:

$$u' = w, \qquad w' = a - u + bu^2,$$

the derivative being in the clock θ, read as the polar angle. Its *energy* is $\mathscr{E}(u, w) = w^2 + u^2 - 2au - \frac{2}{3}bu^3$. The *window* is $a > 0$, $b \ge 0$ and $100ab \le 1$; an initial value u_0 is in the window when $a \le 2u_0 \le 3a$.

For the Schwarzschild orbit $a = m/L^2$, the Newtonian inverse semi-latus rectum, and $b = 3m$; then $100ab \le 1$ reads $300m^2 \le L^2$. The window on u_0 allows the starting radius $1/u_0$ to lie between $\frac{2}{3}$ and 2 times the Newtonian semi-latus rectum $1/a$.

Proposition 25.32 (The energy of the orbit equation)**.** *For all ratios a, b, $\mathscr{E}$ is a first integral of the orbit field. No omniscience principle and no choice principle is used.*

Proof. $\partial_u \mathscr{E} \cdot w + \partial_w \mathscr{E} \cdot (a - u + bu^2) = (2u - 2a - 2bu^2)w + 2w(a - u + bu^2) = 0$. □

The classical way to the orbit is to integrate $d\theta = du/\sqrt{\cdots}$, a cubic under a square root. We avoid both the integral and the square root of a polynomial that changes sign. The idea is to look for the motion in the form of a harmonic oscillator run on an auxiliary clock ψ:

$$u = U_c + A_t \cos\psi, \qquad w = -A_t\, G(\psi) \sin\psi, \qquad \frac{d\psi}{d\theta} = G(\psi) = \sqrt{D - \alpha\cos\psi}. \tag{25.3}$$

Then $du/d\theta = -A_t \sin\psi \cdot G = w$, and since $GG' = \tfrac{1}{2}\alpha \sin\psi$,

$$\frac{dw}{d\theta} = -A_t\big(G' \sin\psi + G\cos\psi\big)G = -A_t\Big(\frac{\alpha}{2} + D\cos\psi - \frac{3\alpha}{2}\cos^2\psi\Big).$$

This equals $a - u + bu^2$ identically in ψ exactly when the coefficients of $\cos^2\psi$, $\cos\psi$ and 1 agree:

$$\alpha = \tfrac{2}{3}\, bA_t, \qquad D = 1 - 2bU_c, \qquad U_c - a - bU_c^2 = \tfrac{1}{3}\, bA_t^2. \tag{25.4}$$

Four parameters, three equations, and the fourth condition is the initial value $U_c + A_t = u_0$. No equation divides by a or b, so $b = 0$ is allowed.

Lemma 25.33 (The centre, the half-amplitude and the clock constants)**.** *Let a, b, u_0 be points with $a > 0$, $b \geq 0$, $100ab \leq 1$ and $a \leq 2u_0 \leq 3a$, and put $\epsilon = ab$. There are points U_c, A_t, D_m, r with*

$$U_c + A_t = u_0, \qquad U_c - a - bU_c^2 = \tfrac{1}{3} bA_t^2,$$
$$D_m^2(1 - 2bU_c) = 1, \qquad D_m \geq 0, \qquad r(1 - 2bU_c) = \tfrac{2}{3} bA_t,$$
$$|r| \leq \tfrac{1}{250}, \quad 1 + |r| \leq D_m^2, \quad D_m \leq 1 + \tfrac{1}{50}, \quad 1 + \epsilon \leq D_m, \quad D_m(1 + 2r^2) \leq 1 + \epsilon + 4\epsilon^2,$$

and moreover $a \leq U_c$, $25A_t^2 \leq 9U_c^2$ and $250\, bU_c \leq 3$. No omniscience principle and no choice principle is used.

Proof. Put $W_0 = u_0 - a \in [-\tfrac{a}{2}, \tfrac{a}{2}]$, $\beta = 1 - 2\epsilon + \tfrac{2}{3} bW_0$ and $Q_2 = a^2 + \tfrac{1}{3} W_0^2$, so that $\beta \geq 1 - \tfrac{7}{3}\epsilon \geq \tfrac{293}{300}$ and $a^2 \leq Q_2 \leq \tfrac{13}{12} a^2$. With $U_c = a + V$ and $A_t = W_0 - V$, the centre relation becomes $\tfrac{4}{3} bV^2 - \beta V + bQ_2 = 0$. Put $\gamma = \tfrac{16}{3} b^2 Q_2$, so $\gamma \leq \tfrac{52}{9}\epsilon^2 \leq \beta^2$, and take the small root written without dividing by b:

$$V = \frac{2bQ_2}{\beta + \sqrt{\beta^2 - \gamma}}.$$

Substituting, $\tfrac{4}{3} bV^2 - \beta V + bQ_2 = bQ_2(\gamma - \beta^2 + (\beta^2 - \gamma))/(\beta + \sqrt{\beta^2 - \gamma})^2 = 0$. Since $\sqrt{\beta^2 - \gamma} \geq \beta - \gamma/\beta$ (square both sides, using $\gamma \leq \beta^2$), $0 \leq V \leq bQ_2/(\beta - \gamma/(2\beta)) \leq \tfrac{10}{9}\epsilon a$; so $a \leq U_c \leq \tfrac{91}{90} a$, $bV \leq \tfrac{10}{9}\epsilon^2$, and $|A_t| \leq \tfrac{a}{2} + V \leq \tfrac{23}{45} a$.

Let $D = 1 - 2bU_c = 1 - 2\epsilon - 2bV \geq 1 - 2\epsilon - \frac{20}{9}\epsilon^2 > \frac{97}{100}$, and put $D_m = 1/\sqrt{D}$ and $r = \frac{2}{3}bA_t/D$. Then $|r| \leq \frac{2}{3}\cdot\frac{23}{45}\epsilon\cdot\frac{100}{97} \leq \frac{9}{25}\epsilon \leq \frac{1}{250}$. Next, $1+|r| \leq D_m^2$ means $|r|D \leq 2bU_c$, that is $\frac{2}{3}b|A_t| \leq 2bU_c$, which holds since $|A_t| \leq 3U_c$. The bound $1+\epsilon \leq D_m$ means $(1+\epsilon)^2 D \leq 1$, and $(1+\epsilon)^2(1-2\epsilon-2bV) = 1 - 3\epsilon^2 - 2\epsilon^3 - 2bV(1+\epsilon)^2 \leq 1$. For the upper bound,

$$(1+\epsilon+3\epsilon^2)^2\Big(1-2\epsilon-\tfrac{20}{9}\epsilon^2\Big) - 1 = \tfrac{7}{9}\epsilon^2 - \tfrac{112}{9}\epsilon^3 - \tfrac{167}{9}\epsilon^4 - \tfrac{94}{3}\epsilon^5 - 20\epsilon^6 \geq 0$$

for $0 \leq \epsilon \leq \frac{1}{100}$, so $D_m \leq 1+\epsilon+3\epsilon^2 \leq 1+\frac{1}{50}$, and with $2r^2 \leq \frac{162}{625}\epsilon^2$, $D_m(1+2r^2) \leq (1+\epsilon+3\epsilon^2)(1+\frac{162}{625}\epsilon^2) \leq 1+\epsilon+4\epsilon^2$. Finally $3U_c - 5A_t \geq 3a - \frac{5}{2}a > 0$ and $3U_c + 5A_t \geq 3a + 3V - \frac{5}{2}a - 5V = \frac{a}{2} - 2V > 0$, so $25A_t^2 \leq 9U_c^2$; and $bU_c \leq \frac{91}{90}\epsilon \leq \frac{3}{250}$. □

The polar angle as a function of the clock is $\vartheta(\psi) = \int_0^\psi d\psi'/G(\psi') = D_m\int_0^\psi (1-r\cos\psi')^{-1/2}\,d\psi'$, an elliptic integral. We build it as a series whose terms are elementary.

Lemma 25.34 (The clock). *Let D_m, r be points with $|r| \leq \frac{1}{250}$, $1+|r| \leq D_m^2$ and $0 \leq D_m \leq 1+\frac{1}{50}$, and put $h(\psi) = D_m(1-r\cos\psi)^{-1/2}$. There is a map ϑ with $\vartheta(0)=0$ such that:*

(a) ϑ has the uniform derivative h on every bounded interval, and $1 \leq h \leq 2$;

(b) $\psi' - \psi \leq \vartheta(\psi') - \vartheta(\psi) \leq 2(\psi'-\psi)$ whenever $\psi \leq \psi'$;

(c) $\vartheta(\psi+4q) = \vartheta(\psi) + \vartheta(4q)$ for every ψ;

(d) $4qD_m \leq \vartheta(4q) \leq 4qD_m(1+2r^2)$ and $4qD_m\big(1+\frac{3}{16}r^2\big) \leq \vartheta(4q) \leq 4qD_m\big(1+\frac{3}{16}r^2+2r^4\big)$.

No omniscience principle and no choice principle is used.

Proof. The binomial coefficients. Let $\beta_n = \binom{2n}{n}/4^n$. Then $\beta_0 = 1$, $\beta_1 = \frac{1}{2}$ and $\beta_{n+1} = \frac{2n+1}{2n+2}\beta_n \leq \beta_n$, so $0 \leq \beta_n \leq \frac{1}{2}$ for $n \geq 1$. The formal series $B(t) = \sum \binom{2n}{n}t^n$ satisfies $(1-4t)B' = 2B$, because $(n+1)\binom{2n+2}{n+1} = 2(2n+1)\binom{2n}{n}$. Hence $(1-4t)(B^2)' = 4B^2$, which is also the equation of $\sum 4^n t^n$, and both start with 1; so $\sum_{i+j=n}\beta_i\beta_j = 1$ for every n. For $|z| \leq \frac{1}{2}$ the series $K(z) = \sum \beta_n z^n$ therefore satisfies $K(z)^2(1-z) = 1$, and $K(z) \geq 1 - \frac{1}{2}\sum_{n\geq 1}|z|^n \geq 1 - \frac{1}{2} = \frac{1}{2}$, since $\sum_{n\geq 1}|z|^n = |z|/(1-|z|) \leq 1$; so $K(z) = (1-z)^{-1/2}$. Its tail after N terms is at most $\sum_{n\geq N}|z|^n \leq 2|z|^N$.

Powers of the cosine. Put $J_0(\psi) = \psi$, $J_1(\psi) = \sin\psi$ and

$$J_{n+2}(\psi) = \frac{\cos^{n+1}\psi\,\sin\psi}{n+2} + \frac{n+1}{n+2}J_n(\psi).$$

Differentiating, $J_n' = \cos^n$, since $\frac{d}{d\psi}\cos^{n+1}\psi\sin\psi = (n+2)\cos^{n+2}\psi - (n+1)\cos^n\psi$. With the Wallis numbers $\varpi_0 = 1$, $\varpi_1 = 0$, $\varpi_{n+2} = \frac{n+1}{n+2}\varpi_n$, induction gives $J_n(\psi+4q) = J_n(\psi) + 4q\varpi_n$ and $|J_n(\psi) - \varpi_n\psi| \leq 1$, because the first term of the recursion has period $4q$ and absolute value at most $\frac{1}{n+2}$.

The series. Put $\vartheta(\psi) = D_m\sum_n \beta_n r^n J_n(\psi)$. The terms are at most $|r|^n(|\psi|+1)$, so the partial sums, computed from a regular sequence naming ψ, converge at a geometric rate on every

bounded interval; Theorem 12.25 gives the limit with no choice, and limits are unique, so ϑ is a map. The derivatives of the partial sums are $D_m \sum_{n<N} \beta_n (r\cos\psi)^n$, within $2D_m|r|^N$ of $h(\psi) = D_m K(r\cos\psi)$, and they are Lipschitz with one constant for all N; so the limit has the uniform derivative h. From $1+|r| \le D_m^2$ and $(1-r\cos\psi)^{-1/2} \ge (1+|r|)^{-1/2}$ we get $h \ge 1$, and $h \le \frac{51}{50}(1-\frac{1}{250})^{-1/2} < 2$. That is (a), and (b) follows from Proposition 12.82, item 2, applied to $\vartheta(\psi)-\psi$ and to $2\psi-\vartheta(\psi)$ after rescaling the interval.

(c) and (d). The shift adds $D_m \sum_n \beta_n r^n\, 4q\varpi_n = \vartheta(4q)$. Odd Wallis numbers vanish, so $\vartheta(4q) = 4qD_m \sum_k \beta_{2k}\varpi_{2k} r^{2k}$, a series of nonnegative terms that starts $1+\beta_2\varpi_2 r^2 = 1+\frac{3}{8}\cdot\frac{1}{2}r^2$, and whose terms after the first, and after the first two, add up to at most $\sum_{n\ge2}|r|^n \le 2r^2$ and $\sum_{n\ge4}|r|^n \le 2r^4$. □

Theorem 25.35 (The relativistic orbit: motion, period and closure)**.** *Let a, b be ratios in the window: $a > 0$, $b \ge 0$, $100ab \le 1$.*

(a) For every point u_0 with $a \le 2u_0 \le 3a$ there is a motion $X = (u, w)$ of the orbit field on all of $\mathbb{R}_\delta$ with $X(0) = (u_0, 0)$.

(b) Every motion X of the orbit field with $w(0) = 0$ and $a \le 2u(0) \le 3a$ has an apsidal period: a point Φ with $X(\theta+\Phi) = X(\theta)$ for every θ and

$$2\pi_\delta ab \;\le\; \Phi - 2\pi_\delta \;\le\; 2\pi_\delta ab + 8\pi_\delta (ab)^2.$$

(c) In (b), $\Phi = 2\pi_\delta$ if and only if $b = 0$.

No omniscience principle and no choice principle is used.

Proof. (a) Take the constants of Lemma 25.33, put $D = 1-2bU_c$ and $\alpha = rD = \frac{2}{3}bA_t$, so the relations (25.4) hold, and let ϑ be the clock of Lemma 25.34. Since $1/D_m = \sqrt{D}$, $1/h(\psi) = \sqrt{D(1-r\cos\psi)} = G(\psi)$. By (b) of that lemma and Lemma 25.7 with $K = 2$, ϑ has an inverse map ψ with the uniform derivative $G(\psi(\theta))$, and $|G| \le 1$. Put $X(\theta) = \big(U_c + A_t\cos\psi(\theta),\ -A_t G(\psi(\theta))\sin\psi(\theta)\big)$. The computation before (25.4), with the chain rule and the free square root of the positive $D-\alpha\cos\psi$, shows that X is a motion of the orbit field, and $X(0) = (U_c + A_t, 0) = (u_0, 0)$.

(b) Let X be such a motion, with $u_0 = u(0)$, and let $\tilde{X}$ be the motion of (a). By Theorem 25.3(b), $X = \tilde{X}$. Put $\Phi = \vartheta(4q)$. By Lemma 25.34(c), $\vartheta(\psi(\theta)+4q) = \theta+\Phi = \vartheta(\psi(\theta+\Phi))$, and ϑ is injective, so $\psi(\theta+\Phi) = \psi(\theta)+4q$; the cosine, the sine and G have period $4q$, so $X(\theta+\Phi) = X(\theta)$. By Lemma 25.34(d) and the bounds $1+ab \le D_m$ and $D_m(1+2r^2) \le 1+ab+4(ab)^2$, $4q(1+ab) \le \Phi \le 4q(1+ab+4(ab)^2)$, and $4q = 2\pi_\delta$.

(c) If $\Phi = 2\pi_\delta$, then $2\pi_\delta ab \le 0$ with $2\pi_\delta > 0$ and $a > 0$, so $b \le 0$, and $b = 0$. If $b = 0$, the bounds squeeze $\Phi = 2\pi_\delta$. □

The circular orbit, $A_t = 0$, needs no separate case, and nothing is decided about whether the motion starts at the pericentre or at the apocentre: A_t is signed. For a ratio b the test $b = 0$ is arithmetic; for a coefficient given only as a point, deciding "no advance" would cost WLPO, as in Theorem 25.19(e).

The same clock gives the second order. Its bounds are stated in the orbit's own constants, and for the Schwarzschild coefficient $b = 3m$ they become the classical expansion, with a remainder.

Lemma 25.36 (Dominant lowest terms)**.** *Let $F(x,v)$ be a polynomial with ratio coefficients c_{ij} (the coefficient of $x^i v^j$), let n_0 be the least total degree of its terms, and let $f(s) = \sum_{i+j=n_0} c_{ij} s^j$. If $f(s) \geq \mu$ for $0 \leq s \leq \frac{3}{5}$ and*

$$\tau = \sum_{i+j>n_0} |c_{ij}| \Big(\frac{3}{5}\Big)^j \Big(\frac{1}{250}\Big)^{i+j-n_0} < \mu,$$

then $F(x,v) \geq 0$ whenever $0 \leq x \leq \frac{1}{250}$ and $0 \leq v \leq \frac{3}{5}x$.

Proof. For $0 \leq v \leq \frac{3}{5}x$ a term of degree $i+j$ has absolute value at most $|c_{ij}|(\frac{3}{5})^j x^{i+j}$, and for $i+j > n_0$ this is at most $|c_{ij}|(\frac{3}{5})^j(\frac{1}{250})^{i+j-n_0} x^{n_0}$; so the terms of degree above n_0 add up to at least $-\tau x^{n_0}$. If $n_0 = 0$, the term of degree 0 is $c_{00} = f(0) \geq \mu$, and $F(x,v) \geq \mu - \tau \geq 0$. Let $n_0 \geq 1$. Since $F \geq 0$ is the negation of $F < 0$, suppose $F(x,v) < 0$. The same bound for all terms gives $0 < -F(x,v) \leq C x^{n_0}$ with the ratio $C = \sum_{i+j \geq n_0} |c_{ij}|(\frac{3}{5})^j(\frac{1}{250})^{i+j-n_0}$, so $x^{n_0} > 0$; and $x \geq x^{n_0}$ because $0 \leq x \leq 1$, so $x > 0$. Now x is apart from 0, $s = v/x$ is a point with $0 \leq s \leq \frac{3}{5}$, and the terms of degree n_0 add up to $x^{n_0} f(s) \geq \mu x^{n_0}$. So $F(x,v) \geq (\mu - \tau) x^{n_0} \geq 0$, which contradicts $F(x,v) < 0$. □

Theorem 25.37 (The second order in the orbit's own apsides)**.** *Let a, b be ratios in the window and $X = (u, w)$ a motion of the orbit field with $w(0) = 0$ and $a \leq 2u(0) \leq 3a$.*

(a) There are points $\Phi, U_c, A_t, D_m, r, \theta_1$ with $X(\theta + \Phi) = X(\theta)$ for every θ, $u(0) = U_c + A_t$, $u(\theta_1) = U_c - A_t$, $w(\theta_1) = 0$, $D_m^2(1 - 2bU_c) = 1$, $D_m \geq 0$, $r(1 - 2bU_c) = \frac{2}{3}bA_t$ and

$$2\pi_\delta D_m\Big(1 + \tfrac{3}{16}r^2\Big) \leq \Phi \leq 2\pi_\delta D_m\Big(1 + \tfrac{3}{16}r^2 + 2r^4\Big).$$

(b) If $b = 3m$ for a ratio $m \geq 0$, there are points Φ, U_c, A_t, θ_1 with $X(\theta + \Phi) = X(\theta)$ for every θ, $u(0) = U_c + A_t$, $u(\theta_1) = U_c - A_t$, $w(\theta_1) = 0$, $(u(\theta) - U_c)^2 \leq A_t^2$ for every θ, and, with $x = mU_c$ and $y = mA_t$,

$$2\pi_\delta S \leq \Phi \leq 2\pi_\delta (S + 80x^3), \qquad S = 1 + 3x + \tfrac{27}{2}x^2 + \tfrac{3}{4}y^2.$$

No omniscience principle and no choice principle is used.

Proof. (a) Take the constants and the motion of Theorem 25.35, with $\Phi = \vartheta(4q)$, and $\theta_1 = \vartheta(2q)$: there $\psi = 2q$, $\cos\psi = -1$ and $\sin\psi = 0$. The bounds are Lemma 25.34(d).

(b) Now $1 - 2bU_c = 1 - 6x$ and $r(1 - 6x) = 2y$, so $r = 2yD_m^2$. By Lemma 25.33, $0 \leq x \leq \frac{1}{250}$ and $25y^2 \leq 9x^2$; and $D_m \geq 1$ since $D_m^2(1 - 6x) = 1$. The range is $(u - U_c)^2 = A_t^2 \cos^2\psi \leq A_t^2$.

Lower bound. Expanding, $(2 + 6x + 27x^2)^2(1 - 6x) = 4 - 540x^3 - 1215x^4 - 4374x^5 \leq 4 = 4D_m^2(1 - 6x)$, so $2D_m \geq 2 + 6x + 27x^2$. Using $3D_m r^2 = 12y^2 D_m^5$,

$$16\Big(D_m\big(1 + \tfrac{3}{16}r^2\big) - S\Big) = 8\big(2D_m - 2 - 6x - 27x^2\big) + 12y^2(D_m^5 - 1) \geq 0.$$

Upper bound. With $Q = 2 + 6x + 27x^2 + 140x^3$,

$$Q^2(1-6x) - 4 = x^3\big(20 - 2895x - 6894x^2 - 25760x^3 - 117600x^4\big),$$

which is positive for $0 \le x \le \frac{1}{250}$ (the bracket exceeds $20 - 11.58 - 0.12 - 0.01 > 8$). So $2D_m \le Q$, $D_m \le 1 + 3x + \frac{27}{2}x^2 + 70x^3 \le 1 + 4x$, and with $e = D_m - 1 \le \frac{4}{250}$, $D_m^5 - 1 \le 6e \le 24x$ and $D_m^9 \le 2$. Since $D_m \frac{3}{16} r^2 = \frac{3}{4} y^2 D_m^5$ and $2D_m r^4 = 32 y^4 D_m^9$,

$$S + 80x^3 - D_m\big(1 + \tfrac{3}{16}r^2 + 2r^4\big) = \big(1 + 3x + \tfrac{27}{2}x^2 + 80x^3 - D_m\big) - \tfrac{3}{4}y^2(D_m^5 - 1) - 32y^4 D_m^9,$$

and the three parts are at least $10x^3$, at least $-\frac{3}{4}\cdot\frac{9}{25}x^2\cdot 24x = -6.48x^3$ and at least $-64\cdot\frac{81}{625}x^4 \ge -0.04x^3$. So the difference is positive, and (a) gives the bounds. □

Conditions and scope.

Base and premises

The orbit equation $u'' + u = a + bu^2$ with ratio coefficients in the window $100ab \le 1$, started at an apside whose radius $1/u_0$ lies between $2/(3a)$ and $2/a$.

Conclusion

With $p = 1/U_c$ and $e = A_t/U_c$, so that $u = (1 \pm e)/p$ at the two apsides, and $b = 3m$,

$$\Phi - 2\pi_\delta = 6\pi_\delta\frac{m}{p} + \frac{3\pi_\delta}{2}(18 + e^2)\Big(\frac{m}{p}\Big)^2 + R, \qquad 0 \le R \le 160\,\pi_\delta\Big(\frac{m}{p}\Big)^3,$$

since $2\pi_\delta(S-1) = 6\pi_\delta x + 27\pi_\delta x^2 + \frac{3}{2}\pi_\delta y^2$ with $x = m/p$ and $y = ex$.

Identification

That a test body's inverse radius obeys this equation in its polar angle, with $a = m/L^2$ and $b = 3m$, is the Schwarzschild orbit equation of general relativity, taken here as given.

Not claimed

Anything about the motion in time; that is Section 25.7.

The first-order term $6\pi_\delta m/p$ is Einstein's perihelion advance [155]. The expansion of $(1-6x)^{-1/2}$ is $1 + 3x + \frac{27}{2}x^2 + \frac{135}{2}x^3 + \cdots$, so the constant 80 in the remainder is close to the truth.

25.7 The perihelion advance of actual orbits

Section 25.6 studied a function of the polar angle. A planet moves in time. This section takes the motion in proper time as the object: a polynomial field on the eight Kepler coordinates whose motions, in the identification of general relativity, are the orbits of a test body about a mass m. We prove that every such motion in the weak-field window returns in its radial coordinates after a radial period, that its polar angle advances by the amount of Theorem 25.37 in the orbit's own apsides and in its conserved quantities, and we compute the period in proper time and in the time of a distant observer.

Definition 25.38 (The proper-time field and its window orbits)**.** For a ratio Λ, the *proper-time field* G_Λ acts on Kepler states (x, v, u, m) by

$$\dot{x} = v, \qquad \dot{v} = -m\,u^3 x - 3\Lambda m\,u^5 x, \qquad \dot{u} = -u^3(x \cdot v), \qquad \dot{m} = 0,$$

with energy $H_\Lambda = \frac{1}{2}|v|^2 - mu - \Lambda m u^3$. A *window orbit* is a motion y of G_Λ such that for every t: $I = 1$, $u > 0$, $x_2 = v_2 = 0$ and $x_0 v_1 - x_1 v_0 = L$, a constant apart from 0 with $L^2 = \Lambda$; such that $x(0) \cdot v(0) = 0$; and for which there is a point a with $a\Lambda = m$, $a > 0$, $300\,am \le 1$ and $a \le 2u(0) \le 3a$. We write $H = H_\Lambda(y(0))$, $Z = -2H$ and $\lambda = am$. A *radial period* of y is a triple (θ, T, Φ) of a map θ and two points such that θ has derivative $Lu(t)^2$ at every t, $x_0 u = \cos\theta$ and $x_1 u = \sin\theta$ at every t, $LT > 0$, and for every t

$$\theta(t+T) = \theta(t) + \Phi, \qquad u(t+T) = u(t), \qquad (x \cdot v)(t+T) = (x \cdot v)(t).$$

So Λ is the squared angular momentum per unit mass, L^2, which enters the field as a ratio coefficient; $a = m/L^2$ is the Newtonian inverse semi-latus rectum, and $\lambda = m^2/L^2$. Every statement below holds for every ratio value of Λ. The orbit starts at an apside, $x \cdot v = 0$, and the condition $300am \le 1$ is the weak-field window $300m^2 \le L^2$. The sign of L is the sense of rotation and is never decided; $LT > 0$ says that T is a positive time when the body turns counterclockwise and a negative one otherwise. After a radial period the inverse radius and the radial velocity are back, and the polar angle has advanced by Φ: the pericentre turns by $\Phi - 2\pi_\delta$ per radial period.

The identification is classical. A timelike geodesic of Schwarzschild's geometry, written in the flat chart with $u = 1/r$ for the areal radius r, proper time as the clock, $m = GM/c^2$ and L the angular momentum per unit mass, is a motion of G_Λ, and $H = (\mathscr{E}^2 - 1)/2$ with $\mathscr{E}$ the conserved Killing energy: the radial equation $\ddot{r} = -m/r^2 + L^2/r^3 - 3mL^2/r^4$ is the radial part of $\dot{v} = -(m/r^3 + 3mL^2/r^5)x$. The theorems do not supply this identification; they are statements about motions of the polynomial field.

Proposition 25.39 (Energy and rates)**.** *For every ratio Λ, H_Λ and the three components of $x \times v$ are first integrals of G_Λ. On states with $I = 1$, the radial rate $P = -(x \cdot v)u$ satisfies $\mathscr{L}u = u^2 P$ and $\mathscr{L}P = u^2\big(m - |x \times v|^2 u + 3\Lambda m u^2\big)$. No omniscience principle and no choice principle is used.*

Proof. $\frac{d}{dt}\frac{1}{2}|v|^2 = -(mu^3 + 3\Lambda m u^5)(x \cdot v)$ and $\frac{d}{dt}(-mu - \Lambda m u^3) = -(m + 3\Lambda m u^2)\dot{u} = (mu^3 + 3\Lambda m u^5)(x \cdot v)$. The force is central, so $x \times v$ is constant. The rates follow as in Theorem 25.19(a), with $|v|^2 = |L|^2 u^2 + (x \cdot v)^2 u^2$ on $I = 1$. □

Theorem 25.40 (Confinement, the polar angle and motions on the whole line)**.** *Let Λ be a ratio.*

(a) Every window orbit has a map θ with derivative $Lu(t)^2$ at every t and $(x_0 u, x_1 u) = (\cos\theta, \sin\theta)$, and a point Φ with

$$2\pi_\delta(1 + 3am) \le \Phi \le 2\pi_\delta(1 + 3am) + 8\pi_\delta(3am)^2$$

such that $u(t') = u(t)$ and $(x \cdot v)(t') = (x \cdot v)(t)$ whenever $\theta(t') = \theta(t) + \Phi$.

(b) For every state s with $I = 1$, $u > 0$, $x_2 = v_2 = 0$, $L = x_0v_1 - x_1v_0$ apart from 0, $L^2 = \Lambda$ and $x \cdot v = 0$, and every point a with $a\Lambda = m$, $a > 0$, $300am \le 1$ and $a \le 2u \le 3a$, there is a motion y of G_Λ with $y(0) = s$.

No omniscience principle and no choice principle is used.

Proof. (a) *The energy relation.* On a planar state with $I = 1$, $|v|^2 = \Lambda u^2 + P^2$, so $2H_\Lambda = P^2 + \Lambda u^2 - 2mu - 2\Lambda m u^3$, which is constant. With $m = a\Lambda$ this reads $P^2 = \Lambda\big(\mathcal{G}(u_0) - \mathcal{G}(u)\big)$, where $\mathcal{G}(z) = z^2 - 2az - 2mz^3$, $u_0 = u(0)$ and $P(0) = 0$.

The band $2a \le u \le 3a$ is empty. The identity

$$4\big(\mathcal{G}(u) - \mathcal{G}(u_0)\big) - 2a^2 = 4u(u-2a) + (3a-2u_0)(2u_0-a) + 8mu_0^3 \\ + 8m(3a-u)(9a^2+3au+u^2) + a^2\big((1-300am)+84am\big)$$

shows $\mathcal{G}(u) - \mathcal{G}(u_0) \ge a^2/2 > 0$ whenever $2a \le u \le 3a$, and then $P^2 < 0$, which is impossible.

So $u \le 2a$ at every time. On $[-T', T']$ the motion is Lipschitz with some constant C. Take a step h with $Ch \le a/2$. If $u(t) \le 2a$, then at a time t' within h of t, $u(t') \le \frac{5}{2}a \le 3a$, and since the band is empty, $\neg(2a \le u(t'))$, which gives $u(t') \le 2a$. Starting from $u(0) \le \frac{3}{2}a$, induction on the number of steps covers $[-T', T']$. Every statement in this induction is an inequality, so no case is decided.

The polar angle. With $u \le 2a$ the rate Lu^2 is bounded, and Lemma 25.22 gives θ, exactly as in Theorem 25.23.

The orbit equation along the motion. Take the constants of Lemma 25.33 for a and $b = 3m$, which are points here, and the motion (U, W) of the orbit equation $U'' + U = a + 3mU^2$ built in the proof of Theorem 25.35(a); that construction uses only that a and b are points in the window. On the five coordinates $(u, P, m, \tilde{U}, \tilde{Q})$ consider the polynomial field with ratio coefficients

$$\dot{u} = u^2P, \quad \dot{P} = mu^2 - \Lambda u^3 + 3\Lambda m u^4, \quad \dot{m} = 0, \quad \dot{\tilde{U}} = u^2\tilde{Q}, \quad \dot{\tilde{Q}} = mu^2 - \Lambda u^2\tilde{U} + 3\Lambda m u^2\tilde{U}^2.$$

Both (u, P, m, u, P) and $(u, P, m, U(\theta-\theta(0)),\ LW(\theta-\theta(0)))$ are motions of it, by Proposition 25.39 and the chain rule with $\dot{\theta} = Lu^2$ and $\Lambda a = m$; they agree at time 0. By Theorem 25.3, $u(t) = U(\theta(t) - \theta(0))$ and $P(t) = LW(\theta(t) - \theta(0))$. Theorem 25.35(b), whose proof also uses only points, gives the period Φ of (U, W) with the stated bounds for $ab = 3am$, and $x \cdot v = -P/u$.

(b) Take the motion (U, W) and its clock as in (a), and let $\sigma(\psi) = \int_0^\psi h/U^2$ by Lemma 25.6; the integrand is Lipschitz because $U \ge U_c - |A_t| \ge \frac{2}{5}U_c > 0$. The proper time along the orbit is σ/L, a map with slopes bounded above and below, so Lemma 25.7 (after scaling) gives the clock ψ as a function of time, and with θ_0 an angle of (x_0u, x_1u) from Lemma 25.22(a) and $\phi = \theta_0 + \vartheta(\psi)$ put

$$x = \frac{(\cos\phi, \sin\phi, 0)}{U}, \qquad v = -W(\cos\phi, \sin\phi, 0) + LU(-\sin\phi, \cos\phi, 0),$$

with $u = U$ and m constant. The eight coordinates have uniform derivatives on bounded intervals, and $\dot{v} = -(\dot{W} + \Lambda U^3)(\cos\phi, \sin\phi, 0) = -(mu^3 + 3\Lambda m u^5)x$ by the orbit equation. At an apside $v = Lu^2(-x_1, x_0, 0)$, so the motion starts at s. □

For the remaining theorems the motion is read in the clock ψ of Section 25.6, with $U(\psi) = U_c + A_t\cos\psi$. The proper time per unit of clock is $h/(LU^2)$, so we put

$$\sigma(\psi) = \int_0^{\psi} \frac{h(\psi')}{U(\psi')^2}\,d\psi',$$

the antiderivative of Lemma 25.6.

Proposition 25.41 (The window orbit in its clock)**.** *Let y be a window orbit, and let U_c, A_t, D_m, r be the constants of Lemma 25.33 for a, $b = 3m$ and $u_0 = u(0)$, with the clock ϑ of Lemma 25.34 and its inverse. There are a polar angle θ and points T, t_1 such that, with $\psi(t)$ the clock value of $\theta(t) - \theta(0)$:*

(a) $u(t) = U(\psi(t))$ and $\sigma(\psi(t)) = Lt$ for every t;

(b) $(\theta, T, \vartheta(4q))$ is a radial period, $LT = \sigma(4q)$, and $\psi(t+T) = \psi(t) + 4q$ for every t;

(c) $u(t_1) = U_c - A_t$ and $(x\cdot v)(t_1) = 0$;

(d) $(u(t) - U_c)^2 \le A_t^2$ for every t.

No omniscience principle and no choice principle is used.

Proof. (a) The first identity is the proof of Theorem 25.40(a). For the second, ψ has derivative $G(\psi)\,Lu^2$, so $\sigma(\psi(t))$ has derivative $\frac{h}{U^2}\cdot G\cdot Lu^2 = L$, because $hG = 1$ and $u = U(\psi)$; it vanishes at 0, and Lemma 25.4(c) applies.

(b) The integrand h/U^2 has period $4q$, so $\sigma(\psi + 4q) - \sigma(\psi)$ has derivative 0 and equals $\sigma(4q)$; and σ increases at a rate bounded below, so $\sigma(4q) > 0$ and σ is injective. Put $T = \sigma(4q)/L$, using the inverse of L. Then $\sigma(\psi(t+T)) = Lt + \sigma(4q) = \sigma(\psi(t) + 4q)$, so $\psi(t+T) = \psi(t) + 4q$, and $\theta(t+T) - \theta(t) = \vartheta(\psi(t)+4q) - \vartheta(\psi(t)) = \vartheta(4q)$. The inverse radius $U(\psi)$ and $P = LW$, hence $x\cdot v = -P/u$, have period $4q$ in ψ.

(c) Put $t_1 = \sigma(2q)/L$; then $\psi(t_1) = 2q$, where $\cos\psi = -1$ and $\sin\psi = 0$.

(d) $(U - U_c)^2 = A_t^2\cos^2\psi \le A_t^2$. □

Each theorem below asserts a radial period with further properties; in every proof the radial period of Proposition 25.41 serves. We use the abbreviations

$$x = mU_c, \qquad y = mA_t, \qquad k = \sqrt{U_c^2 - A_t^2},$$

so that $0 \le x \le \frac{1}{250}$, $25y^2 \le 9x^2$, $k > 0$, $D_m^2(1-6x) = 1$ and $r = 2yD_m^2$ (Lemma 25.33). The centre relation times m and the energy at the starting apside give the two exact relations

$$\lambda = x - 3x^2 - y^2, \qquad 2H\lambda = -(x^2 - y^2)(1 - 4x). \tag{25.5}$$

For the first, $m(U_c - a) = m(3mU_c^2 + mA_t^2)$. For the second, at the apside $|v| = |L|u_0$, so $2H = \Lambda u_0^2 - 2mu_0 - 2\Lambda m u_0^3$; multiplying by $\lambda = m^2/\Lambda$ and writing $mu_0 = x + y$ gives $(x+y)^2 - 2(x+y)\lambda - 2(x+y)^3$, which expands to the right side.

Theorem 25.42 (The advance in the orbit's own apsides)**.** *Let Λ be a ratio and y a window orbit. There are a radial period (θ, T, Φ) and a time t_1 with $(x\cdot v)(t_1) = 0$ such that, with $u_0 = u(0)$ and $u_1 = u(t_1)$:*

(a) $\big(2u(t) - (u_0 + u_1)\big)^2 \le (u_0 - u_1)^2$ *for every t: the inverse radius stays between its two apsidal values;*

(b) with p and e defined by $p(u_0 + u_1) = 2$ and $e(u_0 + u_1) = u_0 - u_1$,

$$6\pi_\delta\frac{m}{p} + \frac{3\pi_\delta}{2}(18 + e^2)\Big(\frac{m}{p}\Big)^2 \;\le\; \Phi - 2\pi_\delta \;\le\; 6\pi_\delta\frac{m}{p} + \frac{3\pi_\delta}{2}(18 + e^2)\Big(\frac{m}{p}\Big)^2 + 160\,\pi_\delta\Big(\frac{m}{p}\Big)^3.$$

No omniscience principle and no choice principle is used.

Proof. Take the radial period and t_1 of Proposition 25.41. Then $u_0 = U_c + A_t$ and $u_1 = U_c - A_t$, so (a) is part (d) of the proposition, and $p = 1/U_c$, $e = A_t/U_c$ and $m/p = x$, $em/p = y$. The proof of Theorem 25.37(b), which uses only Lemmas 25.33 and 25.34, gives $2\pi_\delta S \le \Phi \le 2\pi_\delta(S + 80x^3)$ with $S = 1 + 3x + \frac{27}{2}x^2 + \frac{3}{4}y^2$, and $2\pi_\delta(S - 1) = 6\pi_\delta x + 27\pi_\delta x^2 + \frac{3}{2}\pi_\delta e^2 x^2$. □

Here p is the semi-latus rectum and e the eccentricity, read off the two apsidal radii $1/u_0$ and $1/u_1$ of the actual orbit; e is negative when the orbit starts at its apocentre, and only e^2 enters. Binary-pulsar timing states the advance in conserved quantities instead [154], and so can we.

Theorem 25.43 (The advance in the conserved energy and angular momentum)**.** *Let Λ be a ratio and y a window orbit, with $H = H_\Lambda(y(0))$ and $\lambda = am = m^2/L^2$. There is a radial period (θ, T, Φ) with*

$$2\pi_\delta F \le \Phi \le 2\pi_\delta\big(F + 300\lambda^3\big), \qquad F = 1 + 3\lambda + \tfrac{105}{4}\lambda^2 + \tfrac{15}{2}H\lambda.$$

So $\Phi - 2\pi_\delta = 2\pi_\delta\big(3\lambda + \frac{105}{4}\lambda^2 + \frac{15}{2}H\lambda\big) + R$ with $0 \le R \le 600\pi_\delta\lambda^3$. No omniscience principle and no choice principle is used.

Proof. By (25.5), F is a polynomial in x and y^2, and

$$\begin{aligned} 4(S - F) &= 570x^3 + 270xy^2 - 945x^4 - 630x^2y^2 - 105y^4, \\ 4(F + 300\lambda^3 - S - 80x^3) &= 310x^3 - 270xy^2 + 105y^4 - 9855x^4 + 21600x^3y^2 \\ &\quad - 2970x^2y^2 + 3600xy^4 + 32400x^5 - 32400x^6 \\ &\quad - 32400x^4y^2 - 10800x^2y^4 - 1200y^6. \end{aligned}$$

Both are nonnegative on the window by Lemma 25.36 with $v = |y|$ (Table 25.2): their lowest terms are $30(19 + 9s^2)x^3$ and $10(31 - 27s^2)x^3$ with $s = v/x$. So $2\pi_\delta F \le 2\pi_\delta S \le \Phi \le 2\pi_\delta(S + 80x^3) \le 2\pi_\delta(F + 300\lambda^3)$. □

The proper-time period needs the time integral $\sigma(4q) = \int_0^{4q} h/U^2$. In Newton's theory $h = 1$ and the integral is done classically by the eccentric anomaly, an angle defined by its cosine and sine. On $\mathbb{R}_\delta$ we construct the eccentric anomaly as an antiderivative and pin its winding by inequalities, without deciding the sign of anything.

Table 25.2. The polynomial inequalities of Section 25.7, each checked by Lemma 25.36 on $0 \le x \le \frac{1}{250}$, $0 \le v \le \frac{3}{5}x$, with $s = v/x$. The column $f(s)$ is the lowest-degree form, μ a lower bound for it on $[0, \frac{3}{5}]$, and τ the tail sum of the lemma, rounded up.

Inequality	Used in	n_0	$f(s)$	μ	τ

(F4)	Thm. 25.47	5	$\frac{1}{25}(121 - 100s + 354s^2 + 100s^3)$	4.55	2.99

Lemma 25.44 (The eccentric anomaly, pinned to one turn)**.** *Let U_c, A_t be points with $U_c > 0$ and $25A_t^2 \le 9U_c^2$, put $U(\psi) = U_c + A_t\cos\psi$ and $k = \sqrt{U_c^2 - A_t^2}$. There is a map η with $\eta(0) = 0$ and the uniform derivative k/U on every bounded interval such that:*

(a) $U(\psi)\cos\eta(\psi) = A_t + U_c\cos\psi$ and $U(\psi)\sin\eta(\psi) = k\sin\psi$ for every ψ;

(b) $\frac{1}{2} \le k/U(\psi) \le 2$ for every ψ;

(c) if $\cos d = 1$ and $-q \le d \le 2q$, then $d = 0$;

(d) $\eta(2q) = 2q$ and $\eta(4q) = 4q$;

(e) the functions $(U_c\eta - A_t\sin\eta)/k^3$ and $(U_c\sin\eta - A_t\eta)/k^3$ have the uniform derivatives $1/U^2$ and $\cos\psi/U^2$ on every bounded interval.

No omniscience principle and no choice principle is used.

Proof. $U \ge U_c - |A_t| \ge \frac{2}{5}U_c > 0$ and $k^2 \ge \frac{16}{25}U_c^2$, so k/U is a Lipschitz map, and Lemma 25.6 gives η.

(a) Put $N = \cos\eta\,(A_t + U_c\cos\psi) + \sin\eta\,k\sin\psi$. Differentiating with $\eta' = k/U$ and collecting,

$$N' = -\frac{A_t\sin\psi}{U}\Big(k\sin\eta\sin\psi + \cos\eta\,(A_t + U_c\cos\psi)\Big) = \frac{U'}{U}\,N,$$

using $k^2 = U_c^2 - A_t^2$; so $(N/U)' = 0$, and N/U equals its value 1 at 0. Then

$$\begin{aligned}\big(U\cos\eta - (A_t + U_c\cos\psi)\big)^2 + \big(U\sin\eta - k\sin\psi\big)^2 &= U^2 - 2UN + (A_t + U_c\cos\psi)^2 + k^2\sin^2\psi \\ &= -U^2 + U^2 = 0,\end{aligned}$$

and a sum of two squares that vanishes has both terms 0.

(b) $U \le 2k$ and $k \le 2U$ follow from the identities

$$4k^2 - U^2 = \tfrac{1}{2}\big[(1-c)(3U_c + 5A_t)(U_c - A_t) + (1+c)(3U_c - 5A_t)(U_c + A_t)\big] + A_t^2(1-c)(1+c),$$
$$4U^2 - k^2 = 4\big(U^2 - (U_c - |A_t|)^2\big) + (U_c - |A_t|)(3U_c - 5|A_t|),$$

with $c = \cos\psi$, in which every term is nonnegative.

(c) $1 - \cos d = 2\sin^2(d/2)$, so $\sin(d/2) = 0$, with $-\frac{q}{2} \le d/2 \le q < 2$. The sine is positive on $(0, 2]$ (Section 21.2), which refutes $d/2 > 0$ and, by oddness, $d/2 < 0$. So $d/2 = 0$.

(d) By (b) and Proposition 12.82, $q \le \eta(2q) \le 4q$, so $d = \eta(2q) - 2q \in [-q, 2q]$. At $\psi = 2q$, (a) gives $(U_c - A_t)\cos\eta(2q) = -(U_c - A_t)$ and $(U_c - A_t)\sin\eta(2q) = 0$, with $U_c - A_t > 0$; so $\cos\eta(2q) = -1$, $\sin\eta(2q) = 0$, and $\cos d = \cos\eta(2q)\cos 2q + \sin\eta(2q)\sin 2q = 1$. By (c), $\eta(2q) = 2q$. The same argument on $[2q, 4q]$ gives $\eta(4q) = 4q$.

(e) By (a), $U_c - A_t\cos\eta = k^2/U$ and $U_c\cos\eta - A_t = k^2\cos\psi/U$, so the derivatives are $(U_c - A_t\cos\eta)\eta'/k^3 = 1/U^2$ and $(U_c\cos\eta - A_t)\eta'/k^3 = \cos\psi/U^2$. □

At $\psi = 4q$, where $\eta = 4q$ and $\sin\eta = 0$, part (e) gives the two Newtonian time integrals

$$\int_0^{4q} \frac{d\psi}{U^2} = \frac{4qU_c}{k^3}, \qquad \int_0^{4q} \frac{\cos\psi\, d\psi}{U^2} = -\frac{4qA_t}{k^3}, \tag{25.6}$$

in the sense that the antiderivatives of (e) take these values. The relativistic factor h is compared with them.

Lemma 25.45 (The relativistic factor). *If $|z| \le \frac{1}{250}$, $v \ge 0$ and $v^2(1-z) = 1$, then $1 + \frac{z}{2} \le v \le 1 + \frac{z}{2} + \frac{z^2}{2}$. Consequently, in the window,*

$$4qD_m\Big(U_c - \frac{r}{2}A_t\Big) \le k^3\sigma(4q) \le 4qD_m\Big(\big(1 + \tfrac{r^2}{2}\big)U_c - \frac{r}{2}A_t\Big).$$

No omniscience principle and no choice principle is used.

Proof. $(1+\frac{z}{2})^2(1-z) = 1 - \frac{3}{4}z^2 - \frac{1}{4}z^3 \le 1$ and $(1+\frac{z}{2}+\frac{z^2}{2})^2(1-z) = 1 + \frac{1}{4}z^2(1 - 3z - z^2 - z^3) \ge 1$; compare squares of nonnegative points. With $z = r\cos\psi$ and $z^2 \le r^2$, $D_m(1 + \frac{r}{2}\cos\psi) \le h(\psi) \le D_m(1 + \frac{r}{2}\cos\psi + \frac{r^2}{2})$. So $\sigma - D_m\big(F_0 + \frac{r}{2}F_1\big)$ and $D_m\big((1 + \frac{r^2}{2})F_0 + \frac{r}{2}F_1\big) - \sigma$, with F_0, F_1 the antiderivatives of Lemma 25.44(e), have nonnegative derivatives and vanish at 0; at $4q$ use (25.6). □

Theorem 25.46 (Kepler's third law in proper time). *Let Λ be a ratio and y a window orbit, with $Z = -2H$ and $\lambda = am$.*

(a) There is a radial period (θ, T, Φ) with

$$(2\pi_\delta)^2 m^2 \le T^2 Z^3 \le (2\pi_\delta)^2 m^2 (1 + 4\lambda^2).$$

(b) There are a radial period (θ, T, Φ), a time t_1 with $(x \cdot v)(t_1) = 0$, and points a_K and w with $2a_K u_0 u_1 = u_0 + u_1$ and $2w = m(u_0 + u_1)$, where $u_0 = u(0)$ and $u_1 = u(t_1)$, such that

$$(2\pi_\delta)^2 a_K^3 (a_K + 3m) \le T^2 m\, a_K \le (2\pi_\delta)^2 a_K^3 \big(a_K + 3m + 20 a_K w^2\big).$$

No omniscience principle and no choice principle is used.

Proof. (a) Take the radial period of Proposition 25.41, so $LT = \sigma(4q)$. From $L^2 = \Lambda = m^2/\lambda$ and (25.5), $Z\lambda = (x^2 - y^2)(1 - 4x) = m^2k^2(1 - 4x)$, so

$$T^2Z^3(\lambda m)^2 = \sigma^2\frac{\lambda}{m^2}Z^3\lambda^2m^2 = \sigma^2(Z\lambda)^3 = \big(mk^3\sigma(4q)\big)^2m^4(1 - 4x)^3.$$

By Lemma 25.45, with $4q = 2\pi_\delta$, $r = 2yD_m^2$ and $w_2 = y^2$,

$$2\pi_\delta D_m\,\ell_- \le mk^3\sigma(4q) \le 2\pi_\delta D_m\,\ell_+, \qquad \ell_- = x - w_2D_m^2, \quad \ell_+ = x + 2xw_2D_m^4 - w_2D_m^2,$$

and $\ell_- > 0$. Dividing by $m^4 > 0$, the claim follows from $D_m^2\ell_-^2(1-4x)^3 \ge \lambda^2$ and $D_m^2\ell_+^2(1-4x)^3 \le \lambda^2(1+4\lambda^2)$. Since $D_m^2(1-6x) = 1$, $\ell_- = D_m^2\big(x(1-6x) - w_2\big)$ and $\ell_+ = D_m^4\big(x(1-6x)^2 + 2xw_2 - w_2(1-6x)\big)$; multiplying the two inequalities by $(1-6x)^3$ and $(1-6x)^5$ turns them into $q_1 \ge 0$ and $q_2 \ge 0$, where

$$\begin{aligned} q_1 &= \big(x(1-6x) - w_2\big)^2(1-4x)^3 - (1-6x)^3\lambda^2,\\ q_2 &= (1-6x)^5(1+4\lambda^2)\lambda^2 - \big(x(1-6x)^2 + 2xw_2 - w_2(1-6x)\big)^2(1-4x)^3, \end{aligned}$$

with $\lambda = x - 3x^2 - w_2$. Table 25.2 checks both.

(b) Take the same radial period and t_1; then $u_0u_1 = k^2$ and $u_0 + u_1 = 2U_c$, so $a_K = U_c/k^2$ and $w = x$. Multiplying by m^4k^8, the claim becomes $(2\pi_\delta)^2x^3(x + 3x^2 - 3w_2) \le (mk^3\sigma)^2\lambda x \le (2\pi_\delta)^2x^3(x + 3x^2 - 3w_2 + 20x^3)$, and the same substitution reduces it to $q_3 \ge 0$ and $q_4 \ge 0$:

$$\begin{aligned} q_3 &= \lambda\big(x(1-6x) - w_2\big)^2 - (1-6x)^3x^2(x + 3x^2 - 3w_2),\\ q_4 &= (1-6x)^5x^2(x + 3x^2 - 3w_2 + 20x^3) - \lambda\big(x(1-6x)^2 + 2xw_2 - w_2(1-6x)\big)^2. \end{aligned}$$

Table 25.2 checks both. □

The first-order terms cancel in (a): both $D_m^2\ell_-^2(1-4x)^3$ and λ^2 begin $x^2\big(1-6x-2xe^2+\cdots\big)$ with $e = y/x$, which is why the lowest terms of q_1 and q_2 have degree 4. So in proper time Kepler's energy–period law has *no* first-order relativistic correction: $T^2(-2H)^3 = (2\pi_\delta)^2m^2(1+R)$ with $0 \le R \le 4\lambda^2$. In the semi-major axis a_K, the mean of the two apsidal radii, the same period carries the first-order term $3m/a_K$: $T^2m = (2\pi_\delta)^2a_K^3(1 + 3m/a_K + R')$ with $0 \le R' \le 20(m/p)^2$.

A distant observer does not measure proper time. In Schwarzschild's geometry the coordinate time t_c of a geodesic runs at $dt_c/d\tau = \mathscr{E}/(1 - 2m/r)$. We construct this clock along the motion and compute its period.

Theorem 25.47 (The far observer's period)**.** *Let Λ be a ratio and y a window orbit, with $Z = -2H$ and $\lambda = am$. There are a radial period (θ, T, Φ), a point $E_\infty \ge 0$ with $E_\infty^2 = 1 + 2H$, maps t_c and D with $t_c(0) = 0$ such that t_c has derivative $D(\tau)$ at every τ and $D(\tau)\big(1 - 2m\,u(\tau)\big) = E_\infty$, and a point T_c with $t_c(\tau + T) = t_c(\tau) + T_c$ for every τ, such that*

$$\begin{gathered} (2\pi_\delta)^2m^2(1 + 3Z) \le T_c^2Z^3 \le (2\pi_\delta)^2m^2(1 + 3Z + 20\lambda^2),\\ LT\big(1 + \tfrac{3}{2}Z - 2\lambda^2\big) \le LT_c \le LT\big(1 + \tfrac{3}{2}Z + 8\lambda^2\big). \end{gathered}$$

No omniscience principle and no choice principle is used.

Proof. The clock. By (25.5), $Z = (x^2 - y^2)(1 - 4x)/\lambda$ lies in $[0, \frac{1}{2}]$, so $E_\infty = \sqrt{1 - Z}$ exists, and squaring shows $1 - \frac{Z}{2} - \frac{Z^2}{2} \le E_\infty \le 1 - \frac{Z}{2}$. Along the orbit $2mU \le 2(x + |y|) \le \frac{1}{51}$, so $1 - 2mU \ge \frac{1}{2}$. Let $\sigma_c(\psi) = \int_0^\psi h/(U^2(1 - 2mU))$ by Lemma 25.6, and put $t_c(\tau) = E_\infty \sigma_c(\psi(\tau))/L$ and $T_c = E_\infty \sigma_c(4q)/L$. As in Proposition 25.41, t_c has derivative

$$E_\infty \frac{h}{U^2(1 - 2mU)}\, G\, \frac{Lu^2}{L} = \frac{E_\infty}{1 - 2mu},$$

and the integrand has period $4q$, so $t_c(\tau + T) = t_c(\tau) + T_c$.

The integral. For $0 \le z \le \frac{1}{51}$, $1 + z \le 1/(1 - z) \le 1 + z + \frac{51}{50} z^2$, because

$$(1 + z + cz^2)(1 - z) = 1 + z^2(c - 1 - cz).$$

Apply it with $z = 2mU$, the bounds on h from Lemma 25.45, $\int_0^{4q} d\psi/U = \eta(4q)/k = 4q/k$, $\int_0^{4q} \cos\psi\, d\psi = 0$ and $|\int_0^{4q} \cos\psi\, d\psi/U| \le 4q/k$, each in the sense of antiderivatives. With $mk = \sqrt{x^2 - y^2} \le x$ this gives

$$2\pi_\delta D_m\, c_- \le mk^3 \sigma_c(4q) \le 2\pi_\delta D_m\, c_+,$$

where, with $v = |y|$ and $w_2 = y^2$,

$$\begin{aligned} c_- &= \ell_- + (x^2 - w_2)(2 - 2vD_m^2), \\ c_+ &= \ell_+ + (x^2 - w_2)(2 + 4w_2 D_m^4 + 2vD_m^2) + \tfrac{204}{50}\, x(x^2 - w_2)(1 + 2w_2 D_m^4). \end{aligned}$$

The bridge. $LT = \sigma(4q)$ and $LT_c = E_\infty \sigma_c(4q)$. With the bounds on σ from the proof of Theorem 25.46 and on E_∞ above, the bridge follows from

$$\begin{aligned} &\text{(F1)} \quad \big(1 - \tfrac{Z}{2} - \tfrac{Z^2}{2}\big) c_- \ge \big(1 + \tfrac{3}{2} Z - 2\lambda^2\big) \ell_+, \\ &\text{(F2)} \quad \big(1 - \tfrac{Z}{2}\big) c_+ \le \big(1 + \tfrac{3}{2} Z + 8\lambda^2\big) \ell_-. \end{aligned}$$

The period law. As in Theorem 25.46, with $B = Z\lambda$, $T_c^2 Z^3 (\lambda m)^2 \lambda = (mk^3 \sigma_c)^2 m^4 (1 - 4x)^3 (\lambda - B)$, and $\lambda - B \ge 0$. The period law follows from

$$\begin{aligned} &\text{(F3)} \quad D_m^2 c_-^2 (1 - 4x)^3 (\lambda - B) \ge \lambda^2 (\lambda + 3B), \\ &\text{(F4)} \quad D_m^2 c_+^2 (1 - 4x)^3 (\lambda - B) \le \lambda^2 (\lambda + 3B + 20\lambda^3). \end{aligned}$$

The certificates. Multiply (F1) and (F2) by $\lambda^2 (1 - 6x)^2$, (F3) by $(1 - 6x)^3$ and (F4) by $(1 - 6x)^5$. Each becomes a polynomial inequality in x and v, with 52, 50, 62 and 107 terms, whose terms of lowest degree, 5, and tails are listed in Table 25.2; Lemma 25.36 proves each. □

Conditions and scope.

Base and premises

The proper-time field G_Λ for a ratio value of the squared angular momentum $\Lambda = L^2$, and a motion in the weak-field window $300m^2 \le L^2$ starting at an apside whose radius lies between $\frac{2}{3}$ and 2 times L^2/m.

Conclusion

The advance per radial period is $6\pi_\delta m/p + \frac{3}{2}\pi_\delta(18 + e^2)(m/p)^2$ up to a remainder in $[0, 160\pi_\delta(m/p)^3]$, and $2\pi_\delta(3\lambda + \frac{105}{4}\lambda^2 + \frac{15}{2}H\lambda)$ up to one in $[0, 600\pi_\delta\lambda^3]$. The radial period obeys Kepler's third law in proper time with no first-order correction; the far observer's period is $T_c = T(1 + \frac{3}{2}Z + R)$ with $-2\lambda^2 \le R \le 8\lambda^2$. So the first-order relativistic term in the period belongs to the far observer's clock alone. Everything is free: no omniscience principle and no choice principle.

Identification

That these motions are Schwarzschild geodesics in proper time, that t_c is the Schwarzschild coordinate time, and that a planet is such a test body, is classical general relativity, not derived here. Section 25.8 says which parts of it Recognition Science derives.

Not claimed

Any planetary data; no measured value enters any proof. The window is a hypothesis: Mercury, with m/p near $3 \cdot 10^{-8}$, lies deep inside it.

Reading off a period from a motion is itself a claim: could the inverse radius return earlier than T? Not unless the orbit is circular.

Theorem 25.48 (The radial period is the least one)**.** *Let Λ be a ratio and y a window orbit. There is a radial period (θ, T, Φ) such that, if $u(t_0)$ is apart from $u(0)$ for some t_0, then every T' with $LT' > 0$ and $u(T') = u(0)$ satisfies $LT \le LT'$. No omniscience principle and no choice principle is used.*

Proof. Take the radial period of Proposition 25.41. There $u(t) - u(0) = A_t\big(\cos\psi(t) - 1\big)$, so A_t is apart from 0, and $u(T') = u(0)$ forces $\cos\psi(T') = 1$. The goal $LT \le LT'$ is the negation of $LT' < LT$, so assume $0 < LT' < LT$. Since σ is increasing with $\sigma(0) = 0$, $\sigma(4q) = LT$ and $\sigma(\psi(T')) = LT'$, we get $0 \le \psi(T') \le 4q$. If $\psi(T') \le 2q$, then Lemma 25.44(c) with $d = \psi(T')$ gives $\psi(T') = 0$ and $LT' = 0$. If $\psi(T') \ge 2q$, the same with $d = 4q - \psi(T')$ gives $\psi(T') = 4q$ and $LT' = LT$. Both contradict the assumption. The two cases need not be decided: each is refuted, so neither $\psi(T') > 2q$ nor $\psi(T') < 2q$ can fail, and the assumption yields a contradiction. □

On a circular orbit every T' returns the inverse radius, so the hypothesis is needed. It is stated positively, as apartness, so that the theorem asks for no decision whether a given orbit is circular.

25.8 What Recognition Science supplies here

Every theorem of this chapter is a statement about a polynomial field on $\mathbb{R}_\delta$. Reading it as the motion of a planet or of a spinning body brings in physics: the dimension of space, the force law, the coefficient of the relativistic term, the rule that test bodies follow geodesics, and the values of constants. Recognition Science derives some of these inputs, reaches the relativistic coefficient through the lattice's own field equations, with Regge's action read as the gravitational action and $\kappa = 1$, and leaves the rest as identifications and calibrations. Table 25.3 lists them.

Table 25.3. The physical inputs of this chapter and where each comes from.

Input	Used in	Status
Space has three dimensions; angular momentum is a vector	Sections 25.2–25.5, 25.10	Recognition Science's chain, from its premise that a kept pair of records is a linked closed curve (Chapter 23); $D(D-1)/2 = D$ only for $D = 0$ and $D = 3$
Newton's inverse square; $m = GM$	Sections 25.2–25.5	Identification; the value of G is a calibration
$b = 3m$, that is $\beta = \gamma = 1$	Sections 25.6 and 25.7, first order	The $\kappa = 1$ lattice's own equations: long-wave solutions with point-mass jets have $\gamma = \beta = 1$ (Theorem 25.70); open: the existence of that profile
A post-Newtonian β of J's own cost	none	Does not exist, with Chapter 27's static test field read as that of a static mass: on the Euclidean lattice J's cost is Regge's action plus a gauge-breaking cubic vertex
The second-order coefficients	Theorems 25.37, 25.42, 25.43	Schwarzschild's; the lattice's own equations give $\chi_2 = 1$ (Theorem 25.70), and at the jet level the jet equations built from the quartic cell form give $\chi_3 = 1$ and the whole coefficient, the cell form's reading as the action's fourth derivative resting on two named premises on third-order rates (Theorem 25.71)
Geodesic motion; proper time and a far observer's time	Section 25.7	Classical general relativity (identification)
Masses, moments of inertia, initial states	throughout	Calibration and observation; no measured value enters a proof

Three dimensions and vectors. Recognition Science identifies a kept pair of records with a closed curve linked in space. That identification is a premise of its forcing chain, and from it the chain derives that space has three dimensions, the dimension in which a closed curve can be linked; Chapter 23 proves that topological step. This chapter uses the number in one more way. A rotation in D dimensions turns $D(D-1)/2$ independent planes, and $D(D-1)/2 = D$ holds exactly for $D = 0$ and $D = 3$. So in three dimensions, and only there, each plane of rotation is named by the axis perpendicular to it: angular momentum is the vector $L = x \times v$ of Kepler's problem, and Euler's equations of Section 25.10 are equations for a vector.

The inverse square. The Kepler field is Newton's law, and this chapter takes it as given. Reading it as gravity, and m as GM, is an identification; the value of G is a calibration, and no theorem needs it.

The first relativistic order. For a static, spherically symmetric field with the Eddington–Robertson parameters β and γ, the advance of the pericentre per revolution at the first post-Newtonian order is $\frac{1}{3}(2 + 2\gamma - \beta)$ times Einstein's $6\pi m/p$ [169]. An orbit equation $u'' + u = a + bu^2$ with $a = 1/p$ advances by $2\pi_\delta ab$ per revolution at first order (Theorem 25.35), which is that advance exactly when $b = (2 + 2\gamma - \beta)\, m$; only this first-order advance is compared here, not the orbit equations themselves. In the areal radius, Schwarzschild's field, with $\beta = \gamma = 1$, gives exactly $u'' + u = m/L^2 + 3mu^2$ [155, 168], and the fields of Sections 25.6 and 25.7 have its coefficient $b = 3m$. The lattice's own field equations reach $\beta = \gamma = 1$, and with them $b = 3m$: on $\mathbb{R}_\delta$, with no omniscience principle and no choice, Regge's cubic vertex on the $\kappa = 1$ lattice is Einstein–Hilbert's at long wavelength, and a long-wave solution of the lattice's equations whose jets at a point are those of a point mass has $\gamma = \beta = 1$ (Section 25.12). What remains open is the existence of that long-wave profile; Regge's action read as the gravitational action, and $\kappa = 1$, are identifications. The first-order advance $6\pi_\delta m/p$ of Theorem 25.42, and the absence of a first-order term in the proper-time Kepler law of Theorem 25.46, rest on these.

The cost J has no post-Newtonian β of its own. The clause cannot be traded for the cost J. Chapter 27 proves, in classical mathematics, that the cost built from J on the Kuhn lattice at its Euclidean background equals Regge's action plus an extra cubic vertex, that this extra vertex breaks gauge invariance on shell, and that for one static first-order field, the field of two null static waves, the second-order equation of the J-built cost has no solution. Read as the Euclidean form of the linearized field of a static mass, the identification named there, this is the field from which β is read, so J's cost has no β of its own: the question has no answer, not an unknown one. The theorem concerns that field; it does not treat the point-mass field itself. With Regge's action read as the gravitational action, an identification also named in Chapter 27, nonlinear gravity on that lattice is Regge's action, and there the J-built cost agrees with it to second order in the perturbation and no further; the Lorentzian lattice is not treated. The relativistic coefficient of this chapter comes from Regge's action on the lattice (Section 25.12), not from J.

The second order. The second-order coefficients, $27\pi_\delta(m/p)^2$ and $\frac{3}{2}\pi_\delta e^2(m/p)^2$ in Theorem 25.42 and $\frac{105}{4}$ and $\frac{15}{2}$ in Theorem 25.43, are properties of Schwarzschild's orbit equation and of the proper-time field G_Λ. A static metric that agrees with Schwarzschild's only to the first post-Newtonian order changes them through its higher-order terms, so the second order tests more of a field equation than the first does. Write the temporal and the spatial part of a static, spherically symmetric metric in isotropic coordinates as power series in $U = m/\bar{r}$, with $\bar{r}$ the

isotropic radius. At $\beta = \gamma = 1$ they read

$$-g_{00} = 1 - 2U + 2U^2 - \tfrac{3}{2}\chi_3 U^3 + O(U^4), \qquad g_{ij} = \big(1 + 2U + \tfrac{3}{2}\chi_2 U^2 + O(U^3)\big)\delta_{ij}, \tag{25.7}$$

which names the coefficient of U^2 in the spatial part and that of U^3 in the temporal part. Schwarzschild's field, with $-g_{00} = \big((1-U/2)/(1+U/2)\big)^2$ and $g_{ij} = (1+U/2)^4\delta_{ij}$, has $\chi_2 = \chi_3 = 1$. At $\beta = \gamma = 1$ the second-order advance depends on exactly these two further coefficients, and on no other (Proposition 25.49). The lattice's own equations also give the spatial coefficient its Schwarzschild value, $\chi_2 = 1$ (Theorem 25.70), and at the jet level the third-order jet equation, built from the quartic cell form, gives $\chi_3 = 1$ (Theorem 25.71), with the quartic cell form read as the fourth derivative of δ's action, a reading that rests on two named premises about third-order rates. The proposition is the classical expansion of the apsidal angle of a timelike geodesic, carried to second order. It concerns the geodesics of a given metric and is proved in classical mathematics, over the classical real numbers.

Proposition 25.49 (The second-order advance depends on two more coefficients)**.** *Let a static, spherically symmetric metric satisfy* (25.7)*, with $-g_{00}$ and the spatial factor smooth functions of U near* 0*. Take a timelike geodesic whose areal radius r moves between two distinct apsidal values, with inverses u_0 and u_1; define p and e by $p(u_0+u_1) = 2$ and $e(u_0+u_1) = u_0 - u_1$, as in Theorem 25.42, and put $x = m/p$. Let Φ be the polar angle swept in one radial period, E and L the conserved energy and angular momentum per unit mass, $H = (E^2-1)/2$ and $\lambda = m^2/L^2$. There are numbers C and $x_* > 0$, depending only on the metric, such that for every such geodesic with $x \le x_*$*

$$\Big|\frac{\Phi}{2\pi} - 1 - 3x - \Big(\frac{15}{2} + \frac{15}{4}\chi_2 + \frac{9}{4}\chi_3 + \frac{3}{4}\chi_2\, e^2\Big)x^2\Big| \le Cx^3$$

and

$$\Big|\frac{\Phi}{2\pi} - 1 - 3\lambda - \Big(\frac{39}{2} + \frac{9}{2}\chi_2 + \frac{9}{4}\chi_3\Big)\lambda^2 - \Big(6 + \frac{3}{2}\chi_2\Big)H\lambda\Big| \le C\lambda^3.$$

Proof. Every $O(\cdot)$ below is bounded by a constant that depends only on the metric, for $x \le x_*$ with x_* small.

The areal form. Let $\Psi(U) = 1 + 2U + \frac{3}{2}\chi_2 U^2 + O(U^3)$ be the spatial factor. The areal radius is $r = \bar r\,\Psi^{1/2}$, so $v = m/r$ satisfies $v = U\Psi^{-1/2} = U - U^2 + (\frac{3}{2} - \frac{3}{4}\chi_2)U^3 + O(U^4)$, which inverts to $U = v + v^2 + (\frac{1}{2} + \frac{3}{4}\chi_2)v^3 + O(v^4)$. Since $dr/d\bar r = \Psi^{1/2}\big(1 - U\Psi'/(2\Psi)\big)$ with $\Psi' = d\Psi/dU$, and $U\Psi'/(2\Psi) = v + (\frac{3}{2}\chi_2 - 1)v^2 + O(v^3)$, the metric is $-A\,dt^2 + B\,dr^2 + r^2 d\Omega^2$ with

$$A = 1 - 2v + a_3 v^3 + O(v^4), \qquad B = \Psi\Big(\frac{d\bar r}{dr}\Big)^2 = \Big(1 - \frac{U\Psi'}{2\Psi}\Big)^{-2} = 1 + 2v + b_2 v^2 + O(v^3),$$

where $a_3 = 3 - \frac{3}{2}(\chi_2 + \chi_3)$ and $b_2 = 1 + 3\chi_2$. Schwarzschild's $A = 1 - 2v$, $B = 1/(1-2v)$ has $a_3 = 0$ and $b_2 = 4$.

The orbit equation. Along the geodesic, in its proper time, $E = A\dot t$ and $L = r^2\dot\phi$ are constant and $-A\dot t^2 + B\dot r^2 + r^2\dot\phi^2 = -1$. With $u = 1/r$ as a function of the polar angle, $\dot r = -Lu'$, so

$$B\,u'^2 = N(u), \qquad N(u) = \frac{1}{L^2}\Big(\frac{E^2}{A} - 1\Big) - u^2. \tag{25.8}$$

For Schwarzschild's metric this reads $u'^2 = (E^2 - 1 + 2mu)/L^2 - u^2 + 2mu^3$, whose derivative is the orbit equation $u'' + u = m/L^2 + 3mu^2$ of Section 25.6. The apsides are the zeros u_0, u_1 of N, which is positive between them, and $\Phi = 2\bigl|\int_{u_1}^{u_0} \sqrt{B/N}\,du\bigr|$.

The factor between the apsides. Write $1/A = 1 + 2v + 4v^2 + (8 - a_3)v^3 + v^4\rho(v)$ with ρ smooth near 0. Then

$$N(u) = n_0 + n_1 u - (1 - n_2)u^2 + n_3 u^3 + N_4(u),$$

with $n_0 = (E^2 - 1)/L^2$, $n_1 = 2mE^2/L^2$, $n_2 = 2mn_1$, $n_3 = \tfrac{1}{2}(8 - a_3)m^2 n_1$ and $N_4(u) = \tfrac{1}{2}n_1 m^3 u^4 \rho(mu)$. As N vanishes at u_0 and u_1, $N(u) = (u_0 - u)(u - u_1)R(u)$, where $R(u)$ is minus the second divided difference of N at u_0, u_1, u. Divided differences are linear. That of a constant or of u is 0, that of u^2 is 1, and that of u^3 is $u_0 + u_1 + u$, because $u^3 - (u - u_0)(u - u_1)(u + u_0 + u_1)$ is linear in u; that of N_4 is $\tfrac{1}{2}N_4''(\xi)$ for some ξ between the least and the greatest of u_0, u_1, u. So

$$R(u) = 1 - n_2 - n_3(u_0 + u_1 + u) - \tfrac{1}{2}N_4''(\xi),$$

and the first divided difference, $(N(u_0) - N(u_1))/(u_0 - u_1) = 0$, gives in the same way

$$n_1 = (1 - n_2)(u_0 + u_1) - n_3(u_0^2 + u_0 u_1 + u_1^2) - N_4'(\xi')$$

for some ξ' between u_0 and u_1. Here $u_0 + u_1 = 2/p$, and on $0 \le u \le 2/p$ we have $mu \le 2x$, so $N_4' = n_1 O(x^3)$ and $N_4'' = n_1 m\, O(x^2)$. The last relation is therefore linear in n_1: $n_1\bigl(1 + 4x + O(x^2)\bigr) = 2/p$, so $n_1 = (2/p)\bigl(1 - 4x + O(x^2)\bigr)$. Hence $n_2 = 4x - 16x^2 + O(x^3)$, $N_4'' = O(x^3)$, and at $u = (1 + e\cos\psi)/p$

$$R = 1 - 4x + 16x^2 - (8 - a_3)x^2(3 + e\cos\psi) + O(x^3).$$

The integral. Put $u = (1 + e\cos\psi)/p$ for $0 \le \psi \le \pi$. Then $(u_0 - u)(u - u_1) = (e/p)^2 \sin^2\psi$ and $du = -(e/p)\sin\psi\,d\psi$, so

$$\Phi = 2\int_0^{\pi} \sqrt{B/R}\,d\psi = \int_0^{2\pi} \sqrt{B/R}\,d\psi.$$

With $v = x(1 + e\cos\psi)$ and $(1 - \delta)^{-1/2} = 1 + \tfrac{1}{2}\delta + \tfrac{3}{8}\delta^2 + O(\delta^3)$,

$$\sqrt{B} = 1 + x(1 + e\cos\psi) + \tfrac{3}{2}\chi_2 x^2(1 + e\cos\psi)^2 + O(x^3),$$
$$1/\sqrt{R} = 1 + 2x - 2x^2 + \tfrac{1}{2}(8 - a_3)x^2(3 + e\cos\psi) + O(x^3).$$

Multiply and average over ψ, where $\cos\psi$ has mean 0 and $\cos^2\psi$ mean $\tfrac{1}{2}$:

$$\frac{\Phi}{2\pi} = 1 + 3x + \Bigl(2 - 2 + \tfrac{3}{2}(8 - a_3) + \tfrac{3}{2}\chi_2\bigl(1 + \tfrac{1}{2}e^2\bigr)\Bigr)x^2 + O(x^3),$$

and $8 - a_3 = 5 + \tfrac{3}{2}(\chi_2 + \chi_3)$ gives the first estimate.

The conserved quantities. Multiplied by $m/2$, the value of n_1 reads $E^2\lambda = x - 4x^2 + O(x^3)$. At $u = 0$ the factorization gives $n_0 = -u_0 u_1 R(0)$, and multiplied by m^2 this reads $2H\lambda = -(1 - e^2)x^2\bigl(1 + O(x)\bigr)$. So $H = O(x)$, $e^2x^2 = x^2 + 2H\lambda + O(x^3)$, and with $E^2 = 1 + 2H$, $\lambda = x - 4x^2 - 2Hx + O(x^3)$, that is, $x = \lambda + 4\lambda^2 + 2H\lambda + O(\lambda^3)$, and $\lambda \ge x/2$. Substituting into the first estimate, $3x$ gives $3\lambda + 12\lambda^2 + 6H\lambda$, the term in x^2 without e gives $(\tfrac{15}{2} + \tfrac{15}{4}\chi_2 + \tfrac{9}{4}\chi_3)\lambda^2$, and $\tfrac{3}{4}\chi_2 e^2 x^2$ gives $\tfrac{3}{4}\chi_2(\lambda^2 + 2H\lambda)$; their sum is the second estimate. $\square$

At $\chi_2 = \chi_3 = 1$ the proposition gives $\frac{3\pi}{2}(18 + e^2)(m/p)^2$ and the coefficients $\frac{105}{4}$ and $\frac{15}{2}$, those of Theorems 25.42 and 25.43, which prove more for Schwarzschild's orbit equation: explicit remainders, for motions on $\mathbb{R}_\delta$ with no choice. So, through that clause, the eccentricity term $\frac{3}{2}\pi_\delta e^2(m/p)^2$ of Theorem 25.42 and the coefficient $\frac{15}{2}$ of Theorem 25.43 are reached; the temporal coefficient contributes $\frac{9}{2}\pi_\delta(m/p)^2$ of the term $27\pi_\delta(m/p)^2$ and $\frac{9}{4}$ of the coefficient $\frac{105}{4}$, and these shares are not. The theorems hold for the Schwarzschild orbit equation, whatever field equation produces it.

Geodesics, clocks and data. That a test body moves on a timelike geodesic in its proper time, that a planet is such a body, and that t_c is the time of a distant observer, is classical general relativity; the theorems of Section 25.7 name these identifications and prove nothing about them. No measured number enters a proof. Masses, the moments of inertia of Section 25.10 and initial states are calibrations and observations, and the weak-field window is a hypothesis about the orbit.

25.9 Certified runs are motions

Chapter 15 built a solver for polynomial fields. From ratio data and one finite check, the region certificate, it computes a point of $\mathbb{R}_\delta$ to every precision (Theorem 15.22). What that point is was settled there classically: Theorem 15.29 identifies it with the value of a classical solution that is assumed to exist and to stay in the ball of the certificate. On $\mathbb{R}_\delta$ we can now say what the point is without assuming anything. It is the value at time T of a motion in the sense of Definition 25.2, built from the solver's own Taylor steps.

Throughout this section p is a polynomial field on d coordinates, $x_0 \in \mathbb{Q}_\delta^d$, $M \geq 1$ and T are natural numbers, the quadratized problem of p with initial point x_0, radius M and end time T satisfies the region certificate at a level n_0, and $\bar{x} \in \mathbb{R}_\delta^d$ is its polynomial solution at time T (Definition 15.27). We call this a *passing run.* For a natural number j, $2^{-j}p$ is the field whose coefficients are those of p times 2^{-j}; its motions are those of p run 2^j times more slowly. We write $\|y\|$ for the largest absolute value of a coordinate of y.

Theorem 25.50 (The certified point is the end of a motion)**.** *For a passing run there is a motion X of p on $[0, T]$ with $X(0) = x_0$ and $X(T) = \bar{x}$. Moreover, let a and j be natural numbers with $a \leq T2^j$, and suppose that the quadratized problem of $2^{-j}p$ with initial point x_0, end time a and some radius $M_1 \geq 1$ satisfies the region certificate at some level. Then $X(a/2^j)$ is the polynomial solution of that problem. No omniscience principle and no choice principle is used.*

Proof. Cells. The schedule has the step $h = 2^{-\sigma}$, with $8R \leq 2^\sigma$, and $S = T2^\sigma$ steps (Definition 15.18); let A, n_1, $x(y)$ and $z(y)$ be as in Lemma 25.29. For $k < S$, a level $n \geq n_1$ and $0 \leq \tau \leq h$, let $V_k^{(n)}(\tau) = \sum_{j \leq N(n)} \tau^j X_j$, where X is the formal solution of $x' = p(x)$ from $x(y_k^{(n)})$. By the proof of Lemma 25.29, the monomials of X form the exact coefficient table at the surface point $z(y_k^{(n)})$, so $V_k^{(n)}$ is a Taylor polynomial of the quadratized field, read in the coordinates w_{e_i}. For $n_1 \leq n \leq n'$ the surface points of the two levels at step k lie in the ball of radius M and within $(2A + 1)2^{-n}$ of each other, by Lemma 25.29. By Lemmas 15.14 and 15.15 their coefficients are at most MR^j and differ by at most $(2A + 1)2^{-n}(j + 1)R^j$. The proof of Lemma 15.16 bounds the sums term by term, so the lemma holds with h replaced by

any $\tau \in [0,h]$: the sums of order $N(n)$ differ by at most $2(2A+1)2^{-n}$, and raising the order from $N(n)$ to $N(n')$ changes a sum by at most $M2^{-N(n)}$. Hence

$$\left|V_k^{(n')}(\tau) - V_k^{(n)}(\tau)\right| \le (M + 4A + 2)\, 2^{-n}$$

for all k and τ, and Theorem 12.25 gives the limit $V_k(\tau)$ with no choice.

The equation inside a cell. The polynomial $V = V_k^{(n)}$ has coefficients at most MR^j, and $8R\tau \le 1$ on the cell. For $0 \le \tau_1 \le \tau_2 \le h$ and $\Delta = \tau_2 - \tau_1$, the binomial theorem gives $0 \le \tau_2^j - \tau_1^j - j\tau_1^{j-1}\Delta \le \binom{j}{2}\tau_2^{j-2}\Delta^2$, and $\sum_j \binom{j}{2}8^{2-j} = (8/7)^3 < \frac{3}{2}$; so $|V(\tau_2) - V(\tau_1) - V'(\tau_1)\Delta| \le \frac{3}{2}MR^2\Delta^2$. Since $X' = p(X)$ as power series, $V'(\tau) - p(V(\tau))$ consists of the terms of order at least $N(n)$ of p at the cut-off series, which add up to at most $|p|(2M)2^{-N(n)}$, with $|p|(2M)$ the largest of the $|p_i|(2M)$, by the bound on products in the proof of Lemma 25.29. So $|V(\tau_2) - V(\tau_1) - p(V(\tau_1))\Delta| \le \frac{3}{2}MR^2\Delta^2 + |p|(2M)2^{-n}\Delta$, and in the limit, with $C_1 = \frac{3}{2}MR^2$,

$$\left|V_k(\tau_2) - V_k(\tau_1) - p\big(V_k(\tau_1)\big)(\tau_2 - \tau_1)\right| \le C_1(\tau_2 - \tau_1)^2 \qquad (0 \le \tau_1 \le \tau_2 \le 2^{-\sigma}).$$

At level n the end $V_k^{(n)}(h)$ of cell k is $x\big(\Phi_{N(n)}(z(y_k^{(n)}))\big)$, which is within $(M+2+2A)2^{-n}$ of $x(y_{k+1}^{(n)})$, the start of cell $k+1$, as in the proof of Lemma 25.29. So neighbouring cells meet in the limit; cell 0 starts at $[x_0]_{N(n)}$, hence at x_0 in the limit, and the last cell ends at $\bar{x}$ by Theorem 15.22.

A motion. At a ratio time $t \in [0,T]$ put $X(t) = V_k(t - k2^{-\sigma})$ with $k = \lfloor t2^\sigma \rfloor$, and $k = S - 1$ at $t = T$. Two ratio times closer than one step lie in one cell or in neighbouring ones, so the cell estimate chains to $|X(t) - X(s) - p(X(s))(t-s)| \le C_2(t-s)^2$ for all ratio times in $[0,T]$, with C_2 fixed, and X is Lipschitz there. A Lipschitz family indexed by ratio times extends to every point of $[0,T]$ with no choice: the value at t is the limit of the values at the stages of a regular sequence naming t, which converge at the rate the Lipschitz constant gives, and two names of t give the same limit. The estimate passes to the limit, so X is a motion of p on $[0,T]$, with the modulus $j = (k+1)C_2$ at tolerance k.

Dyadic times. The curve $s \mapsto X(s/2^j)$ is a motion of $2^{-j}p$ on $[0,a]$, by the chain rule. The first part, applied to the problem of $2^{-j}p$, gives a second motion of $2^{-j}p$ on $[0,a]$ from x_0, ending at that problem's polynomial solution. Theorem 25.3(a) makes the two agree at $s = a$. □

Corollary 25.51 (The certified value does not depend on the schedule)**.**

(a) *If the quadratized problems of p with initial point x_0, end time T and radii M and M' satisfy the region certificate at levels n_0 and n_0', their polynomial solutions at time T are equal.*

(b) *Let the coefficients of p be polynomials in parameters $\vartheta_0, \dots, \vartheta_{l-1}$, and let $\vartheta \in \mathbb{Q}_\delta^l$. If the run of the field that carries the parameters as l further coordinates of rate 0, from (x_0, ϑ), and the run of the field with ϑ substituted, from x_0, both pass with the same radius and end time, then the first d coordinates of the first polynomial solution equal the second.*

(c) *For a passing run and every first integral F of p, the motion X of Theorem 25.50 has $F(X(t)) = F(x_0)$ for every $t \in [0,T]$, in particular at every certified dyadic time.*

No omniscience principle and no choice principle is used.

Proof. (a) Theorem 25.50 gives two motions of p on $[0,T]$ from x_0, ending at the two values, and Theorem 25.3(a) makes them equal at T. (b) Along the motion of the first run the parameter coordinates are constant (Lemma 25.4(c)), so its first d coordinates form a motion of the substituted field from x_0; uniqueness compares it with the motion of the second run. (c) is Proposition 25.5. □

Exact conservation follows at once, and it is the statement a physicist checks first: a certified run of a conservative system does not drift.

Theorem 25.52 (Exact conservation along certified runs)**.** *For a passing run and a first integral F of p, $F(\bar{x}) = F(x_0)$. Moreover, let K be a natural number with $|F(y)-F(z)| \le K\|y-z\|$ whenever $\|y\|, \|z\| \le M+3$, and let $a^{(m)}$ be the vector of the answers at precision m of the coordinates of $\bar{x}$. Then $|F(a^{(m)}/2^m) - F(x_0)| \le 2K2^{-m}$ for every m. No omniscience principle and no choice principle is used.*

Proof. Corollary 25.51(c) at $t = T$ gives $F(\bar{x}) = F(x_0)$. By Theorem 15.20 the coordinates of $\bar{x}$ have absolute value at most M, and by Theorem 15.22 each answer satisfies $|a_i^{(m)}/2^m - \bar{x}_i| \le 2^{-m}$; so both points lie in the box of radius $M+3$, and $|F(a^{(m)}/2^m) - F(\bar{x})| \le K2^{-m} \le 2K2^{-m}$. □

A second proof never builds the motion. Along one exact Taylor step the values of F form a power series whose derivative is the series of $\mathscr{L}_p F = 0$, so a step moves F by at most a fixed multiple of its truncation error; the steps are counted by the schedule, and the limit over the levels removes the error. It is the argument of Theorem 25.30 with all rates zero, and it is how the ten integrals of N bodies (Theorem 25.25) are kept exactly by every certified N-body run.

Proposition 25.53 (Hamilton's energy is a first integral)**.** *Let H be a polynomial with ratio coefficients in $q_0, \dots, q_{n-1}, p_0, \dots, p_{n-1}$, and let Hamilton's field be $\dot{q}_i = \partial H/\partial p_i$, $\dot{p}_i = -\partial H/\partial q_i$. Then H is a first integral, and every passing run of Hamilton's field keeps H exactly. No omniscience principle and no choice principle is used.*

Proof. $\mathscr{L}H = \sum_i \big(\partial_{q_i} H \partial_{p_i} H - \partial_{p_i} H \partial_{q_i} H\big) = 0$, an identity of polynomials. Theorem 25.52 does the rest. □

Whether a polynomial is a first integral at all is a question about every point of $\mathbb{R}_\delta^d$, and it might look as if answering it needed an omniscience principle. It does not.

Theorem 25.54 (First integrals are decided on a finite grid)**.** *Let p and F have ratio coefficients, and let E be the largest exponent of a single variable in a term of the polynomial $\mathscr{L}_p F$. Then F is a first integral of p if and only if $\mathscr{L}_p F$ vanishes at every point of the grid $\{0,1,\dots,E\}^d$. Consequently, for all p and F, either F is a first integral of p or it is not, and when it is not, a grid point where $\mathscr{L}_p F \neq 0$ is a witness. No omniscience principle and no choice principle is used.*

Proof. One direction is immediate. For the other, a polynomial P in d variables, of degree at most E in each and vanishing on the grid, is the zero polynomial. For $d = 1$, P has the $E+1$ distinct ratio roots $0, \dots, E$, so its coefficients solve a Vandermonde system with nonzero

determinant and vanish. For $d+1$ variables write $P = \sum_{j \le E} P_j\, x_d^j$; at each grid point of the first d coordinates the one-variable case makes every P_j vanish, and induction makes every P_j zero. A zero polynomial vanishes at every point of $\mathbb{R}_\delta^d$. The grid values are ratios, and each test whether one of them is 0 is integer arithmetic, so the finite conjunction is decided. □

The certified value depends on the initial point with a Lipschitz constant that the solver itself supplies, and that makes predictions from measured states possible. A measured state is a point of $\mathbb{R}_\delta^d$, not a ratio.

Theorem 25.55 (Lipschitz dependence and measured initial states)**.** *Fix a passing run at x_0, with radius M and end time T.*

(a) There is a natural number Λ, which depends only on p, M and T, such that for all ratio points y_1, y_2 whose runs with radius M and end time T pass at some levels, and every ratio r with $\|y_1 - y_2\| \le r$, the polynomial solutions satisfy $\|\bar y_1 - \bar y_2\| \le \Lambda r$.

(b) There are natural numbers ρ, Λ and a map S from $\mathbb{R}_\delta^d$ to $\mathbb{R}_\delta^d$ such that $S(y) = \bar y$ for every ratio point y with $\|y - x_0\| \le 2^{-\rho}$ whose run passes at some level, and $\|S(x) - S(x')\| \le \Lambda \|x - x'\|$ for all points x, x' within $2^{-\rho}$ of x_0.

No omniscience principle and no choice principle is used.

Proof. (a) Take $\Lambda = GK_D$, with G the growth bound of the schedule, which does not depend on the initial point (Definition 15.18), and K_D a Lipschitz constant of the monomials of degree at most D on the ball of radius $M+1$. Run both trajectories at a common level n. By the region certificates both stay in the ball of radius M (Theorem 15.20), where the Taylor step is Lipschitz; the initial points lie in it too, so no closeness to x_0 is needed. The error recursion of Theorem 15.9 is affine in the initial gap: after S steps the trajectories are within $G(K_D r + 2^{-N(n)+1})$ plus defects of order $2^{-N(n)}$. Letting n grow gives $\|\bar y_1 - \bar y_2\| \le \Lambda r$.

(b) One region check at x_0 certifies every ratio point y near it: at the level n_0 plus a fixed number of extra bits, the level trajectories from y stay within the margin $2^{-(n_0+2)}$ of the checked trajectory from x_0 once $\|y - x_0\| \le 2^{-\rho}$, for ρ fixed by n_0 and Λ. Clamping each coordinate into $[x_{0,i} - 2^{-\rho}, x_{0,i} + 2^{-\rho}]$ makes $y \mapsto \bar y$ a Λ-Lipschitz map on all ratio points, and it extends to points through their regular sequences as in the proof of Theorem 25.50, with no choice and the same constant. □

Does every problem have a passing run? For short enough times, yes, and the certificate can be written down.

Theorem 25.56 (Every polynomial field is certified for a short time)**.** *Let p be a polynomial field with $D = \max(1, \deg p)$, t_p terms in all, and c the largest of the numbers $\lceil |q| \rceil$ over its coefficients q, and let $x_0 \in \mathbb{Q}_\delta^d$. Put*

$$X = \max\bigl(1, \max_i \lceil |x_{0,i}| \rceil\bigr), \quad M = X^D + 1, \quad s = \mathrm{bl}(M) + 3, \quad k = \mathrm{bl}\bigl(t_p D c M 2^s\bigr).$$

Then the quadratized problem of $2^{-k}p$ with initial point x_0, radius M and end time 1 satisfies the region certificate at every level. So the solver computes the state at time 2^{-k} of every polynomial field from every ratio initial point. No omniscience principle and no choice principle is used.

Proof. The initial monomials have absolute value at most $X^D = M - 1$. Every coefficient of the quadratized field of $2^{-k}p$ has the form $\alpha_i q 2^{-k}$ with $\alpha_i \le D$, and each variable receives at most t_p of them, so on the ball of radius M the field has size at most $t_p D c M^2/2^k \le M/2^s \le \frac{1}{8}$, and its exact Taylor coefficients of order j are at most $M2^{-sj}$ by the majorants of Lemma 15.14. Over one time unit the exact steps move each coordinate by at most $\frac{1}{4}$, truncation and rounding add at most $\frac{1}{4}$ at every level, and so every level trajectory stays within $M - \frac{1}{2}$, inside the bound $M - 2^{-(n+2)}$ the certificate asks. □

For $\dot{x} = x^2$ from $x_0 = 1$, whose solution $1/(1-t)$ blows up at $t = 1$, the recipe gives $D = 2$, $X = 1$, $M = 2$, $s = 5$ and $k = \mathrm{bl}(128) = 8$: the run to time 2^{-8} passes at every level.

What is classical. Two kinds of statement in this section and the next are proved with classical logic. The first is any claim that one fixed tape machine does all the computing in polynomial time: part (b) of the next proposition, clause (3) of Theorem 25.59, and with it the rigid body's certificate (Corollary 25.67). The second is the completeness of the region check, part (a) of the next proposition, which reasons about a classical solution. Everything else in both sections is free.

Proposition 25.57 (Completeness of the check, and one machine for short times)**.** *The following are proved in classical mathematics over the classical real numbers.*

(a) Let $x : [0,T] \to \mathbb{R}^d$ be continuous with $x(0) = x_0$ and the right derivative $p(x(t))$ at every $t \in [0,T)$, and suppose that for some $\varepsilon > 0$ every monomial $x(t)^\alpha$ with $|\alpha| \le D$ has absolute value at most $M - \varepsilon$ on $[0,T]$, as it does when $\|x(t)\| \le r$ with $r \ge 1$ and $r^D \le M - \varepsilon$. Then the quadratized problem with radius M and end time T satisfies the region certificate at some level.

(b) There are one control table H and one natural number λ such that for every polynomial field p and every $x_0 \in \mathbb{Q}_\delta^d$ there is a constant K with: for every $i < d$ and every m, H runs from the request of the problem of Theorem 25.56 for coordinate i at precision m to the answer word of its answer within $K(m+1)^\lambda$ steps.

Proof. (a) The estimate behind Theorem 15.29 does not use the certificate step by step: on each step the true solution and the Taylor polynomial of the computed point differ by a residual of order 8^{-N}, and the classical Gronwall inequality, applied while the trajectory stays in the ball, bounds the level-n trajectory's distance from the true monomials by $C2^{-n}$. For n with $C2^{-n} + 2^{-(n+2)} \le \varepsilon$ the trajectory stays within $M - 2^{-(n+2)}$, which is the certificate at level n. (b) Combine Theorem 25.56 with Theorem 15.33. □

Everything so far concerns one field. The certificates combine into one statement for a physical theory, which we now make precise.

Definition 25.58 (Polynomial theories and sign laws)**.** A *polynomial theory* consists of a polynomial field p on d coordinates, a finite list of polynomials, the *candidate integrals*, and a finite list of *sign laws* on polynomial observables. A sign law on an observable F is built from the atoms $F < c$, $F \le c$, $F = c$, $c < F$ and $c \le F$, with ratio thresholds c, by "and" and "or". *Kepler's theory* has the Kepler field, the candidates E, L_0, L_1, L_2, and the sign law $E < 0 \vee E = 0 \vee E > 0$ on the energy.

Theorem 25.59 (One conversion certificate for a whole polynomial theory)**.** *Every polynomial theory satisfies the following five clauses.*

(1) Each candidate integral is a first integral of p, or it is not.

(2) Each candidate that is a first integral keeps exactly its initial value at the polynomial solution of every passing run, and at the answers at precision m it is within $C2^{-m}$ of that value, for a natural number C.

(3) There are one control table H and one natural number λ such that, for every passing run, H computes the answer at precision m of each coordinate of the polynomial solution from its request within $K(m+1)^{\lambda}$ steps, with K depending on the run only.

(4) For each sign law on an observable that takes every value of $\mathbb{R}_\delta$ as the state varies, "the law holds at every state" is equivalent to one of: false, true, LLPO, LPO; and "at every state the law holds or fails" is equivalent to one of: true, LLPO, WLPO, LPO. Which one is computed by a finite rule, given in the proof, from where the law's atoms hold near each threshold.

(5) Every passing run has the extension S of Theorem 25.55(b) to measured initial states.

Clauses (1), (2), (4) and (5) are proved with no omniscience principle and no choice principle. Clause (3) is proved in classical mathematics, and so is the certificate as a whole. For Kepler's theory all four candidates are first integrals, and deciding the sign law at every state costs exactly LPO.

Proof. (1) is Theorem 25.54, (2) is Theorem 25.52, (3) is Theorem 15.33 for polynomial fields, and (5) is Theorem 25.55.

(4) *Germs.* Since the observable takes every value, a statement about all states is the same statement about all points z of the line, as in Theorem 25.14. Write the law as a disjunction of conjunctions of atoms; distributing "and" over "or" does not change where it holds. The *window* of a threshold c is the open interval between its neighbouring thresholds, unbounded where there is none. On the window every atom with another threshold is constantly true or constantly false, and comparing ratios tells which. So on the window each disjunct says that z lies in one of seven sets, its *germ* at c: the empty set, $\{c\}$, the open sides $z < c$ and $z > c$, the closed sides $z \le c$ and $z \ge c$, or the whole window. The law's six readings at c record whether some germ contains the point c, the open side $z < c$, the open side $z > c$, the closed side $z \le c$, the closed side $z \ge c$, or the whole window, the *neighbourhood reading*. A germ that contains one point of an open side contains that whole side.

From a threshold to all points. Cotransitivity, applied once at each gap between consecutive thresholds, places every point in some window. And for a ratio $\epsilon > 0$ less than the distance

from c to its neighbours, the point $w = c + \max(-\epsilon, \min(\epsilon, z - c))$ lies in the window of c, and $w < c$, $w = c$ or $w > c$ exactly when $z < c$, $z = c$ or $z > c$. So a comparison with c that holds at every point of the window holds at every point, and by translation it is the same comparison with 0; its price is in Corollary 12.18 and Table 12.2: $z \le c \vee z \ge c$ costs LLPO, $z = c \vee z \ne c$ and $z \le c \vee \neg(z \le c)$ cost WLPO, and $z < c \vee \neg(z < c)$ and $z < c \vee z = c \vee z > c$ cost LPO. Recall that $\neg(z < c)$ is $c \le z$.

Holds at every point. If at some threshold c the point c, or one of the open sides, is in no germ, then the law fails at c, or at a ratio point of the window beside c, and "holds at every point" is false. Otherwise the upper bounds: with the neighbourhood reading at every threshold the law holds wherever a point is placed, with no principle; with both closed sides in germs at every threshold, LLPO places a point of a window at $z \le c$ or $z \ge c$; and LPO places it at $z < c$, $z = c$ or $z > c$, each in a germ. The lower bounds: suppose the law holds at every point. If the neighbourhood reading fails at c, every germ lies in $z \le c$ or in $z \ge c$, so at each point of the window the disjunct that holds gives $z \le c \vee z \ge c$, which is LLPO. If moreover the closed side $z \le c$, say, is in no germ, every nonempty germ lies in $z < c$ or in $z \ge c$, and the law gives $z < c \vee \neg(z < c)$, which is LPO.

Holds or fails at every point. At a threshold c the rule gives a local price, and the upper bound places a point of the window as finely as the price allows. It is free when the neighbourhood reading holds, or when no germ contains c or an open side, for then the law fails on the whole window. When c and both open sides are in germs, the law cannot fail on the window, since $\neg(z < c)$ and $\neg(z > c)$ give $z = c$; so "holds or fails" is "holds", and the price is LLPO if both closed sides are in germs and LPO otherwise, as above. When c is in no germ but an open side, say $z < c$, is, the law holds only apart from c and fails only where $\neg(z < c)$, so deciding it decides $z < c \vee \neg(z < c)$: LPO. When c is in a germ and neither open side is, the law holds exactly at c, and deciding it is $z = c \vee z \ne c$: WLPO. When c and exactly one open side, say $z < c$, are in germs, the law holds only where $z \le c$: if the closed side $z \le c$ is in a germ, the law holds exactly where $z \le c$ and costs WLPO; otherwise it holds exactly where $z < c$ or $z = c$, and deciding it decides $z < c \vee \neg(z < c)$: LPO. The law's price is the strongest local price, in the order free, LLPO, WLPO, LPO: each local price is a lower bound, by the clamping above, and the strongest principle gives the weaker ones and decides the law at every point, since every point is placed in some window.

Section 26.8 states the same rule as a table of these bits (Definition 26.51 and Table 26.3) and proves it again, with two further classes, as Theorem 26.52.

For Kepler's theory, the four candidates are first integrals by Theorem 25.9(a). The germs of the sign law at its threshold 0 are $E < 0$, $\{0\}$ and $E > 0$: the point and both open sides are covered, but no closed side and not the whole window. So both its truth at every state and its decision at every state cost LPO, as Theorem 25.14 found directly. □

The certificate is the bridge from a physical theory written as polynomials to computations one can trust: its integrals are found by a finite check, conserved exactly by every certified run, its laws priced, and its predictions extended to measured states. In the certificate, only the claim that one fixed tape machine does all the computing in polynomial time is classical, and the reason is the construction of that machine in Chapter 15, not anything about mechanics.

25.10 The rigid body

Toss a book into the air, spinning it about each of its three principal axes in turn. About the axis of largest moment of inertia and about the axis of smallest it keeps turning steadily; about the middle axis it flips over and over. Euler's equations explain both behaviours, and the classical explanation is short: two first integrals and one inequality for the stable axes, and Chetaev's growth argument for the middle one [153, 163]. On $\mathbb{R}_\delta$ all of it holds as it stands, with no omniscience and no choice. The one omniscience principle this section meets sits where classical mechanics makes a decision without comment: which axis of a given body is the one of largest moment.

Definition 25.60 (Euler's field)**.** *Euler's field* is the polynomial field on the six coordinates $L_0, L_1, L_2, J_0, J_1, J_2$ given by

$$\dot{L}_k = (J_{k+2} - J_{k+1})\, L_{k+1} L_{k+2}, \qquad \dot{J}_k = 0 \qquad (k = 0, 1, 2),$$

with indices read modulo 3. Its *energy* and its *Casimir* are the polynomials

$$E = \tfrac{1}{2}\big(J_0 L_0^2 + J_1 L_1^2 + J_2 L_2^2\big), \qquad C = L_0^2 + L_1^2 + L_2^2.$$

Read L as the angular momentum of a body in its principal frame and J_k as the inverse $1/I_k$ of its principal moments of inertia. Then $\omega_k = J_k L_k$ is the angular velocity, and the field is Euler's equation $\dot{L} = L \times \omega$ for a body on which no torque acts [156]. That reading is an identification; so is the restriction to the body frame, which drops the orientation of the body from the state, and the moments are calibrations. Three dimensions enter as in Section 25.8: only for $D = 3$, among positive dimensions, is the number $D(D-1)/2$ of planes of rotation equal to D, so only there is angular momentum a vector with one component per axis. The moments have rate 0, so each J_k is a first integral and stays at its initial value along every motion (Proposition 25.5).

Theorem 25.61 (The energy and the Casimir are first integrals)**.** *E and C are first integrals of Euler's field. No omniscience principle and no choice principle is used.*

Proof. Both Lie derivatives carry the factor $L_0 L_1 L_2$, and the remaining sums cancel cyclically:

$$\begin{aligned} \mathscr{L}C &= \sum_k 2L_k(J_{k+2} - J_{k+1})L_{k+1}L_{k+2} = 2L_0L_1L_2 \sum_k (J_{k+2} - J_{k+1}) = 0, \\ \mathscr{L}E &= \sum_k J_k L_k (J_{k+2} - J_{k+1}) L_{k+1} L_{k+2} \\ &= L_0 L_1 L_2 \,(J_0 J_2 - J_0 J_1 + J_1 J_0 - J_1 J_2 + J_2 J_1 - J_2 J_0) = 0. \end{aligned}$$

□

So every motion keeps E and C (Proposition 25.5), every passing run keeps them exactly (Theorem 25.52), and L moves on the intersection of the sphere $C = \text{const}$ with the ellipsoid $E = \text{const}$. Here is the stability argument in a small case. Take $J = (1, 2, 3)$, so that axis 0 has the largest moment, and start at $L = (1, \frac{1}{10}, \frac{1}{10})$. The combination $2E - J_0 C$ removes L_0:

$$2E - J_0 C = (J_1 - J_0)L_1^2 + (J_2 - J_0)L_2^2 = L_1^2 + 2L_2^2,$$

and its value $\frac{3}{100}$ is kept along the motion. So $L_1^2 + L_2^2 \le \frac{3}{100}$ at every time: the part of L transverse to axis 0, of length $\sqrt{2}/10$ at the start, never exceeds $\sqrt{3}/10$. The argument uses only that $J_1 - J_0$ and $J_2 - J_0$ are positive.

Theorem 25.62 (Rotation about an extreme axis is stable, with an explicit bound)**.** *Let s and s' be states of Euler's field with the same moments, the same energy and the same Casimir. Write J_k and L_k for the coordinates of s, L'_k for those of s', and put $\alpha = J_1 - J_0$, $\beta = J_2 - J_0$.*

(a) At every state and for each k, $2E - J_k C = (J_{k+1} - J_k)L_{k+1}^2 + (J_{k+2} - J_k)L_{k+2}^2$.

(b) If $J_0 < J_1$ and $J_0 < J_2$, then

$$\min(\alpha, \beta)\,(L_1'^2 + L_2'^2) \le \max(\alpha, \beta)\,(L_1^2 + L_2^2),$$

and $L_1'^2 + L_2'^2 \le \varepsilon$ for every ε with $\max(\alpha, \beta)(L_1^2 + L_2^2) \le \min(\alpha, \beta)\,\varepsilon$.

(c) If $J_1 < J_0$ and $J_2 < J_0$, then $L_1'^2 + L_2'^2 \le \varepsilon$ for every ε with

$$\max(J_0 - J_1, J_0 - J_2)\,(L_1^2 + L_2^2) \le \min(J_0 - J_1, J_0 - J_2)\,\varepsilon.$$

(d) With no order among the moments assumed, the first inequality of (b) holds between $X(t)$ and $X(0)$ for every motion X of Euler's field on $[0, 1]$ and every $t \in [0, 1]$, with α and β read at $X(0)$; between the polynomial solution of every passing run of Euler's field and its initial point; and, for every passing run at x_0, between $S(x)$ and x for every point x within $2^{-\rho}$ of x_0 in each coordinate, for some natural number ρ and a map S that agrees with the polynomial solution at every ratio point of that cube whose run passes.

No omniscience principle and no choice principle is used.

Proof. (a) $2E - J_k C = \sum_i (J_i - J_k)L_i^2$, and the term $i = k$ vanishes.

(b) By (a), $Q = \alpha L_1^2 + \beta L_2^2$ equals $2E - J_0 C$, so it has the same value at s and at s'. Put $\underline{m} = \min(\alpha, \beta)$ and $\overline{m} = \max(\alpha, \beta)$, which exist on the line with no choice (Proposition 12.19). Since $\alpha - \underline{m}$, $\beta - \underline{m}$, $\overline{m} - \alpha$, $\overline{m} - \beta$ and all squares are nonnegative, and products of nonnegative points are nonnegative,

$$\underline{m}\,(L_1'^2 + L_2'^2) \le Q(s') = Q(s) \le \overline{m}\,(L_1^2 + L_2^2).$$

This uses no order among the moments. When $\alpha > 0$ and $\beta > 0$ are witnessed, so is $\underline{m} > 0$, and $\underline{m}$ is invertible (Proposition 12.19); multiplying $\underline{m}(L_1'^2 + L_2'^2) \le \overline{m}(L_1^2 + L_2^2) \le \underline{m}\,\varepsilon$ by its inverse gives $L_1'^2 + L_2'^2 \le \varepsilon$.

(c) The same argument applied to $J_0 C - 2E = (J_0 - J_1)L_1^2 + (J_0 - J_2)L_2^2$.

(d) Along a motion on $[0, 1]$ the moments, E and C are constant (Theorem 25.61 and Proposition 25.5), and the displayed inequality of (b), whose proof used no order, applies to $s = X(0)$ and $s' = X(t)$. For a passing run, Theorem 25.52 keeps E, C and each J_k exactly at the polynomial solution. For measured states, take ρ and S from Theorem 25.55(b); its proof shows that every ratio point of the cube has a passing run. At such a point y, $S(y)$ is the polynomial solution and keeps every first integral F by Theorem 25.52. A point x of the cube is the limit of ratio points y_n of the cube, S is Lipschitz and F is a polynomial, so $F(S(x)) = \lim F(S(y_n)) = \lim F(y_n) = F(x)$, and the inequality holds between $S(x)$ and x. □

Conditions and scope.

Base and premises
Euler's field on $\mathbb{R}^6_\delta$; two states on the same level sets of the moments, the energy and the Casimir; for the bound, the strict inequalities $J_0 < J_1$ and $J_0 < J_2$ given with their witnesses.

Conclusion
Rotation about the axis of largest moment, and likewise about the axis of smallest, is stable with an explicit modulus: a transverse part with $L_1^2 + L_2^2 \le \varepsilon \min(\alpha, \beta)/\max(\alpha, \beta)$ at the start stays at most ε, along every motion, at every certified end state and for measured initial states.

Identification
L is a free body's angular momentum in its principal frame and J_k its inverse principal moments; three dimensions are those Recognition Science derives from its premise that a kept pair of records is a linked closed curve (Section 25.8). The moments are calibrations.

Not claimed
That axis 0 of a given body is its axis of largest moment: deciding that for all bodies costs LPO (Theorem 25.63).

The hypothesis of (b) is a decision about three points of the line: since $J_k = 1/I_k$, it says that axis 0 is the axis of largest moment. For a body whose moments are ratios it is integer arithmetic. For moments that are general points it is not free, and the price is exact.

Theorem 25.63 (Deciding the axis of largest moment costs exactly LPO)**.** *The statement "for all $J_0, J_1, J_2 \in \mathbb{R}_\delta$, either $J_0 < J_1$ and $J_0 < J_2$, or not" is equivalent to LPO. No choice principle is used.*

Proof. Assume LPO. By Corollary 12.18 every point x satisfies $x > 0 \vee x = 0 \vee x < 0$. Applied to $J_1 - J_0$ this decides $J_0 < J_1$, since the last two cases refute it; likewise $J_0 < J_2$, and a conjunction of two decided statements is decided.

Conversely, take $J_1 = J_2 = 0$. The statement then decides $J_0 < 0$ for every point J_0, so with $J_0 = -z$ it decides $z > 0$ for every z. Given a binary sequence α, let z be the point of its positive jump presentation (Chapter 12). If $z > 0$, a stage of the presentation exceeds its tolerance, and the bounded search at that stage finds an n with $\alpha(n) = 1$, as in the proof of Theorem 12.7. If not $z > 0$, then $z \le 0$; every numerator of the presentation is nonnegative, so $z \ge 0$, hence $z = 0$, and Lemma 12.5 makes every $\alpha(k)$ zero. This is LPO. The values can be taken positive, as the inverse moments of a body are: the point z of a jump presentation satisfies $0 \le z \le 1$, so $J_1 = J_2 = 2$ and $J_0 = 2 - z$ are all positive, and $J_0 < J_1$ exactly when $z > 0$. So deciding, for all bodies, whether axis 0 is the axis of largest moment already gives LPO. □

The middle axis behaves differently, and the difference is visible in the energy–Casimir form of axis 1: $2E - J_1 C = (J_2 - J_1)L_2^2 + (J_0 - J_1)L_0^2$ has one coefficient of each sign when $J_2 < J_1 < J_0$, so its level set through the axis is not a small closed curve but a pair of crossing curves. For $J = (3, 2, 1)$, the states $(0, \sqrt{2}, 0)$ and $(1, 0, 1)$ both have $C = 2$ and $2E = 4$: one turns exactly about the middle axis, the other is perpendicular to it, and the integrals cannot tell them apart.

Theorem 25.64 (Chetaev: rotation about the middle axis is unstable). *Let $J_0, J_1, J_2 \in \mathbb{R}_\delta$ with $J_2 < J_1 < J_0$, so that axis 1 has the middle moment.*

(a) For every $K \in \mathbb{R}_\delta$ there are states s and s' with moments J_0, J_1, J_2, the same energy and the same Casimir, such that $K(L_0^2 + L_2^2) < L_0'^2 + L_2'^2$. So no bound $L_0'^2 + L_2'^2 \le K(L_0^2 + L_2^2)$ holds on the level sets of the integrals.

(b) Let X be a motion of Euler's field on $[0,1]$ whose moments at time 0 are J_0, J_1, J_2, let $W(t) = -L_0(t)L_2(t)$, and let $\mu \ge 0$ with $\mu^2 \le (J_0 - J_1)(J_1 - J_2)$ and $\ell_1 \ge 0$. If $L_1(t) \ge \ell_1$ for every $t \in [0,1]$, then

$$2W(0)\,(1 + 2\mu\ell_1 h)^n \le C\big(X(0)\big)$$

for every $h \ge 0$ and every natural number n with $nh \le 1$. Consequently, if $C(X(0)) < 2W(0)(1 + 2\mu\ell_1 h)^n$ for one such h and n, then it is not the case that $L_1(t) \ge \ell_1$ for every $t \in [0,1]$.

No omniscience principle and no choice principle is used.

Proof. (a) The points $J_0 - J_2$, $J_1 - J_2$ and $J_0 - J_1$ are positive, so they have square roots with no choice (Proposition 12.19). Let s have $L = (0, \sqrt{J_0 - J_2}, 0)$ and s' have $L' = (\sqrt{J_1 - J_2}, 0, \sqrt{J_0 - J_1})$, both with moments J_0, J_1, J_2. Both have $C = J_0 - J_2$, and

$$2E(s') = J_0(J_1 - J_2) + J_2(J_0 - J_1) = J_1(J_0 - J_2) = 2E(s).$$

At s, $K(L_0^2 + L_2^2) = 0$, while $L_0'^2 + L_2'^2 = J_0 - J_2 > 0$.

(b) Suppose $L_1(t) \ge \ell_1$ on $[0,1]$. The moments are constant along X. With $a = J_0 - J_1 > 0$ and $b = J_1 - J_2 > 0$, Lemma 25.4(b) gives W the uniform derivative

$$\dot W = -(\dot L_0 L_2 + L_0 \dot L_2) = L_1\big(bL_2^2 + aL_0^2\big)$$

on $[0,1]$. Completing the square,

$$a\big(bL_2^2 + aL_0^2 + 2\mu L_0 L_2\big) = (aL_0 + \mu L_2)^2 + (ab - \mu^2)L_2^2 \ge 0,$$

and $a > 0$, so $bL_2^2 + aL_0^2 \ge 2\mu W$. With $L_1 \ge \ell_1 \ge 0$ and $bL_2^2 + aL_0^2 \ge 0$ this gives, on $[0,1]$,

$$\dot W \ge 0 \qquad \text{and} \qquad \dot W \ge \ell_1\big(bL_2^2 + aL_0^2\big) \ge 2\mu\ell_1 W.$$

A function f whose uniform derivative is at least γ on $[s,t]$ satisfies $f(t) - f(s) \ge \gamma(t-s)$: divide $[s,t]$ into steps within the modulus at tolerance k, so that each step gains at least $(\gamma - \frac{1}{k+1})$ times its length, and let k grow. With $\gamma = 0$, W is nondecreasing on $[0,1]$. On $[s, s+h]$ the derivative is then at least $2\mu\ell_1 W(s)$, since $2\mu\ell_1 \ge 0$, so $W(s+h) \ge W(s)(1 + 2\mu\ell_1 h)$. Induction, multiplying by the positive factor $1 + 2\mu\ell_1 h$ at each step, gives $W(nh) \ge W(0)(1 + 2\mu\ell_1 h)^n$ whenever $nh \le 1$. Finally $2W = -2L_0L_2 \le L_0^2 + L_2^2 \le C$, because $(L_0 + L_2)^2 \ge 0$, and C is constant along X. So $2W(0)(1 + 2\mu\ell_1 h)^n \le 2W(nh) \le C(X(nh)) = C(X(0))$. Under the strict inequality of the last sentence, the assumption would give $C(X(0)) < C(X(0))$. □

The best choice is $\mu = \sqrt{(J_0 - J_1)(J_1 - J_2)}$, which the line supplies with no choice. As $h = t/n$ shrinks, $(1 + 2\mu\ell_1 t/n)^n$ increases to $e^{2\mu\ell_1 t}$, so while $L_1 \geq \ell_1$ the product W grows at least like $e^{2\lambda t}$ with $\lambda = \ell_1\sqrt{(J_0 - J_1)(J_1 - J_2)}$, the growth rate of the classical linearization about steady rotation with $L_1 = \ell_1$. A state near the middle axis with $W(0) > 0$ must therefore leave the region $L_1 \geq \ell_1$ within a time of about $(2\lambda)^{-1}\log\bigl(C/2W(0)\bigr)$. The window $[0, 1]$ loses nothing: Euler's field is homogeneous of degree two in L, so $t \mapsto (cL(ct), J)$ is a motion on $[0, 1]$ whenever (L, J) is one on $[0, c]$. The escape is not only forced; it can be written down.

Proposition 25.65 (The separatrix leaves the middle axis at the rate λ)**.** *Let $u, v, h, r, J_1, \tau \in \mathbb{R}_\delta$ with $h^2 = u^2 + v^2$, put $\lambda = uvhr$ and $\phi(t) = \lambda(t - \tau)$, and write $\operatorname{sech} z = 2/(e^z + e^{-z})$ and $\tanh z = (e^z - e^{-z})/(e^z + e^{-z})$. The curve with moments $(J_1 + v^2, J_1, J_1 - u^2)$ and*

$$L(t) = \bigl(-ur\operatorname{sech}\phi(t),\ -hr\tanh\phi(t),\ vr\operatorname{sech}\phi(t)\bigr)$$

is a motion of Euler's field on $[0, 1]$. Along it $C = h^2r^2$ at every time; at time 0, $L_0^2 + L_2^2 \leq h^2r^2\,(2e^{-\lambda\tau})^2$; at time τ the state is $L = (-ur, 0, vr)$ with the same moments; and

$$\lambda^2 = (J_0 - J_1)(J_1 - J_2)\,C.$$

No omniscience principle and no choice principle is used.

Proof. For every z, $e^z + e^{-z} - 2 = (e^{z/2} - e^{-z/2})^2 \geq 0$, so the denominator is apart from 0 and has an inverse with no choice (Proposition 12.19); the exponential is free (Proposition 12.88). By the chain and quotient rules, $S = \operatorname{sech}\phi$ and $T = \tanh\phi$ have the uniform derivatives $-\lambda ST$ and λS^2 on $[0, 1]$, and $S^2 + T^2 = 1$ is algebra. The moments give $J_0 - J_1 = v^2$, $J_1 - J_2 = u^2$ and $J_0 - J_2 = h^2$, and

$$\begin{aligned}
\dot L_0 &= ur\lambda ST = u^2vhr^2ST = (-u^2)(-hrT)(vrS) = (J_2 - J_1)L_1L_2,\\
\dot L_1 &= -hr\lambda S^2 = -uvh^2r^2S^2 = h^2(vrS)(-urS) = (J_0 - J_2)L_2L_0,\\
\dot L_2 &= -vr\lambda ST = -uv^2hr^2ST = (-v^2)(-urS)(-hrT) = (J_1 - J_0)L_0L_1.
\end{aligned}$$

Further $C = (u^2 + v^2)r^2S^2 + h^2r^2T^2 = h^2r^2$. At $t = 0$, $\phi = -\lambda\tau$, and sech is even with $0 < \operatorname{sech} z \leq 2e^{-z}$, because $e^z + e^{-z} \geq e^z$; so $L_0^2 + L_2^2 = h^2r^2\operatorname{sech}^2(\lambda\tau) \leq h^2r^2(2e^{-\lambda\tau})^2$. At $t = \tau$, $S = 1$ and $T = 0$. Finally $\lambda^2 = u^2v^2 \cdot h^2r^2 = (J_1 - J_2)(J_0 - J_1)\,C$. □

For $u, v, r > 0$ and $0 \leq \tau \leq 1$ the body starts with its angular momentum within relative distance $2e^{-\lambda\tau}$ of the middle axis, in the sense $\sqrt{L_0^2 + L_2^2} \leq 2e^{-\lambda\tau}\sqrt{C}$, and at time τ it has turned fully across it, $L_1 = 0$. The rate λ is the one of Theorem 25.64 with $\ell_1 = \sqrt{C}$. The time to flip grows only like the logarithm of the initial distance: this is the tumbling of a tennis racket or a wing nut thrown about its middle axis [151].

When two moments are equal the body is a symmetric top, and the motion is a uniform turning.

Proposition 25.66 (The free symmetric top precesses)**.** *Let $A, B, c, j, \kappa \in \mathbb{R}_\delta$ and $\Omega = (\kappa - j)c$. The curve with moments (j, j, κ) and*

$$L(t) = \big(A\cos\Omega t + B\sin\Omega t,\ B\cos\Omega t - A\sin\Omega t,\ c\big)$$

is a motion of Euler's field on $[0,1]$. No omniscience principle and no choice principle is used.

Proof. With $J_0 = J_1 = j$ and $J_2 = \kappa$ the field reads $\dot L_0 = (\kappa - j)L_1L_2$, $\dot L_1 = (j - \kappa)L_2L_0$, $\dot L_2 = 0$; at $L_2 = c$ these are $\dot L_0 = \Omega L_1$ and $\dot L_1 = -\Omega L_0$, which the curve satisfies because the derivatives of cos and sin are $-$ sin and cos. What needs checking on $\mathbb{R}_\delta$ is a uniform derivative at every speed Ω, with one modulus on $[0,1]$. For $|y - x| \le 1$ the addition formulas of Section 21.2 give, with $h = y - x$,

$$\cos y - \cos x + h\sin x = \cos x(\cos h - 1) - \sin x(\sin h - h),$$

and the alternating series give $|\cos h - 1| \le h^2/2$ and $|\sin h - h| \le |h|^3/6$; with $|\cos x|, |\sin x| \le 1$ the right side is at most h^2. The same holds for $\sin y - \sin x - h\cos x = \sin x(\cos h - 1) + \cos x(\sin h - h)$. Hence $|g(\Omega t) - g(\Omega s) - \Omega g'(\Omega s)(t - s)| \le \Omega^2(t - s)^2$ whenever $|\Omega(t - s)| \le 1$, for $g = \cos$ and $g = \sin$, which is a uniform derivative with an explicit modulus; sums and constant multiples keep it. □

In the body frame the angular momentum of a free symmetric top turns about the symmetry axis at the constant rate $\Omega = (1/I_2 - 1/I_0)L_2$, on a circle of the sphere $C = A^2 + B^2 + c^2$. The reading is again an identification.

Last, the certificate of Section 25.9 applies to the rigid body as a whole.

Corollary 25.67 (The rigid body's conversion certificate)**.** *The polynomial theory with Euler's field, the candidate integrals E and C and no sign laws satisfies the five clauses of Theorem 25.59, and both candidates are first integrals. Clauses (1), (2), (4) and (5) are proved with no omniscience principle and no choice principle; clause (3), and with it the corollary as stated, is proved in classical mathematics.*

Proof. Theorem 25.59 applies to every polynomial theory, and Theorem 25.61 shows that both candidates are first integrals. Clause (4) has no laws to price. □

So a certified simulation of a tumbling body cannot drift off its level sets: its energy and its $|L|^2$ are exactly those of the initial state at every certified time, and by Theorem 25.62(d) its transverse part obeys the stability bound there too.

25.11 Pulsar timing in far time

A binary pulsar is timed, not watched. The pulsar is a clock riding the orbit; it ticks in its own proper time τ. A timer far away reads the time t_c of a distant observer, and from the arrival times fits three things: the rate at which the pericentre turns per unit of far time, the delay of the pulsar's clock against its mean rate inside each period, and how these two are related. Section 25.7 proved that every window orbit returns after a radial period T of proper time, that its pericentre turns by $\Phi - 2\pi_\delta$, and that the far clock advances by the same T_c in every

period (Theorem 25.47). Here we turn those statements into the three observables. Each is proved on $\mathbb{R}_\delta$ with no omniscience principle and no choice principle, for every ratio Λ; as in Definition 25.38, Λ is the squared angular momentum per unit mass, L^2, entering the field as a coefficient, not a cosmological term.

Fix a window orbit y of G_Λ. A *timing frame* of y consists of a radial period (θ, T, Φ); a time t_1 with $(x\cdot v)(t_1)=0$ such that $\big(2u(t)-(u_0+u_1)\big)^2 \le (u_0-u_1)^2$ for every t, where $u_0=u(0)$ and $u_1=u(t_1)$; the eccentricity e and the ratio $w=m/p$ read off the apsides, $e(u_0+u_1)=u_0-u_1$ and $2w=m(u_0+u_1)$; a point $E_\infty\ge 0$ with $E_\infty^2=1+2H_\Lambda(y(0))$; and a far clock t_c with $t_c(0)=0$, derivative $D(\tau)$ at every τ with $D(\tau)\big(1-2m\,u(\tau)\big)=E_\infty$, and a point T_c with $t_c(\tau+T)=t_c(\tau)+T_c$ for every τ. The *Einstein delay* is $\Delta(\tau)=t_c(\tau)-(T_c/T)\,\tau$: the far clock minus its mean rate. The *Kepler radius* a_K is read off the apsides by $2a_Ku_0u_1=u_0+u_1$.

Theorem 25.68 (The advance as a rate, the Einstein delay, and a mass-free identity)**.** *Let Λ be a ratio and y a window orbit. Then y has a timing frame, and:*

(a) The advance as a rate. *With $K=(6\pi_\delta)^3(2\pi_\delta)^2m^2$,*

$$K\Big(1+\big(\tfrac{39}{2}-\tfrac{21}{4}e^2\big)w\Big)\ \le\ T_c^2\big((\Phi-2\pi_\delta)(1-e^2)\big)^3\ \le\ K\Big(1+\big(\tfrac{39}{2}-\tfrac{21}{4}e^2\big)w+300\,w^2\Big).$$

(b) The Einstein delay. *With $k\ge 0$, $k^2=u_0u_1$ and $\lambda=am$, for every proper time τ*

$$\big|kL\big(Tt_c(\tau)-T_c\,\tau-2T(x\cdot v)(\tau)\big)\big|\ \le\ 20\,m\,|e|\,\lambda\,|T|,$$

that is, $|\Delta(\tau)-2(x\cdot v)(\tau)|\le 20|e|\lambda m/(|L|k)$.

(c) The timing identity. *At every proper time τ at which $u(\tau)a_K=1$,*

$$2|e|(1-e^2)(\Phi-2\pi_\delta)\,TT_c\,(1-3w)\ \le\ 3(2\pi_\delta)^2\big|Tt_c(\tau)-T_c\,\tau\big|\ \le\ 2|e|(1-e^2)(\Phi-2\pi_\delta)\,TT_c\,(1-2w),$$

that is, $3(2\pi_\delta)^2|\Delta| = 2|e|(1-e^2)(\Phi-2\pi_\delta)T_c(1+R)$ with $-3w\le R\le -2w$.

No omniscience principle and no choice principle is used.

Conditions and scope.

Base and premises

Motions of the polynomial field G_Λ in the weak-field window of Definition 25.38, for every ratio Λ, on $\mathbb{R}_\delta$. Free.

Conclusion

(a) is the binary-pulsar law $\dot\omega(1-e^2)=3\,n^{5/3}m^{2/3}\big(1+(\tfrac{13}{2}-\tfrac{7}{4}e^2)\tfrac{m}{p}\big)$, with $\dot\omega=(\Phi-2\pi_\delta)/T_c$ and $n=2\pi_\delta/T_c$, in the test-mass limit, cubed so that no fractional power appears, with its first relativistic correction exact and a proved remainder. (b) says that the clock part of the timing record is a polynomial in the orbit's state, $2\,x\cdot v=2r\,dr/d\tau$, up to a remainder proportional to e; it vanishes on circular orbits. (c) ties the clock record to the advance with no mass in it; its leading 3 is the post-Newtonian combination $2+2\gamma-\beta$.

Identification

A timelike Schwarzschild geodesic as a motion of G_Λ, E_∞ as its Killing energy and t_c as the static observer's time at infinity (Section 25.7); the pulsar's proper time as its clock.

Not claimed

Light-travel delays (Roemer and Shapiro), the companion's mass, and any timing data.

Proof. All three parts start from one construction on one orbit. As in Proposition 25.41, write the orbit in its clock angle ψ: $u = U_c + A_t \cos\psi$, $L\,d\tau = (h/U^2)\,d\psi$, with the radial period $T = L^{-1}\sigma(4q)$ and the far clock $t_c = E_\infty \sigma_c(\psi)/L$, $T_c = E_\infty \sigma_c(4q)/L$ (Theorem 25.47); $p = 1/U_c$, $e = A_t/U_c$ and $w = x = mU_c$.

(a) Theorem 25.42 gives $6\pi_\delta w + \frac{3\pi_\delta}{2}(18+e^2)w^2 \le \Phi - 2\pi_\delta \le \text{that} + 160\pi_\delta w^3$, and Theorem 25.47 gives $(2\pi_\delta)^2 m^2(1+3Z) \le T_c^2 Z^3 \le (2\pi_\delta)^2 m^2(1+3Z+20\lambda^2)$, with $Z = -2H$. The conserved quantities satisfy $\lambda = x(1-(3+e^2)x)$ and $Z\lambda = x^2(1-e^2)(1-4x)$. Multiplying each target bound by $8(Z\lambda)^3$ and cancelling with explicit inverses leaves two polynomial inequalities $x^2 q(x, e^2) \ge 0$ on the window $x \le \frac{1}{250}$, $e^2 \le \frac{9}{25}$, which exact Bernstein certificates close (degrees $(5,6)$ and $(8,6)$, with nonnegative rational coefficients over 3^{12}). The second-order margin of the lower inequality is at least 127.5, and the upper one stays at least 25.4 below the allowed 300.

(b) With $\tau = L^{-1}\sigma(\psi)$, $T t_c - T_c \tau = L^{-2} E_\infty W(\psi)$ for the Wronskian of the two clocks

$$W(s) = \sigma(4q)\big(\sigma_c - \sigma\big)(s) - \big(\sigma_c - \sigma\big)(4q)\,\sigma(s),$$

which has period $4q$ exactly; and $T t_c - T_c \tau - 2T(x \cdot \nu) = L^{-2} F(\psi)$ with F explicit. In the Wronskian the secular parts of the two clocks cancel identically, which a bound on the mean rate T_c/T alone could not achieve, since its remainder is not proportional to e. By periodicity, extended constructively by cotransitivity and induction, it suffices to bound kF for $|\psi| \le 3q$. There the clock integrals are exact through the eccentric anomaly, $\int d\psi/U = \text{ecc}/k$, $\int d\psi/U^2 = (U_c\,\text{ecc} - A_t \sin\text{ecc})/k^3$, with second-order expansions of $(1 - r\cos\psi)^{-1/2}$ and $1/(1-2mU)$ and explicit third-order remainders. The one transcendental function left, the true minus the eccentric anomaly, is bounded by its three-term series $2\beta\sin\psi - \beta^2 \sin 2\psi + \frac{2}{3}\beta^3 \sin 3\psi$, $\beta = e/(1+\sqrt{1-e^2})$, through an exact identity and the bounds $|T_3|, |T_4| \le 1$ on Chebyshev polynomials. The coefficients are then bounded by exact certificates; at the edge of the window the normalized bound is 18.5 against the allowed 19.9.

(c) At a crossing $u\,a_K = 1$ the eccentric anomaly is a quarter turn: $A_t \cos(\text{ecc}\,\psi) = 0$, so $|\sin(\psi - \text{ecc}\,\psi)| = |e|$ with no case split on e. The angle $A = |\psi - \text{ecc}\,\psi|$ lies between $|e|$ and $|e| + |e|^3/6 + |e|^5/8$, by the sine bounds and the anomaly bound of (b). Inserting this into the Wronskian of (b), with the bounds of (a) on $\Phi - 2\pi_\delta$ and on the two periods, leaves after clearing $(1-6x)^5(1-2x)^2$ two polynomial inequalities in x and $k/U_c \in [\frac{17}{20}, 1]$, closed by exact certificates; the upper margin at the worst corner $x = \frac{1}{250}$ is 0.13 w in R. □

25.12 The point mass from the lattice's own field equations

The relativistic coefficient $b = 3m$ of this chapter, that is $\beta = \gamma = 1$, rests on the cubic vertex of the gravitational action being Einstein–Hilbert's. Chapter 27 proves this for Regge's action on the Kuhn lattice in classical mathematics (Theorem 27.61). This section proves it on $\mathbb{R}_\delta$ at the Lorentzian background $\kappa = 1$, with no omniscience principle and no choice principle, and goes further: a long-wave solution of the lattice's own field equations whose jets at a point are those of a point mass has $\gamma = 1$, $\beta = 1$ and $\chi_2 = 1$, and at the next order the jet equations built from the quartic cell form give the third-order coefficient its Schwarzschild value.

Use the periodic $\kappa = 1$ Kuhn lattice of side N, the flat field ℓ, and δ's own Regge action S, flat Hessian $\mathscr{H}$ and cubic cell form C of Section 27.7. For integer wave vectors m_0, m_1 and $m_2 = -m_0 - m_1$ and symmetric H_0, H_1, H_2, let $C_N(H; m)$ be the cubic form of S on the three plane waves u_{m_i, H_i} (Theorem 27.30), and let

$$V_{\mathrm{EH}}(H; m_0, m_1) = \sqrt{3}\, W_3\big(g_1^{-1}; H_0, H_1, H_2; m_0, m_1, m_2\big),$$

with W_3 Einstein's cubic vertex of Definition 27.58 at the integer momenta m_i. By Theorem 27.60 this is the cubic vertex of the Einstein–Hilbert density $\sqrt{-\det g}\, R$ around g_1, since $\sqrt{|\det g_1|} = \sqrt{3}$. It is $\sqrt{3}$ times a polynomial with rational coefficients in the entries of the H_i and m_0, m_1.

Theorem 25.69 (Regge's cubic vertex is Einstein–Hilbert's on $\mathbb{R}_\delta$)**.** *On $\mathbb{R}_\delta$, free: for all integer m_0, m_1 and symmetric H_0, H_1, H_2 over $\mathbb{R}_\delta$ there is a constant B such that for every side N such that each of $2m_0$, $2m_1$ and $2m_2$ has a component that N does not divide,*

$$\Big| N^{-2} C_N(H; m) - \tfrac{\pi_\delta^2}{2}\, V_{\mathrm{EH}}(H; m_0, m_1) \Big| \le B\, N^{-2}.$$

The order-zero part of the cubic cell form vanishes on all constant strains, over every commutative ring.

Proof. On the torus the cubic form of three plane waves is N^4 times a cell symbol, a finite sum over the 24 simplices of the integer cubic table of $1152\sqrt{3}\, C$ with cosine phases, as in Theorem 27.30(c); the condition on N removes the aliased frequencies. Expanding the cosines to second order with the remainder bounds of δ's cosine, the order-zero part vanishes (an identity over every commutative ring), the order-one part vanishes by the central inversion, and the order-two part satisfies the integer polynomial identity $3S_2 + 64\, C_{\mathrm{EH}} = 0$, where S_2 is the second-order symbol and $C_{\mathrm{EH}} = 8\, W_3(3g_1^{-1}) = 648\, W_3(g_1^{-1})$ is eight times Einstein's cubic vertex on $3g_1^{-1} = 3 \cdot 1 - \mathbf{1}\mathbf{1}^{\mathsf{T}}$ (W_3 is homogeneous of degree four in the inverse metric), so that $V_{\mathrm{EH}} = \sqrt{3}\, C_{\mathrm{EH}}/648$; this identity is checked coefficient by coefficient. The remainder is bounded by the fourth-order cosine bound, which gives B. □

To pass from vertices to solutions we need what it means for a smooth field to solve the lattice's equations at long wavelength. A *δ-native C^3 jet field* near a point x_0 assigns to each point a symmetric matrix with first and second derivatives, all bounded by a constant K on a ball of radius r, each Lipschitz with constant K, and with second-order Taylor remainder

at most $K|y-z|^3$. Sample such a field h on the edges of the side-N lattice at edge midpoints, $s(e) = d_e^{\mathsf{T}} h(x_e) d_e$. For a symmetric test tensor W and a box of lattice cells around a rational point x_0, the *weak sums* of order one and two are $\mathscr{H}(s_1, t_{\mathrm{box}})$ and $\mathscr{H}(s_2, t_{\mathrm{box}}) + \frac{1}{2}C(s_1, s_1, t_{\mathrm{box}})$, with t_{box} the box test field of W. Let $x_0 = p/q$. A pair (h_1, h_2) is a *long-wave solution* at x_0 when there is a radius $\rho_0 > 0$, with the box of half-width ρ_0 around x_0 inside the unit torus and $8\rho_0$ at most the radius r of the jet bounds, such that for every box of lattice cells of half-width $\rho = 1/(j+1) \le \rho_0$ centred at x_0, every symmetric W and every rational tolerance $\varepsilon > 0$, both weak sums on that box are at most εN^2 on all lattices of large enough side N among the multiples of $q(j+1)$. The box is fixed before the tolerance: on each fixed box the weak sums are $o(N^2)$. The *jet equations* of order one and two at x_0 are the edge-local long-wave equations of $\mathscr{H}$ and of $\mathscr{H} + \frac{1}{2}C$ on the jets of h_1 and (h_1, h_2) at x_0. The *isotropic point-mass jets* with mass m are $h_1 = 2mU(\mathrm{tt} + \gamma S)$ and $h_2 = m^2U^2(\alpha\,\mathrm{tt} + \beta_2 S)$ and, at third order, $h_3 = m^3U^3(\zeta\,\mathrm{tt} + \xi S)$, with tt the time-time strain, S the spatial identity and U the potential, taken at a point x_0 of the lattice's chart. In the notation of (25.7), $\alpha = -2\beta_{\mathrm{PN}}$, $\beta_2 = \frac{3}{2}\chi_2$ and $\zeta = \frac{3}{2}\chi_3$.

Theorem 25.70 (Long-wave solutions with point-mass jets have $\gamma = \beta = \chi_2 = 1$)**.** *On $\mathbb{R}_\delta$, free, at the background $\kappa = 1$:*

(a) at every field within $1/40000000$ of the flat field, cell by cell, and along every direction with entries in $[-1, 1]$, δ's Regge action has the first variation $\sum_t A_t'(\theta_t - \theta_t^{\mathrm{flat}})$ with a uniform quadratic modulus, and along $\ell + xw$ this first variation is $x\,\mathscr{H}(w, \cdot) + \frac{1}{2}x^2 C(w, w, \cdot)$ up to $O(N^4|x|^3)$; the weak sums are the coefficients of this first variation along the box test field;

(b) if (h_1, h_2) is a long-wave solution at a rational point x_0 of two δ-native C^3 jet fields, then the jets at x_0 satisfy the jet equations of order one and two, for every symmetric test tensor;

(c) if moreover those jets are the isotropic point-mass jets with $m \neq 0$, then $\gamma = 1$, $\alpha = -2$ and $\beta_2 = \frac{3}{2}$: the post-Newtonian γ and β, and the second-order spatial coefficient χ_2, are 1.

Conditions and scope.

Base and premises

δ's Regge action on the $\kappa = 1$ Kuhn lattice on $\mathbb{R}_\delta$; the hypothesis of (b), a long-wave solution in weak form with box test profiles. Free; the mass need only be not equal to zero, and no step inverts it, so Markov's principle is not used.

Conclusion

$\beta = \gamma = 1$, and with them $b = 3m$ and the first-order advance $6\pi_\delta m/p$, follow from the lattice's own equations, not from a clause about the action; so does $\chi_2 = 1$.

Not claimed

That an actual lattice solution of a mass is such a C^3 family solving the weak equations: the existence and regularity of the long-wave profile, open in classical mathematics too.

Identification

Regge's action on the $\kappa = 1$ lattice as the gravitational action, $\kappa = 1$ itself (Section 27.8), and the jets as those of a static point mass.

Proof. (a) Schläfli's identity (Theorem 27.32(b)) gives the first variation in Schläfli form at every nondegenerate field, and the moduli of Theorem 27.32(a) make the quadratic remainder uniform; expanding the angle differences to second order around the flat field gives $\mathscr{H}$ and $\frac{1}{2}C$, the cubic term by polarizing the per-hinge cubic identity. Evaluating at the sampled field $\ell + ms_1 + m^2 s_2$ along the box test field identifies the weak sums. (b) The argument is integral-free. Expand each edge's equation for a sampled field: the stencils of $\mathscr{H}$ and of C at $\kappa = 1$ have vanishing zero and first moments, integer identities checked exactly, so the equation at an edge is N^{-2} times an edge-local jet operator plus $O(N^{-3})$; the sum of these operators against the strains of W is exactly the jet operator of the jet equations. The box test sums reorganize, on the torus, by test edges; the N^4 interior edges carry the jet operator at nearby points, the boundary only $O(N)$ terms, and the non-metric part of an actual solution enters only on the boundary. Shrinking the boxes and using the Lipschitz bounds of the jets squeezes the jet equations at x_0 out of the $o(N^2)$ hypothesis. (c) The first-order jet equation with the test tensor $E_{01} + E_{10}$ forces $\gamma = 1$; the second-order equations with E_{00} and $E_{01} + E_{10}$ are two linear equations in α and β_2 with a nonzero determinant once $m \neq 0$, solved by $\alpha = -2$, $\beta_2 = \frac{3}{2}$; the Schwarzschild jets solve all of them. □

At third order the lattice's equation needs the quartic vertex. Its table is the quartic cell form of the $\kappa = 1$ lattice, which is $\sqrt{3}$ times the continued table $-T_4(1)$ of Chapter 27 (Proposition 27.63); that this cell form is the fourth derivative of δ's own Regge action on $\mathbb{R}_\delta$ rests on two named premises about its third-order rates of areas and angles, which are open. The *third-order jet equation* at x_0 with test tensor W is the edge-local equation $\mathscr{H}(s_3) + C(s_1, s_2) + \frac{1}{6}D(s_1, s_1, s_1) = 0$ on the jets, D the quartic cell form.

Theorem 25.71 (The third order at the jet level). *On $\mathbb{R}_\delta$, free, at the background $\kappa = 1$, with the isotropic point-mass jets and $m \neq 0$:*

(a) with the lower-order jets at $\gamma = 1$, $\alpha = -2$ and $\beta_2 = \frac{3}{2}$, the values Theorem 25.70(c) forces, the third-order jet equations with the test tensors E_{00} and $E_{01} + E_{10}$ hold exactly when $\zeta = \frac{3}{2}$ and $\xi = \frac{1}{2}$; so $\chi_3 = \frac{2}{3}\zeta = 1$, and the spatial U^3 coefficient is $\frac{1}{2}$, as in isotropic Schwarzschild, $(1 + U/2)^4$; the Schwarzschild jets solve both equations;

(b) every solution of the first-, second- and third-order jet equations with $m \neq 0$ has $4\varphi_2 = 54 + 3e^2$, where

$$4\varphi_2 = 40 + 48\gamma - 40\beta_{\mathrm{PN}} - 2\beta_{\mathrm{PN}}^2 - 24\beta_{\mathrm{PN}}\gamma + 8\gamma^2 + 15\chi_2 + 9\chi_3 + 3\chi_2 e^2$$

is the second-order perihelion coefficient in the coefficients read off the jets, $\beta_{\mathrm{PN}} = -\alpha/2$, $\chi_2 = \frac{2}{3}\beta_2$, $\chi_3 = \frac{2}{3}\zeta$; at $\beta_{\mathrm{PN}} = \gamma = 1$ it is four times the coefficient $\frac{15}{2} + \frac{15}{4}\chi_2 + \frac{9}{4}\chi_3 + \frac{3}{4}\chi_2 e^2$ of Proposition 25.49. So $\varphi_2 = \frac{27}{2} + \frac{3}{4}e^2$, the coefficient of Theorem 25.42: $\Phi - 2\pi_\delta = 2\pi_\delta(3w + \varphi_2 w^2)$ up to the third order.

Conditions and scope.

Base and premises

The jet equations of the $\kappa = 1$ lattice at one point, with the quartic cell form; free.

Conclusion

At the jet level the jet equations built from the quartic cell form give the Schwarzschild point mass through third order, and with it the whole second-order perihelion advance of Theorem 25.42, $27\pi_\delta(m/p)^2 + \frac{3}{2}\pi_\delta e^2(m/p)^2$.

Not claimed

The bridge of Theorem 25.70(b) at third order; and that the quartic cell form is the fourth derivative of δ's action, which rests on the two named premises on third-order rates.

Proof. On tensor-product jets the third-order operator has closed forms: the quadratic part on the U^3 jet, the mixed cubic part on the first- and second-order jets, and the quartic part with the integer quartic table of the cell form. With $\gamma = 1$, $\alpha = -2$ and $\beta_2 = \frac{3}{2}$ substituted, in units of $\sqrt{3}/3456$ the two components are $432\,m^3(6\zeta - 4\xi - 7)$ and $864\,m^3(-12\zeta + 14\xi + 11)$. With $m \neq 0$, so $m^3 \neq 0$, the two linear equations $6\zeta - 4\xi = 7$ and $12\zeta - 14\xi = 11$ have the unique solution $\zeta = \frac{3}{2}$, $\xi = \frac{1}{2}$. For (b), the first- and second-order jet equations alone give $\gamma = 1$, $\alpha = -2$ and $\beta_2 = \frac{3}{2}$, as in the proof of Theorem 25.70(c), and part (a) gives $\zeta = \frac{3}{2}$; substituting $\beta_{\mathrm{PN}} = \gamma = \chi_2 = \chi_3 = 1$ gives $30 + 15 + 9 + 3e^2$. □

So the chain from the lattice to the planet's orbit has one link left open at first and second order, the existence of the long-wave profile, and at third order two more, the bridge and the third-order rates. Everything else is a theorem on $\mathbb{R}_\delta$ at no price.

Questions to work through

1. (Theorem 25.9.) Take $m = 1$, $u = 1$, $x = (1, 0, 0)$ and $v = (0, \frac{1}{2}, \frac{1}{2})$. Compute E, L and A, check $|A|^2 = 2E|L|^2 + m^2$, and show that the body is at its aphelion. Find the perihelion distance, the eccentricity $|A|/m$, the semi-major axis and the period given by Kepler's third law.

2. (Theorem 25.54.) For the field $\dot{x}_0 = x_1$, $\dot{x}_1 = -x_0 + x_0^2$, show by the grid test that $F = x_0^2 + x_1^2$ is not a first integral, and name a grid point that witnesses it. Then show that $G = \frac{1}{2}x_1^2 + \frac{1}{2}x_0^2 - \frac{1}{3}x_0^3$ is one.

3. (Theorem 25.56.) For $\dot{x} = x^2$ from $x_0 = 3$, compute X, M, s and k. Up to which time does the theorem certify the solution, and how does that compare with the time $\frac{1}{3}$ at which $3/(1 - 3t)$ blows up? Why can no region certificate reach time $\frac{1}{3}$?

4. (Theorem 25.42.) Take as an identification that Mercury's orbit is a window orbit with $m/p = 2.66 \times 10^{-8}$ and $e = 0.206$, completing 415.2 revolutions per century. Compute the advance of its perihelion per century from the first-order term, in seconds of arc, and bound the contributions of the second-order term and of the remainder.

5. (Theorem 25.62.) For $J = (1, 3, 4)$ and $L(0) = (2, \frac{1}{5}, \frac{1}{5})$, give the bound the theorem places on $L_1^2 + L_2^2$ along the motion, and compare it with the exact range allowed by the energy–Casimir form. How small must $L_1^2 + L_2^2$ be at the start to keep it at most 10^{-2}? What goes wrong for $J = (2, 1, 3)$?

6. (Theorem 25.64 and Proposition 25.65.) For $J = (3, 2, 1)$ and $|L|^2 = 200$, find u, v, h, r and λ of the separatrix with $\tau = 1$. How close to the middle axis does it start, and where is it at time 1? Compare λ with the rate of Theorem 25.64(b).

Chapter 26

Fields, heat and the second law

A voxel of Recognition Science keeps three axis accounts. At each tick of its history it either holds or posts one unit to one side of one account, and over many ticks its imbalance spreads out and settles toward a fixed law. Does the voxel's relative cost ever rise under Recognition Science's own tick, and how fast does it fall?

Relative cost is a definite number. For a law p on finitely many configurations with every $p_i > 0$, and a distribution q, the *relative entropy* is

$$D(q \,\|\, p) = \sum_{q_i > 0} q_i \log \frac{q_i}{p_i}.$$

It is 0 at $q = p$ and positive at every other distribution. When p is the Gibbs law of costs c_i at temperature T, that is $p_i = e^{-c_i/T}/Z$, the free energy $F(q) = \sum_i q_i c_i - TS(q)$, with $S(q) = -\sum_i q_i \log q_i$, exceeds its least value by exactly $TD(q \,\|\, p)$ (Section 26.1). Recognition Science takes the costs to be values of the comparison cost J of Chapter 21 and reads this excess as the relative J-cost. A step of a Markov chain with transition matrix K moves q to qK.

Here is a small case. Take three configurations $0, 1, 2$ and the chain

$$K = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix} :$$

from 0 it holds or moves to 1 with equal chances, from 1 it moves to 2, and from 2 back to 0. The law $p = (\frac{1}{2}, \frac{1}{4}, \frac{1}{4})$ is stationary, since $pK = (\frac{1}{4} + \frac{1}{4}, \frac{1}{4}, \frac{1}{4}) = p$. Start from $q_0 = (\frac{2}{3}, 0, \frac{1}{3})$ and step:

tick t	q_t	$D(q_t \,\|\, p)$	value
0	$(\frac{2}{3}, 0, \frac{1}{3})$	$\log \frac{4}{3}$	0.2877
1	$(\frac{2}{3}, \frac{1}{3}, 0)$	$\log \frac{4}{3}$	0.2877
2	$(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$	$\frac{1}{3} \log \frac{2}{3} + \frac{2}{3} \log \frac{4}{3}$	0.0566
3	$(\frac{1}{2}, \frac{1}{6}, \frac{1}{3})$	$\frac{1}{6} \log \frac{2}{3} + \frac{1}{3} \log \frac{4}{3}$	0.0283
4	$(\frac{7}{12}, \frac{1}{4}, \frac{1}{6})$		0.0223

The relative entropy never rises. Yet the first tick produces nothing, although q_0 is not the stationary law and every entry of K^4 is positive. The numbers show why. Configuration 0 is entered from 0 and from 2, and q_0 puts the same multiple $\frac{4}{3}$ of p on both, so the step merges two configurations that it cannot tell apart, and loses nothing. At the second tick configuration 0 is entered from 0, with ratio $q_1(0)/p(0) = \frac{4}{3}$, and from 2, with ratio 0; the merge destroys information and the relative entropy falls by a factor of five.

This chapter answers the opening question by proving what the example suggests. Relative entropy never rises under a stochastic step that keeps p (Theorem 26.10). One step loses nothing exactly when it merges no two configurations with different ratios q_i/p_i (Theorem 26.11), so a strict fall at every tick fails even when some power of K is positive, and holds over every window N with K^N positive (Theorem 26.12). Recognition Science's tick exists and is unique (Theorem 26.21), and, walled into any finite set of states that is closed under inward posts, it lowers relative entropy strictly at every tick (Theorem 26.23). Its numbers on all of $\mathbb{Z}^3$ rest on five numerical properties of its entries, (T1)–(T5) of Section 26.4, which we state and do not prove. Given them, from a start a the tick keeps $D_n(a) \le \log\bigl(1 + 0.9922^{2n}(\varphi^{9+|a|_1} - 1)\bigr)$ after n ticks (Corollary 26.29); its exact pace per tick lies between 0.7726 and 0.98447 (Corollary 26.37); and a spine of k independent voxels settles sharply at $\log k/(-\log r)$ ticks, where r is that pace (Theorem 26.42). Two voxels that each move by Recognition Science's tick and are coupled by the ledger's double entry stay at least 6.247 nats from the law of two independent voxels at equilibrium, at every tick, and, given (T1) and (T2), settle to their own equilibrium at one voxel's pace (Proposition 26.43). The information between them approaches its limit at the square root of that pace, provided two statements about one voxel's walk hold that we name but do not prove (Proposition 26.44).

The chapter has three further subjects. Section 26.1 builds entropy, the Gibbs principle and the H-theorem on $\mathbb{R}_\delta$ and prices the decisions about them. Section 26.7 puts Maxwell's and Schrödinger's equations on a lattice with δ's numbers: an exact Maxwell flow, standing light with its dispersion error, a light cone for lattice propagators and a continuum limit with error of order h^2. Section 26.8 prices physical laws: sign and classification laws, linear laws of two quantities, laws on a half-line, and the lattice premises Recognition Science uses for an inverse-square field.

Table 26.1 records the scope of each part. A result is *free* when its proof uses no omniscience principle and no choice principle, and *proved in classical mathematics* when it is a theorem about the classical real numbers (Section 21.1); we say which before each statement. Every theorem about Recognition Science's tick is proved for every kernel of a stated class. The tick enters through a short list of its properties, which we state where they are used: its existence and uniqueness, proved here, and the five numerical inputs (T1)–(T5), which are not. Every number we give for the tick itself is conditional on the inputs it names.

26.1 Entropy and the Gibbs principle on the line

Thermodynamics needs $-x\log x$ at $x \ge 0$. On $\mathbb{R}_\delta$ the case definition "$-x\log x$ if $x > 0$, and 0 if $x = 0$" is not a map: deciding $x = 0 \vee x > 0$ for every $x \ge 0$ is LPO. Applied to $|x|$ it gives $x > 0 \vee x = 0 \vee x < 0$ for every point, which is LPO by Corollary 12.18, and LPO gives it back; even the weaker $x = 0 \vee x \ne 0$ costs WLPO. We build the function instead, then use it for the Gibbs principle and the H-theorem. The logarithm is that of Definition 21.4. From Section 21.2 we use that every positive point y is $e^{\log y}$, and three order facts of the exponential, free for all points a, b, u:

$$1 + u \le e^u, \qquad e^b(a - b) \le e^a - e^b, \qquad a < b \text{ exactly when } e^a < e^b. \tag{26.1}$$

The second is the *tangent bound*. A function F on $\mathbb{R}_\delta$ is *continuous at* x when for every k there is a j with $|F(y) - F(x)| \le 1/(k+1)$ whenever $|y - x| \le 1/(j+1)$, and *continuous* when it is

Table 26.1. What each part of the chapter proves, and in which setting.

Section	Content	Setting
26.1 Heat on the line	entropy function, Gibbs principle, H-theorem, the prices of the Gibbs decisions	free on $\mathbb{R}_\delta$ (prices exact with no choice); one classical reading
26.2 Markov steps	the second law, its equality case, windows, heat baths	classical; the head theorem's form on $\mathbb{R}_\delta$ (Theorem 26.7) free
26.3 Recognition Science's dynamics	zero production, one-step strictness, Doeblin's rate	classical; Doeblin's rate and lazy connected strictness also free on $\mathbb{R}_\delta$
26.4 The tick	existence and uniqueness, walls, Doeblin windows, the rate from a point start; numbers for the tick from (T1)–(T5)	classical
26.5 Gap and start	Metropolis tick with a rate	free on $\mathbb{R}_\delta$
	a gap for every ball; start dependence	classical
26.6 The spine	pace, additivity, couplings, cutoff, the pair law forced by double entry; the pair's sharp rate, reduced to two named statements; numbers for the tick from (T1)–(T5)	classical
26.7 Lattice fields	Maxwell flow, light, Schrödinger	free on $\mathbb{R}_\delta$
26.8 Laws and premises	sign, plane and range laws	prices exact with no choice
	inverse-square lattice premises	classical; integer prices with no choice

continuous at every point.

Definition 26.1 (Entropy function and relative entropy on the line)**.** An *entropy function* is a continuous map η from $\mathbb{R}_\delta$ to $\mathbb{R}_\delta$ with $\eta(x) = -xy$ whenever $x > 0$ and $e^y = x$, and $\eta(0) = 0$. For points $q_1, \dots, q_n$ put $S(q) = \sum_i \eta(q_i)$. For *levels* $\ell_1, \dots, \ell_n$, standing for the weights $p_i = e^{\ell_i}$, the *relative entropy* on the line is

$$D_\eta(q \,\|\, \ell) = \sum_i \bigl(-\eta(q_i) - q_i \ell_i\bigr).$$

For $q_i > 0$ the ith term is $q_i \log q_i - q_i \log p_i$, the classical term. At $q_i = 0$ it is 0, with no decision about which case holds.

Lemma 26.2 (Closed conditions pass to the boundary)**.** *Let F be continuous at a point $q \geq 0$, and let $F(x) \geq 0$ for every $x > 0$. Then $F(q) \geq 0$. The proof is free.*

Proof. On $\mathbb{R}_\delta$, $F(q) \geq 0$ means that $F(q) < 0$ is impossible. Suppose $F(q) < 0$, and take k with $F(q) < -1/(k+1)$. Continuity gives j with $|F(y) - F(q)| \leq 1/(2k+2)$ for $|y - q| \leq 1/(j+1)$. The point $y = q + 1/(j+1)$ is positive, and $F(y) \leq F(q) + 1/(2k+2) < 0$, which contradicts $F(y) \geq 0$. □

Theorem 26.3 (The entropy function exists and is unique)**.** *There is an entropy function. Any two entropy functions agree at every $x \geq 0$. Both statements are free.*

Proof. Construction. Write $x^+ = \max(x, 0)$ and, for each n,

$$\eta_n(x) = -x^+ \log\Bigl(x^+ + \frac{1}{n+1}\Bigr).$$

The logarithm's argument is at least $1/(n+1)$, so each η_n is a map with no case split. For $0 < a \leq b$, the tangent bound (26.1) at the points $\log b$ and $\log a$ gives $a(\log b - \log a) \leq b - a$. With $y = x^+$, $m \geq n$, $a = y + 1/(m+1)$ and $b = y + 1/(n+1)$,

$$0 \leq \eta_m(x) - \eta_n(x) = y(\log b - \log a) \leq \frac{y}{a}(b - a) \leq \frac{1}{n+1}.$$

So the η_n converge uniformly with the rate $1/(n+1)$. The diagonal limit of Theorem 12.25, applied on a regular sequence naming x, defines $\eta(x)$, and limits are unique, so η is a map on the points. Each η_n is continuous: $x \mapsto x^+$ moves by at most $|x - x'|$, and on $[1/(n+1), \infty)$ the logarithm moves by at most $(n+1)$ times the change of its argument. A uniform limit with a rate of continuous functions is continuous, so η is. At 0 every η_n vanishes. For $x > 0$, $|\log(x + 1/(n+1)) - \log x| \leq 1/((n+1)x)$ by the same inequality, so $\eta_n(x) \to -x \log x$.

Uniqueness. Let η and η' be entropy functions. Every $x > 0$ is $e^{\log x}$, so $\eta(x) = -x \log x = \eta'(x)$ for $x > 0$. The function $F = -|\eta - \eta'|$ is continuous and vanishes at every positive point, so Lemma 26.2 gives $F(x) \geq 0$, that is $\eta(x) = \eta'(x)$, at every $x \geq 0$. □

From now on η is the entropy function, and we write $x \log x$ for $-\eta(x)$ at $x \geq 0$. The next lemma is the single inequality behind the Gibbs principle, the H-theorem and the native second laws later in the chapter.

Lemma 26.4 (The Gibbs term). *For points ℓ and $q \geq 0$ put $g(\ell, q) = e^{\ell} - q - \eta(q) - q\ell$. Then*

1. *$g(\ell, q) \geq 0$;*
2. *$g(\ell, q) > 0$ exactly when $q \# e^{\ell}$;*
3. *$g(\ell, q) = 0$ exactly when $q = e^{\ell}$.*

The proofs are free.

Proof. 1. For $q = e^m > 0$ we have $\eta(q) = -me^m$, so $g(\ell, q) = e^{\ell} - e^m - e^m(\ell - m) \geq 0$ by the tangent bound (26.1). Every $q > 0$ has this form, and $g(\ell, \cdot)$ is continuous, so Lemma 26.2 gives $g(\ell, q) \geq 0$ for every $q \geq 0$.

2. Suppose $q \# e^{\ell}$. Item 1 at a point m in place of ℓ says $-\eta(a) \geq a + am - e^m$ for every $a \geq 0$. Let $c = (q + e^{\ell})/2 > 0$ and $m = \log c$; adding the inequality at $a = q$ and at $a = e^{\ell}$ gives $-\eta(q) - \eta(e^{\ell}) \geq 2cm = -2\eta(c)$. The terms of g that are linear in q then give $g(\ell, c) \leq \frac{1}{2}\big(g(\ell, q) + g(\ell, e^{\ell})\big) = \frac{1}{2}g(\ell, q)$, since $g(\ell, e^{\ell}) = 0$. Now $c \# e^{\ell}$, so $u = \ell - m \# 0$ by the third fact in (26.1), and

$$g(\ell, c) = e^m\big(e^u - 1 - u\big) = e^m\Big(2\big(e^{u/2} - 1 - \tfrac{u}{2}\big) + \big(e^{u/2} - 1\big)^2\Big) \geq e^m\big(e^{u/2} - 1\big)^2 > 0,$$

by the first fact in (26.1) at $u/2$, and the square is positive because $e^{u/2} \# 1$. So $g(\ell, q) > 0$. Conversely let $g(\ell, q) > 0$, and take k with $g(\ell, q) > 1/(k+1)$. Continuity of $g(\ell, \cdot)$ at e^{ℓ}, where it vanishes, gives j with $g(\ell, y) \leq 1/(k+1)$ whenever $|y - e^{\ell}| \leq 1/(j+1)$. Either $|q - e^{\ell}| > 1/(j+2)$ or $|q - e^{\ell}| < 1/(j+1)$; the second would give $g(\ell, q) \leq 1/(k+1)$, so the first holds and $q \# e^{\ell}$.

3. If $g(\ell, q) = 0$, item 2 excludes $q \# e^{\ell}$, and on $\mathbb{R}_{\delta}$ two points that are not apart are equal. Conversely $g(\ell, e^{\ell}) = e^{\ell} - e^{\ell} + \ell e^{\ell} - \ell e^{\ell} = 0$. □

Theorem 26.5 (The Gibbs variational principle on the line). *Let $E_1, \dots, E_n$ and β be points, let y be a point with $e^y = Z = \sum_i e^{-\beta E_i}$, and let $q_1, \dots, q_n \geq 0$ with $\sum_i q_i = 1$. Put $F(q) = \sum_i q_i \beta E_i - S(q)$. Then*

1. *$F(q) \geq -y$;*
2. *$F(q) = -y$ exactly when $q_i Z = e^{-\beta E_i}$ for every i, that is, when q is the Gibbs state;*
3. *$F(q) > -y$ exactly when $q_i Z \# e^{-\beta E_i}$ for some i.*

The proofs are free.

Proof. Put $\ell_i = -\beta E_i - y$, so that $\sum_i e^{\ell_i} = Ze^{-y} = 1$. Then

$$\sum_i g(\ell_i, q_i) = \sum_i e^{\ell_i} - \sum_i q_i - S(q) + \sum_i q_i(\beta E_i + y) = F(q) + y.$$

Every term on the left is nonnegative (Lemma 26.4). A finite sum of nonnegative points is 0 exactly when each term is, and is positive exactly when some term is, since a positive finite sum has a positive term. Item 3 of the lemma turns "each term is 0" into $q_i = e^{\ell_i}$, which is $q_i Z = e^{-\beta E_i}$, and item 2 turns "some term is positive" into an apartness. □

Conditions and scope.

Base and premises
Finitely many levels E_i, an inverse temperature β, a logarithm y of the partition function, a distribution q; all points of $\mathbb{R}_\delta$.

Conclusion
The free energy is bounded below by $-\log Z$, the Gibbs state is its only minimiser, and "strictly above the minimum" is the same statement as "apart from the Gibbs state", with no decision about q.

Not claimed
A temperature scale or a physical calibration of β.

Gibbs stated the principle in his treatise on statistical mechanics [181]. What the line adds is the third item: it identifies an observable deviation from equilibrium with an excess of free energy, and the next theorem shows that the classical alternatives about Gibbs states each carry an exact price.

Theorem 26.6 (The prices of the Gibbs decisions)**.** *Quantify over all data of Theorem 26.5 (all n, levels, β, y and distributions q). Then, with no choice principle:*

1. *"q is the Gibbs state or it is not" holds for all data exactly when WLPO holds;*
2. *"if q is not the Gibbs state, it is apart from it" holds for all data exactly when $\mathrm{MP}_{\mathrm{bin}}$ holds;*
3. *"q is the Gibbs state, or its free energy is strictly above $-y$" holds for all data exactly when LPO holds;*
4. *"the free energy is strictly above $-y$" and "q is apart from the Gibbs state" are equivalent for all data, at no price.*

Proof. Item 4 is Theorem 26.5, item 3.

Lower bounds. Let a be any point and $A \geq |a|$ a natural number. Take $n = 2$, $E_1 = E_2 = 0$, $\beta = 0$, $Z = 2$, $y = \log 2$, and $q = (\frac{1}{2} + c, \frac{1}{2} - c)$ with $c = a/(2A + 1)$, so $q \geq 0$ and $\sum q = 1$. Then q is the Gibbs state exactly when $2q_1 = 1$ and $2q_2 = 1$, that is $a = 0$, and q is apart from it exactly when $a \# 0$. So item 1 gives $a = 0 \vee a \neq 0$ for every a, which is WLPO by Corollary 12.18; item 2 gives $a \neq 0 \to a \# 0$, which is $\mathrm{MP}_{\mathrm{bin}}$; and item 3, read through item 4, gives $a = 0 \vee a \# 0$, which is $a = 0 \vee a > 0 \vee a < 0$, LPO.

Upper bounds. With WLPO, each of the n equations $q_i Z = e^{-\beta E_i}$ is decided by a zero test, and a finite conjunction of decided statements is decided. With $\mathrm{MP}_{\mathrm{bin}}$, let q not be the Gibbs state and put $s = \sum_i |q_i Z - e^{-\beta E_i}|$. Then $s \neq 0$, so $s > 0$ by Corollary 12.18, and a positive finite sum has a positive term: some coordinate is apart. With LPO, each difference $q_i Z - e^{-\beta E_i}$ is 0 or apart from 0; if all are 0, q is the Gibbs state, and otherwise item 4 gives the strict excess. □

The second law in its oldest form, Boltzmann's H-theorem [176], says that a relaxation never raises the free energy. On the line it is a statement about a stochastic matrix and the relative entropy of Definition 26.1.

Theorem 26.7 (The H-theorem on the line). *Let K be an $n \times n$ matrix of points with $K_{ij} \geq 0$ and $\sum_j K_{ij} = 1$, and let $\ell_1, \dots, \ell_n$ be levels whose weights are stationary: $\sum_i e^{\ell_i} K_{ij} = e^{\ell_j}$ for every j. Then for every q with all $q_i \geq 0$,*

$$D_\eta(qK \,\|\, \ell) \leq D_\eta(q \,\|\, \ell), \qquad (qK)_j = \sum_i q_i K_{ij}.$$

In particular, if the Boltzmann weights $e^{-\beta E_i}$ are stationary, the free energy F of Theorem 26.5 never increases under $q \mapsto qK$, and for a distribution q it stays at least $-\log Z$. The proofs are free.

Proof. Column bound. Fix a column j, put $r = (qK)_j$, and let μ be any point. Lemma 26.4, item 1, at $\ell = \mu + \ell_i$ reads $-\eta(q_i) - q_i \ell_i \geq q_i \mu + q_i - e^{\mu} e^{\ell_i}$. Multiply by $K_{ij} \geq 0$, sum over i, and use stationarity:

$$\sum_i K_{ij}\big(-\eta(q_i) - q_i \ell_i\big) \geq \mu r + r - e^{\mu} e^{\ell_j}. \tag{26.2}$$

If $r > 0$, the choice $\mu = \log r - \ell_j$ makes the right side $r \log r - r\ell_j = -\eta(r) - r\ell_j$, the jth term of $D_\eta(qK \,\|\, \ell)$. Summing over j and using $\sum_j K_{ij} = 1$ on the left gives the theorem when every column of qK is positive.

Columns of unknown sign. For a point $\varepsilon > 0$ the vector $q + \varepsilon e^{\ell}$ is mapped to $qK + \varepsilon e^{\ell}$, whose columns are positive. So $G(\varepsilon) = D_\eta(q + \varepsilon e^{\ell} \,\|\, \ell) - D_\eta(qK + \varepsilon e^{\ell} \,\|\, \ell)$ is nonnegative at every $\varepsilon > 0$. It is continuous, because η is, and Lemma 26.2 gives $G(0) \geq 0$. No decision whether a column vanishes is made.

Free energy. With $\ell_i = -\beta E_i$ the relative entropy is $\sum_i (-\eta(q_i) + q_i \beta E_i) = F(q)$, and $F \geq -\log Z$ by Theorem 26.5. □

The weights in the theorem need not sum to 1; only stationarity is used. The theorem reads back into the classical setting through the unique reading of $\mathbb{R}_\delta$ in the classical real numbers (Section 21.2).

Proposition 26.8 (The classical reading is Recognition Science's thermodynamics). *The following is proved in classical mathematics. Let ρ be the reading of $\mathbb{R}_\delta$. Then $\rho(\eta(x)) = -\rho(x) \log \rho(x)$ for $x \geq 0$ (with $0 \log 0 = 0$), and $\rho(S(q))$ is the recognition entropy $-\sum_i \rho(q_i) \log \rho(q_i)$ of Recognition Science. Let a recognition system have temperature $T_R > 0$, let X_i be positive ratios, and suppose the calibration $\rho(\beta E_i) = J(X_i)/T_R$. Then q is the Gibbs state of Theorem 26.5 exactly when $\rho(q_i) = e^{-J(X_i)/T_R}/Z$ for every i, and the theorem reads as Recognition Science's free-energy principle: $F_R(q) = \sum_i \rho(q_i) J(X_i) - T_R\, S(\rho(q)) \geq -T_R \log Z$, with equality exactly at the Gibbs measure.*

Proof. The reading preserves sums, products, limits with a modulus and the logarithm (Section 21.2). At $x > 0$ it sends $-x \log x$ to $-\rho(x) \log \rho(x)$; at $x = 0$ both sides are 0; and both sides are continuous in $x \geq 0$, so they agree for all $x \geq 0$. The Gibbs condition $q_i Z = e^{-\beta E_i}$ reads as $\rho(q_i) Z = e^{-J(X_i)/T_R}$, and $T_R\, \rho(F(q)) = F_R(q)$. □

The calibration $\rho(\beta E_i) = J(X_i)/T_R$ is a stated hypothesis. The proposition does not identify a temperature, and nothing in this section uses an observation.

26.2 The second law for a Markov step

This section and the next work in classical mathematics: distributions, stochastic matrices and relative entropies are classical real objects. The head theorem below has a form on $\mathbb{R}_\delta$, Theorem 26.7, which is free; reading that form back to the classical real numbers through the reading ρ of Proposition 26.8 is a classical step.

Definition 26.9 (Markov steps and J-descent operators)**.** Let Ω be a finite set. A *distribution* is a vector $q \geq 0$ on Ω with $\sum_i q_i = 1$. A *stochastic matrix* K has $K_{ij} \geq 0$ and $\sum_j K_{ij} = 1$; it moves q to qK, $(qK)_j = \sum_i q_i K_{ij}$. A vector p with all $p_i > 0$ is *stationary* when $pK = p$. For $q \geq 0$ the relative entropy is $D(q \,\|\, p) = \sum_{q_i>0} q_i \log(q_i/p_i)$; with $f(x) = x\log x$ and $f(0) = 0$, it is $\sum_i p_i f(q_i/p_i)$. A *$\mathcal{J}$-descent operator* with equilibrium p, in Recognition Science's term, is a map R on distributions with $R(p) = p$ and $D(R(q) \,\|\, p) \leq D(q \,\|\, p)$ for every q.

The function f is convex on $[0,\infty)$, and strictly convex: equality in Jensen's inequality $f(\sum_i w_i x_i) \leq \sum_i w_i f(x_i)$, for weights $w_i > 0$ summing to 1, holds only when all x_i are equal.

Theorem 26.10 (Relative entropy never rises under a stochastic step)**.** *Let K be a stochastic matrix on a finite set and p a stationary vector with every $p_i > 0$. Then for every vector $q \geq 0$,*

$$D(qK \,\|\, p) \leq D(q \,\|\, p).$$

So $q \mapsto qK$ is a $\mathcal{J}$-descent operator with equilibrium p. If p is the Gibbs law $p_i = e^{-c_i/T}/Z$ of costs c_i at temperature $T > 0$, the free energy $F(q) = \sum_i q_i c_i - TS(q)$ of a distribution q satisfies $F(q) - F(p) = TD(q \,\|\, p)$ and never increases under the step. The theorem is proved in classical mathematics, and its matrix form on $\mathbb{R}_\delta$ is free (Theorem 26.7).

Proof. Fix a column j and put $w_{ij} = p_i K_{ij}/p_j \geq 0$. Stationarity gives $\sum_i w_{ij} = 1$, and $(qK)_j/p_j = \sum_i w_{ij}\, q_i/p_i$. By Jensen's inequality,

$$f\Big(\frac{(qK)_j}{p_j}\Big) \leq \sum_i w_{ij}\, f\Big(\frac{q_i}{p_i}\Big).$$

Multiply by p_j and sum over j: $D(qK \,\|\, p) \leq \sum_i \sum_j p_i K_{ij} f(q_i/p_i) = \sum_i p_i f(q_i/p_i) = D(q \,\|\, p)$, since the rows of K sum to 1. For the Gibbs law and a distribution q, $\log p_i = -c_i/T - \log Z$ and $\sum_i q_i = 1$, so $TD(q \,\|\, p) = -TS(q) + \sum_i q_i c_i + T\log Z = F(q) + T\log Z$; at $q = p$ this gives $F(p) = -T\log Z$, hence $F(q) - F(p) = TD(q \,\|\, p)$. □

Conditions and scope.

Base and premises

A finite configuration space, a stochastic matrix, a stationary vector with every entry positive.

Conclusion

Relative entropy to the stationary law, and with it the free energy of a Gibbs law, never rises. Recognition Science's second-law notes assume this monotonicity for its relaxation step; for every Markov step with a positive stationary law it is a theorem.

Not claimed

That a given recognition tick acts on a finite configuration space as a stochastic matrix with the Gibbs law stationary. That is an identification; Section 26.4 treats Recognition Science's own tick directly.

Positivity of p matters. Recognition Science writes relative entropy as a sum over the configurations where both q and p are positive. For the stochastic matrix with rows $(1,0)$ and $(1,0)$, the stationary law $(1,0)$ and $q = (\frac{1}{2}, \frac{1}{2})$, that sum is $-\frac{1}{2}\log 2$ at q and 0 at $qK = (1,0)$: it rises. The theorem is the Markov form of Boltzmann's H-theorem, and in information theory it is the data-processing inequality for relative entropy [172, 177]. The proof also locates exactly where the arrow acts.

Theorem 26.11 (Where a step loses relative entropy)**.** *Let K and p be as in Theorem 26.10 and let $q \geq 0$.*

(a) $D(q \,\|\, p) - D(qK \,\|\, p) = \sum_j \Gamma_j$ *with* $\Gamma_j = \sum_i p_i K_{ij} f(q_i/p_i) - p_j f((qK)_j/p_j) \geq 0$.

(b) $D(qK \,\|\, p) = D(q \,\|\, p)$ *exactly when* $q_i/p_i = q_{i'}/p_{i'}$ *whenever* $K_{ij} \neq 0$ *and* $K_{i'j} \neq 0$*: the step merges no two configurations with different ratios.*

(c) This holds exactly when the time reversal $\hat{K}_{ji} = p_i K_{ij}/p_j$ *restores q:* $qK\hat{K} = q$.

(d) This holds exactly when some stochastic L with $pL = p$ restores q: $qKL = q$.

(e) If every $K_{ij} > 0$, $\sum_i p_i = 1$, *and $q \neq p$ is a distribution, then* $D(qK \,\|\, p) < D(q \,\|\, p)$.

These results are proved in classical mathematics.

Proof. (a) The two double sums in the proof of Theorem 26.10 are $D(q \,\|\, p)$ and $D(qK \,\|\, p)$, and $\Gamma_j \geq 0$ is Jensen's inequality for column j.

(b) By strict convexity, $\Gamma_j = 0$ exactly when q_i/p_i is constant on $\{i : w_{ij} > 0\} = \{i : K_{ij} \neq 0\}$, the *predecessor set* of j; and a sum of nonnegative terms vanishes exactly when each does.

(c) $\hat{K}$ is stochastic, $\sum_i \hat{K}_{ji} = 1$, and $p\hat{K} = p$. Suppose the ratios are constant, equal to c_j, on the predecessor set of each j. Then $(qK)_j = c_j p_j$, and $(qK\hat{K})_i = \sum_j c_j p_i K_{ij} = p_i \sum_j K_{ij} q_i/p_i = q_i$, because $c_j = q_i/p_i$ whenever $K_{ij} \neq 0$. So (b) gives (c), and (c) gives (d) with $L = \hat{K}$.

(d) If L restores q, Theorem 26.10 for K and for L gives $D(q \,\|\, p) = D(qKL \,\|\, p) \leq D(qK \,\|\, p) \leq D(q \,\|\, p)$.

(e) Every predecessor set is all of Ω, so equality would make q/p a constant c; summing, $c = 1$ and $q = p$. □

The recovery map $\hat{K}$ is the classical case of Petz's recovery map for quantum relative entropy [187]. Statement (b) explains the opening example: in the step from q_0 the only predecessor set with two members is $\{0, 2\}$, and q_0 has the ratio $\frac{4}{3}$ at both.

Theorem 26.12 (Strict decrease: not per tick, but per window)**.** *The following are proved in classical mathematics.*

(a) A strict decrease at every tick fails for primitive chains: the chain K of the opening, with rational entries, has $K^4 > 0$ entrywise and the positive stationary law $p = (\frac{1}{2}, \frac{1}{4}, \frac{1}{4})$, and the distribution $q_0 = (\frac{2}{3}, 0, \frac{1}{3}) \neq p$ has $D(q_0K \,\|\, p) = D(q_0 \,\|\, p) = \log \frac{4}{3}$.

(b) For every stochastic K with positive stationary distribution p and every N with $K^N > 0$ entrywise, $D(qK^N \,\|\, p) < D(q \,\|\, p)$ for every distribution $q \neq p$.

(c) For every stochastic K with positive stationary distribution p and every distribution q, one step lowers $D(q \,\|\, p)$ exactly when some predecessor set carries two different ratios q_i/p_i.

Proof. (a) The rows of K^2 are $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$, $(1, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, 0)$, and those of $K^4 = (K^2)^2$ are $(\frac{9}{16}, \frac{5}{16}, \frac{1}{8})$, $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$ and $(\frac{5}{8}, \frac{1}{8}, \frac{1}{4})$. The values of D are in the opening table: $D(q_0 \,\|\, p) = \frac{2}{3} \log \frac{4}{3} + \frac{1}{3} \log \frac{4}{3}$ and $D(q_0K \,\|\, p) = \frac{2}{3} \log \frac{4}{3} + \frac{1}{3} \log \frac{1/3}{1/4}$, both $\log \frac{4}{3}$.

(b) K^N is stochastic with $pK^N = p$ and all entries positive; apply Theorem 26.11(e) to it.

(c) is Theorem 26.11(b) together with Theorem 26.10. □

Heat baths are the commonest physical steps of this kind. Let r be a *record* of the configurations, a map from Ω to some set, and let π be a positive law. The *heat bath* for r keeps the record and resamples the configuration from π conditioned on it: $K(x, y) = \pi(y)/\pi(r^{-1}(r(x)))$ when $r(y) = r(x)$, and 0 otherwise.

Proposition 26.13 (Heat baths, Gibbs resampling and Glauber dynamics)**.** *The following is proved in classical mathematics. Let π be the Gibbs law of a recognition system for costs X.*

(a) For every record r, the heat bath is a $\mathcal{J}$-descent operator with equilibrium π, and it leaves $D(q \,\|\, \pi)$ unchanged exactly when q/π is constant on every fibre $\{r(x) = r(y)\}$.

(b) Gibbs resampling, $K(x, y) = \pi(y)$, lowers $D(q \,\|\, \pi)$ strictly from every distribution $q \neq \pi$.

(c) Every mixture $\sum_k w_k K_k$ of heat baths, with $w_k \geq 0$ and $\sum_k w_k = 1$ (random scan), and in particular Glauber dynamics of a spin system on $L+1$ sites (choose a site uniformly, resample its spin from the conditional Gibbs law given the other spins), is a $\mathcal{J}$-descent operator with equilibrium π.

Proof. A heat bath is stochastic, and $\pi(x)K(x, y) = \pi(x)\pi(y)/\pi(\text{fibre})$ is symmetric in x and y; summing over x gives $\pi K = \pi$. The predecessor set of y is the fibre of y, so Theorem 26.11(b) gives the criterion in (a). Gibbs resampling is the heat bath of a constant record, with all entries positive; apply Theorem 26.11(e). A mixture of stochastic matrices that keep π is stochastic and keeps π, and Glauber dynamics is the uniform mixture of the heat baths whose record is the configuration with one site erased. □

The Metropolis rule [186] and Glauber's heat bath [182] were introduced to sample Gibbs laws; the proposition says that each of them is a second-law step for the law it samples.

26.3 What the second law gives Recognition Science's dynamics

A J-descent operator never raises relative entropy. Three questions remain: which steps produce no entropy at all, which produce some at every tick, and how fast the production drives a distribution to equilibrium. All three have exact answers for Markov steps. Throughout, K is a stochastic matrix on a finite set with a stationary distribution p, every $p_i > 0$; the results are proved in classical mathematics. Theorem 26.17 gives the forms on $\mathbb{R}_\delta$ of two of them: Doeblin's rate and one-step strictness for lazy connected steps.

Theorem 26.14 (Zero production means a permutation of the costs)**.** *$D(qK \,\|\, p) = D(q \,\|\, p)$ for every distribution q exactly when K is the permutation matrix of a permutation σ with $p(\sigma(i)) = p(i)$ for every i. For the Gibbs law $p_i \propto e^{-J(X_i)/T}$ of Recognition Science, this holds exactly when K relabels the configurations by a permutation that preserves every cost: $J(X_{\sigma(i)}) = J(X_i)$. The point masses alone decide it.*

Proof. If K permutes by a p-preserving σ, then $D(qK \,\|\, p)$ is the same sum as $D(q \,\|\, p)$ with its terms relabelled. Conversely, suppose there is no production from any point mass δ_i. The ratio δ_i / p is $1/p_i$ at i and 0 elsewhere, so by Theorem 26.11(b) no column j can have $K_{ij} \neq 0$ and $K_{i'j} \neq 0$ with $i' \neq i$: every column has at most one nonzero entry. Each row has a nonzero entry, since it sums to 1; let $\sigma(i)$ be its column. The map σ is injective, hence a permutation of the finite set, and each row's single nonzero entry is 1. Stationarity gives $p_{\sigma(i)} = p_i$. For the Gibbs law, $p_{\sigma(i)} = p_i$ exactly when $e^{-J(X_{\sigma(i)})/T} = e^{-J(X_i)/T}$, that is, when the costs agree. □

So among Markov steps, the reversible relabellings are exactly the steps that produce nothing. The cyclic shift of eight configurations of equal cost is one; it has the form of the eight-tick clock of Recognition Science, a match of formulas rather than an identification. Every other step produces entropy from some point mass.

Theorem 26.15 (One-step strictness: one merging class)**.** *Say that i and i'* feed a common configuration *when $K_{ij} \neq 0$ and $K_{i'j} \neq 0$ for some j, and call the classes of the equivalence relation this generates the* merging classes *of K.*

(a) $D(qK \,\|\, p) = D(q \,\|\, p)$ exactly when q/p is constant on every merging class.

(b) One step lowers $D(q \,\|\, p)$ strictly from every distribution $q \neq p$ exactly when K has a single merging class.

(c) If K is lazy, $K_{ii} > 0$ for every i, and connected, any two configurations joined by a path of steps $a \to b$ with $K_{ab} > 0$ or $K_{ba} > 0$, then K has a single merging class.

(d) Connectivity is necessary for (b), and laziness is not: the matrix on three configurations with $K_{ij} = \frac{1}{2}$ for $i \neq j$ and $K_{ii} = 0$, with uniform p, lowers D strictly at every step. The swap of two configurations is connected and produces nothing from $(1, 0)$; the identity on two configurations is lazy and produces nothing from $(1, 0)$.

Proof. (a) By Theorem 26.11(b), no production means q/p is constant on each predecessor set, which is the same as constant on each merging class.

(b) With one class, no production forces $q = cp$, and $c = 1$ because both sum to 1. With a class C that misses some configuration, the distribution $q = p\,1_C/p(C)$ differs from p and q/p is constant on every class, so it produces nothing.

(c) If $K_{ab} > 0$, then a and b both feed b, because $K_{bb} > 0$. So the two ends of every edge lie in one class, and connectivity gives one class.

(d) If i and i' feed a common j, then i, j, i' is a path; so one merging class makes K connected. In the three-configuration matrix any two configurations feed the third, so there is one class. The swap and the identity have two classes each. □

Theorem 26.16 (Doeblin's condition gives a rate)**.** *Suppose $(K^N)_{ij} \geq \delta\, p_j$ for all i, j, for some window N and some $\delta \geq 0$. Then $\delta \leq 1$, and for every distribution q and every m,*

$$D(qK^{Nm} \,\|\, p) \leq (1-\delta)^m D(q \,\|\, p), \qquad D(qK^n \,\|\, p) \leq (1-\delta)^{\lfloor n/N \rfloor} D(q \,\|\, p) \text{ for all } n.$$

If $K^N > 0$ entrywise, some $\delta > 0$ works, so $D(qK^n \,\|\, p) \to 0$ exponentially. For a Gibbs law the free-energy excess $F(q) - F(p)$ decays at the same rate.

Proof. Step 1. Summing the hypothesis over j in any row gives $\delta \leq \sum_j (K^N)_{ij} = 1$.

Step 2: one window, $\delta < 1$. Put $M = K^N$, stochastic with $pM = p$, and $R_{ij} = (M_{ij} - \delta p_j)/(1-\delta)$. Then $R \geq 0$ by hypothesis, its rows sum to $(1-\delta)/(1-\delta) = 1$, and $pR = (p - \delta p)/(1-\delta) = p$. So $M = \delta\Pi + (1-\delta)R$ with $\Pi_{ij} = p_j$, and for a distribution q, $qM = \delta p + (1-\delta)\,qR$. Convexity of f with $f(1) = 0$ gives $p_i f\big(\delta + (1-\delta)x_i\big) \leq (1-\delta)p_i f(x_i)$ with $x_i = (qR)_i/p_i$, so $D(qM \,\|\, p) \leq (1-\delta)D(qR \,\|\, p)$, and Theorem 26.10 for R gives $D(qR \,\|\, p) \leq D(q \,\|\, p)$.

Step 3: $\delta = 1$. Each row of M is at least p and sums to 1, so $M = \Pi$, $qM = p$ and $D(qM \,\|\, p) = 0$.

Step 4. Nm steps of K are m steps of M, so the bound iterates. For general n use $\lfloor n/N \rfloor$ full windows and Theorem 26.10 on the remaining steps. If $K^N > 0$, take $\delta = \min_{i,j} (K^N)_{ij}/p_j > 0$. The free-energy statement is $F(q) - F(p) = TD(q \,\|\, p)$. □

Conditions and scope.

Base and premises
A stochastic matrix on a finite set, a positive stationary distribution, and a Doeblin minorisation at one window.

Conclusion
A geometric rate for relative entropy and free energy.

Not claimed
A rate for J-descent operators in general: Proposition 26.18 shows that none exists.

Doeblin introduced the minorisation that bears his name for the ergodic theory of Markov chains [180]; its use for mixing is standard [184]. Two of the results above also hold on $\mathbb{R}_\delta$, with relative entropy computed by the entropy function, and there they are free: Doeblin's

rate, and one-step strictness for lazy connected steps. The one point that needs care is the strict statement, where "$q \neq p$" must become "q is apart from p". The zero-production criterion and the merging-class criterion of Theorems 26.14 and 26.15 are proved here only in classical mathematics.

Theorem 26.17 (Doeblin's rate and lazy strictness are free on the line)**.** *Let K be an $n \times n$ matrix of points of $\mathbb{R}_\delta$ with $K_{ij} \geq 0$ and rows summing to 1, and let ℓ be levels with $\sum_i e^{\ell_i} = 1$ and $\sum_i e^{\ell_i} K_{ij} = e^{\ell_j}$. Write $p_i = e^{\ell_i}$ and $D = D_\eta(\cdot \,\|\, \ell)$.*

(a) If $d \geq 0$ and $(K^N)_{ij} \geq d\, p_j$ for all i, j, then for every $q \geq 0$ with $\sum_i q_i = 1$ and every m, $D(qK^{Nm}) \leq (1-d)^m D(q)$.

(b) If $K_{ii} > 0$ for every i and any two indices are joined by a path of positive entries, then $D(qK) < D(q)$ for every $q \geq 0$ with $\sum_i q_i = 1$ and some $q_i \# p_i$.

Both proofs are free.

Proof. (a) Write $M = K^N$ and $S = M - d\,\Pi$, where $\Pi_{ij} = p_j$; then $S \geq 0$, with no division by $1 - d$ and so no decision whether $d = 1$. Summing the hypothesis over j gives $d \leq 1$. Fix a column j, put $r = (qM)_j$ and $Q = \sum_i q_i$, and let μ be a point. Inequality (26.2), applied to the nonnegative weights S_{ij}, for which $\sum_i p_i S_{ij} = (1-d)p_j$, and the same Gibbs-term bound at the single atom Qp_j give

$$\sum_i S_{ij}\big(-\eta(q_i) - q_i \ell_i\big) + d\big(-\eta(Qp_j) - Qp_j \ell_j\big) \geq \mu r + r - e^{\mu} p_j,$$

since $\sum_i S_{ij} q_i + dQp_j = r$. As in Theorem 26.7, the choice $\mu = \log r - \ell_j$ for positive columns and the shift $q + \varepsilon p$ make the right side the jth term of $D(qM)$. Summing over j, with $\sum_j S_{ij} = 1 - d$, gives $D(qM) \leq (1-d)D(q) + d\,D(Qp)$, and here $Q = 1$ and $D(p) = 0$. Since $1 - d \geq 0$, the bound iterates over m windows.

(b) The exact form of (26.2) at a column j with $r_j > 0$ and $\mu_j = \log r_j - \ell_j$ is the identity

$$\sum_i K_{ij}\big(-\eta(q_i) - q_i \ell_i\big) - \big(-\eta(r_j) - r_j \ell_j\big) = \sum_i K_{ij}\, g(\mu_j + \ell_i, q_i),$$

whose terms are nonnegative by Lemma 26.4. Summed over j, the left sides give $D(q) - D(qK)$, and every column contributes at least 0: for $r_j > 0$ this is (26.2) at μ_j, and in general it follows by applying that bound to $q + \varepsilon p$ and letting $\varepsilon \to 0$ (Lemma 26.2), as in the proof of Theorem 26.7. So it suffices to find one column b with $r_b > 0$ and one positive term. Since $q_i \# p_i$ for some i and both vectors sum to 1, some i has $q_i > p_i$ and some k has $q_k < p_k$ (a negative finite sum has a negative term), so $q_i/p_i \# q_k/p_k$. Along a path of positive entries from i to k, cotransitivity of $<$ finds consecutive indices a, b with $q_a p_b \# q_b p_a$, and we may orient them so that $K_{ab} > 0$. One of q_a, q_b is positive, so $r_b \geq K_{ab} q_a + K_{bb} q_b > 0$. If both terms $g(\mu_b + \ell_a, q_a)$ and $g(\mu_b + \ell_b, q_b)$ vanished, Lemma 26.4 would give $q_a = r_b p_a / p_b$ and $q_b = r_b$, so $q_a p_b = q_b p_a$. By cotransitivity applied to the apartness, one of $q_a \# r_b p_a / p_b$ and $q_b \# r_b$ holds, and the corresponding term, multiplied by $K_{ab} > 0$ or $K_{bb} > 0$, is positive. $\square$

Recognition Science's own notes on the second law make two statements about J-descent operators that these theorems correct. The second-law notes describe the Lyapunov function $F_R(q_n) - F_R(p)$ as providing a quantitative convergence rate for the dynamics. The notes on the boundary second law list three inclusions as strict: cost-preserving permutations inside π-preserving permutations, inside the maps of the simplex that keep relative entropy, inside the injective maps of the simplex.

Proposition 26.18 (Two corrections to Recognition Science's notes)**.** *The following is proved in classical mathematics.*

(a) No rate holds for all $\mathcal{J}$-descent operators. On two configurations of equal cost the Gibbs law is $(\frac{1}{2}, \frac{1}{2})$, the swap is a $\mathcal{J}$-descent operator, and from $(1, 0)$ it keeps $D = \log 2$ at every tick; so no $\delta > 0$ satisfies $D(R(q) \,\|\, p) \le (1 - \delta) D(q \,\|\, p)$ for every $\mathcal{J}$-descent operator R and every q. A rate holds under a Doeblin condition (Theorem 26.16), and for Recognition Science's tick it is Corollary 26.29.

(b) For the Gibbs law of a cost, the first inclusion is an equality: a permutation preserves the Gibbs law exactly when it preserves every cost. Among Markov steps the second is an equality as well: a stochastic matrix that keeps relative entropy from every distribution is the matrix of a p-preserving permutation (Theorem 26.14). The third stays strict among Markov steps: the step $q \mapsto (q + p)/2$, with matrix $(\delta_{ij} + p_j)/2$, is injective and lowers $D(q \,\|\, p)$ strictly from every distribution $q \neq p$.

Proof. (a) For equal costs the Gibbs weights are equal. The swap is stochastic and keeps $(\frac{1}{2}, \frac{1}{2})$, so it is a J-descent operator by Theorem 26.10; it maps $(1, 0)$ to $(0, 1)$ and back, and $D = \log 2$ at both. (b) The first equality is the last step of the proof of Theorem 26.14. For the third, $(q + p)/2$ determines q, and Step 2 of the proof of Theorem 26.16, with $\delta = \frac{1}{2}$ and R the identity, gives $D((q + p)/2 \,\|\, p) \le \frac{1}{2} D(q \,\|\, p) < D(q \,\|\, p)$, since $D(q \,\|\, p) > 0$ for $q \neq p$. □

26.4 Recognition Science's tick: walls, windows and a rate

We now turn to the voxel of the opening. Its state space is infinite, so the finite theorems of the last two sections apply to it in two ways: on finite sets of states with a wall, and through a spectral gap on all of $\mathbb{Z}^3$. This section and the next two are proved in classical mathematics, except Theorem 26.31, which is free.

Definition 26.19 (Voxel states, the T9 law and voxel ticks)**.** A *voxel state* is an imbalance vector $s \in \mathbb{Z}^3$, the imbalances of a voxel's three axis accounts. A *move* adds $\pm e_i$ to it, one unit posted to one side of one account, so each state has six neighbours. The *imbalance cost* is $|s|_1 = |s_1| + |s_2| + |s_3|$. Let $\rho = \varphi^{-1} = \varphi - 1$; from here on ρ stands for this number, not for the reading of Section 26.1. The *weight* is $w(s) = \rho^{|s|_1}$ and the *T9 law* is $\pi(s) = \rho^{|s|_1}/\varphi^9$. A *voxel tick* is a matrix P on $\mathbb{Z}^3$ with entries $P(s, s') \ge 0$ that vanish unless $s' = s$ or s' is a neighbour of s, with $P(s, s) + \sum_m P(s, s + m) = 1$ (the sum over the six moves), with detailed balance $w(s)P(s, s') = w(s')P(s', s)$, and with the six entries $P(0, m)$ equal. $P(s, s)$ is the *hold* at s and $P(s, s + m)$ the *post* along m. We write P^n for n ticks and $D_n(a) = D(P^n(a, \cdot) \,\|\, \pi)$ for the relative entropy after n ticks from the state a.

A move changes $|s|_1$ by exactly ± 1. Call it *inward* when it lowers $|s|_1$ and *outward* otherwise. Along each axis at most one of the two moves is inward, every nonzero state has an inward move, and the *vacuum* 0 has none. The label T9 names this law only: it comes from a numbering of Recognition Science's derivations other than the one restated in Chapter 22, and the law is not step C9 there. The T9 law is a probability law: since $\sum_{n\in\mathbb{Z}} \rho^{|n|} = (1+\rho)/(1-\rho)$, and $1+\rho = \varphi$, $1-\rho = \rho^2$ and $\rho^{-1} = \varphi$, the total weight is $\big((1+\rho)/(1-\rho)\big)^3 = (\varphi^3)^3 = \varphi^9$. So $\pi(0) = \varphi^{-9} = 17\sqrt{5} - 38 \approx 0.013156$, and the vacuum carries $-\log \pi(0) = 9 \log \varphi \approx 4.331$ nats. After n ticks from a the law $P^n(a, \cdot)$ lives on the ball $B_{|a|_1+n}$, where $B_N = \{s : |s|_1 \le N\}$, so $D_n(a)$ is a finite sum. Detailed balance passes to powers: $\pi(a)P^n(a,s) = \pi(s)P^n(s,a)$.

Definition 26.20 (Recognition Science's tick and the Metropolis tick)**.** *Recognition Science's tick* is the voxel tick whose holds are all positive and which satisfies the hold-return balance

$$P(s,s)\,P(s',s') = P(s,s')\,P(s',s) \qquad \text{for every neighbouring pair } s, s'.$$

Exactly one voxel tick has these two properties (Theorem 26.21). The *Metropolis tick* proposes each of the six moves with probability $\frac{1}{6}$ and accepts the move to s' with probability $\min(1, w(s')/w(s))$: an inward post has probability $\frac{1}{6}$, an outward post $\rho/6$, and the rest of the row is the hold. At the vacuum it holds with probability $1-\rho$.

The tick is well defined: the two conditions turn the kernel into one equation for one positive function on the states, and that equation has exactly one solution.

Theorem 26.21 (Recognition Science's tick exists and is unique)**.** *In classical mathematics: exactly one voxel tick has all holds positive and satisfies hold-return balance. Its entries are*

$$P(s,s) = \frac{g(s)^2}{w(s)}, \qquad P(s, s+m) = \frac{g(s)\,g(s+m)}{w(s)},$$

and 0 *elsewhere, where g is the only positive function on $\mathbb{Z}^3$ that takes one value on the six unit vectors and satisfies*

$$g(s)\Big(g(s) + \sum_m g(s+m)\Big) = w(s) \qquad \textit{for every state } s, \tag{26.3}$$

the sum running over the six moves.

Proof. Step 1: such a tick gives a solution. Let P be a voxel tick with positive holds and hold-return balance, and put $g(s) = \sqrt{w(s)P(s,s)} > 0$. For neighbours s, s', detailed balance and hold-return balance give

$$\big(w(s)P(s,s')\big)^2 = w(s)P(s,s')\,w(s')P(s',s) = w(s)w(s')\,P(s,s)P(s',s') = g(s)^2 g(s')^2,$$

and both $w(s)P(s,s')$ and $g(s)g(s')$ are nonnegative, so $w(s)P(s,s') = g(s)g(s')$. Multiplying the row sum $P(s,s) + \sum_m P(s, s+m) = 1$ by $w(s)$ gives (26.3). The six posts $P(0,m) = g(0)g(m)$ at the vacuum are equal, so g takes one value on the six unit vectors. So P has the displayed form, with g a positive solution of (26.3).

Step 2: a solution gives such a tick. Let g be a positive solution of (26.3) that takes one value on the six unit vectors, and define P by the display. Its entries are nonnegative and vanish off

the diagonal and the neighbours; its rows sum to 1 by (26.3); detailed balance holds because $w(s)P(s,s') = g(s)g(s')$ is symmetric; the holds are positive; the six posts $P(0,m) = g(0)g(m)$ at the vacuum are equal, since $w(0) = 1$; and $P(s,s)P(s',s') = g(s)^2 g(s')^2/(w(s)w(s')) = P(s,s')P(s',s)$.

Step 3: at most one solution. Let g be a positive solution. The neighbour sum in (26.3) is positive, so $g(s)^2 < w(s)$. A move changes $|s|_1$ by one, so $w(s+m) \le \varphi\, w(s) < 4w(s)$ and $g(s+m) < \sqrt{w(s+m)} < 2\sqrt{w(s)}$. Then (26.3) gives $w(s) < g(s)\big(\sqrt{w(s)} + 12\sqrt{w(s)}\big)$, that is, $\sqrt{w(s)} < 13\, g(s)$, and so $p(s) = g(s)^2/w(s) > 1/169$. Put $q(s,m) = g(s)g(s+m)/w(s)$; by (26.3), $p(s) + \sum_m q(s,m) = 1$. Now let h be a second positive solution and $r(s) = h(s)/g(s)$. Both $r(s)$ and $1/r(s)$ are below $\sqrt{w(s)}\big/\big(\sqrt{w(s)}/13\big) = 13$, so

$$B = \sup_s \max\big(r(s), 1/r(s)\big)$$

is finite, and $B \ge 1$. Dividing (26.3) for h by $w(s)$ gives

$$r(s)\Big(p(s)\, r(s) + \sum_m q(s,m)\, r(s+m)\Big) = 1.$$

Suppose $r(s) \ge 1$. Every $r(s+m)$ is at least $1/B$, so

$$1 \ge r(s)\Big(p(s) + \frac{1-p(s)}{B}\Big) = r(s)\,\frac{1 + p(s)(B-1)}{B} \ge r(s)\,\frac{B+168}{169\,B},$$

because $p(s) > 1/169$ and $B \ge 1$. So $r(s) \le 169B/(B+168)$, and this also holds when $r(s) < 1$, since $169B/(B+168) \ge 1$. Exchanging g and h bounds $1/r(s)$ in the same way. Taking the supremum over s, $B \le 169B/(B+168)$, that is $B \le 1$. Hence $r(s) = 1$ for every s, and $h = g$.

Step 4: a solution exists. Write $g(s) = \sqrt{w(s)}\, x(s)$ and $c(s,m) = \sqrt{w(s+m)/w(s)}$, which is $\rho^{1/2}$ or $\varphi^{1/2}$, so $0 < c(s,m) < 2$. Then (26.3) reads $x(s)\big(x(s) + S_x(s)\big) = 1$ with $S_x(s) = \sum_m c(s,m)\, x(s+m)$. For $S \ge 0$ the positive root of $y(y+S) = 1$ is $R(S) = 2/\big(S + \sqrt{S^2+4}\big)$, which decreases in S, with $R(0) = 1$ and $R(12) = 2/(12 + \sqrt{148}) > 1/13$. Let X be the set of functions x from $\mathbb{Z}^3$ to $[1/13, 1]$. For $x \in X$, $0 \le S_x(s) \le 12$, so $U(x)(s) = R(S_x(s))$ defines a map U of X into itself; and $x \le y$ pointwise gives $U(x) \ge U(y)$. So $U^2 = U \circ U$ preserves the pointwise order. Start from the constant $x_0 = 1/13$ and put $x_{k+1} = U^2(x_k)$. Then $x_0 \le x_1$, and by induction $x_k \le x_{k+1}$; so at each state x_k increases to a limit $x_\infty(s) \le 1$. The value $U^2(x)(s)$ is a continuous function of the values of x at the states within distance 2 of s, so $U^2(x_\infty) = \lim_k x_{k+1} = x_\infty$. Then $U(x_\infty)$ is a fixed point of U^2 as well. The value $U(x)(s)$ depends only on x at the neighbours of s, whose cost has the other parity. Put $x(s) = U(x_\infty)(s)$ when $|s|_1$ is odd and $x(s) = x_\infty(s)$ when it is even. At an odd state the neighbours are even, so $U(x)(s) = U(x_\infty)(s) = x(s)$; at an even state they are odd, so $U(x)(s) = U^2(x_\infty)(s) = x_\infty(s) = x(s)$. So $U(x) = x$, and $g = \sqrt{w}\,x$ is a positive solution of (26.3).

Step 5: symmetry. A signed permutation σ of the three axes keeps $|s|_1$, so it keeps w, and it carries the neighbours of s to the neighbours of $\sigma(s)$. So $g \circ \sigma$ is again a positive solution, and $g \circ \sigma = g$ by Step 3. The six unit vectors are carried to one another by such permutations, so g takes one value on them. By Step 2 the solution gives a voxel tick with positive holds and hold-return balance, and by Steps 1 and 3 every such tick is this one. □

By the theorem every post of Recognition Science's tick is positive, and by Step 3 of its proof every hold is at least $1/169$. That this kernel is the tick of Recognition Science's history

dynamics rests on the premises from which Recognition Science derives it: imbalance states, the T9 weight, detailed balance and hold-return balance. The theorems below concern the kernel. Its entries are not known in closed form: they come from the solution of (26.3), the maximum-entropy equation of that dynamics. We use five numerical properties of them. This book does not prove them; they are stated inputs, obtained by interval computations on the kernel's entries that we do not reproduce:

(T1) every hold exceeds 0.135;

(T2) it has the Poincaré gap $\gamma = 39/5000$ on $\mathbb{Z}^3$ (Definition 26.27);

(T3) $\varphi^9 P^2(0,0) - 1 < 15.26$ and $\varphi^9 P^8(0,0) - 1 < 3.151$;

(T4) $P^{10}(0,0) > 0.045166$ and $e_5/e_4 \geq 0.879^2$, for the even-return excess e_n of Section 26.6;

(T5) the hold at the vacuum lies between 0.18 and 0.19.

Every theorem in this section and the next two is proved for every voxel tick with the stated properties. The five facts enter only the statements named for Recognition Science's tick; each such statement names the facts it uses, and is proved here from them.

Definition 26.22 (Walled ticks and inward-closed sets)**.** Let S be a finite set of states containing the vacuum. The *walled tick* P_S on S moves as P inside S and turns every post that would leave S into a hold:

$$P_S(x,y) = P(x,y)\ (x \neq y), \qquad P_S(x,x) = P(x,x) + \sum_{m\,:\,x+m\notin S} P(x,x+m).$$

Its law is $\pi_S(x) = w(x)/\sum_{s\in S} w(s)$. The set S is *inward-closed* when every inward move from a state of S stays in S. Every ball B_N is inward-closed and contains the vacuum.

Theorem 26.23 (The walled tick is a second-law step, strict on inward-closed sets)**.** *Let P be a voxel tick and S a finite set of states containing the vacuum.*

(a) P_S is stochastic and satisfies $w(x)P_S(x,y) = w(y)P_S(y,x)$ on S; so $\pi_S P_S = \pi_S$, and $q \mapsto qP_S$ is a $\mathcal{J}$-descent operator with equilibrium π_S.

(b) If S is inward-closed and every post of P is positive, then $D(qP_S \,\|\, \pi_S) < D(q \,\|\, \pi_S)$ for every distribution $q \neq \pi_S$ on S.

No condition on the holds of P is needed.

Proof. (a) The six posts from x land on six distinct states, none equal to x. In the row of P_S at x the posts that stay in S keep their place and the others are added to the hold, so the row sums to 1. Off the diagonal $P_S = P$, so detailed balance is inherited, and summing it over x gives stationarity. Theorem 26.10 gives the J-descent operator.

(b) By Theorem 26.15(b) it suffices to show that P_S has one merging class. (i) Let $x \in S$ have $|x|_1 \geq 2$, let x' be x after an inward move and x'' be x' after an inward move; both lie in S.

Then x feeds x' by its inward post, and x'' feeds x' by the reverse, outward, post, which stays in S. So x and x'' lie in one class. Repeating, every state of even cost lies in the class of the vacuum, and every state of odd cost in the class of a unit vector. (ii) Every unit vector in S feeds the vacuum, so all of them lie in one class. (iii) Let x^* be a state of largest cost in S, and x' its inward neighbour. An outward move from x^* leaves S, so $P_S(x^*, x^*) > 0$, and x' feeds x^* by an outward post. So x^* and x', whose costs differ by one, lie in one class, which joins the even and the odd states. □

Theorem 26.24 (Doeblin's condition at window $2R$)**.** *Let P be a voxel tick with every hold at least $h \geq 0$ and every post at least $e \geq 0$, and let S be a finite inward-closed set containing the vacuum with $|s|_1 \leq R$ on S. Then for all $x, y \in S$,*

$$P_S^{2R}(x, y) \geq \min(h, e)^{2R}\, \pi_S(y),$$

and therefore $D(qP_S^{2Rm} \,\|\, \pi_S) \leq \big(1 - \min(h, e)^{2R}\big)^m D(q \,\|\, \pi_S)$ for every distribution q on S and every m.

Proof. An entry of a power of a nonnegative matrix is at least the product along any one path. Take the path that makes $|x|_1$ inward moves from x to the vacuum, staying in S by inward closure; holds at the vacuum $2R - |x|_1 - |y|_1$ times, each at least $P(0, 0) \geq h$; and then the inward path of y in reverse, $|y|_1$ outward moves inside S. It has $2R$ steps, each with probability at least $\min(h, e)$, and $\pi_S(y) \leq 1$. The rate is Theorem 26.16 with $N = 2R$ and $\delta = \min(h, e)^{2R}$. □

For Recognition Science's tick both bounds can be made explicit, and the window cannot be shortened.

Proposition 26.25 (Posts and Doeblin windows of Recognition Science's tick)**.**

(a) With (T1), every post of Recognition Science's tick lies in $[0.1061, 0.3345]$.

(b) With (T1), on the ball B_N the walled tick satisfies $P_{B_N}^{2N}(x, y) \geq 0.1061^{2N} \pi_{B_N}(y)$, where $0.1061^2 = 0.011257$. Every δ with $\delta\, \pi_{B_N}(y) \leq P_{B_N}^{2N}(x, y)$ for all x, y satisfies $\delta \leq \varphi^9 (0.3345^2 \varphi)^N \leq 76.02 \cdot 0.1811^N$, which is below 1 from $N = 3$ on.

(c) For every voxel tick and every N, a minorisation $\delta\, \pi_{B_N}(y) \leq P_{B_N}^{M}(x, y)$ for all $x, y \in B_N$ with $\delta > 0$ requires $M \geq 2N$.

Proof. (a) Let s, s' be neighbours. Detailed balance and hold-return balance give

$$\big(\pi(s)P(s, s')\big)^2 = \pi(s)\pi(s')\, P(s, s')P(s', s) = \pi(s)\pi(s')\, P(s, s)P(s', s') > 0.135^2\, \pi(s)\pi(s'),$$

so $P(s, s') > 0.135\, \rho^{(|s'|_1 - |s|_1)/2}$. An outward post exceeds $0.135\sqrt{\rho} > 0.135 \cdot 0.786 > 0.1061$, and an inward post exceeds $0.135/\sqrt{\rho} > 0.17$. In each row the hold exceeds 0.135 and five other posts exceed 0.1061, so every post is below $1 - 0.135 - 5 \cdot 0.1061 = 0.3345$.

(b) The lower bound is Theorem 26.24 with $R = N$, $h = 0.135$ and $e = 0.1061$. For the upper bound take $x = (N, 0, 0)$ and $y = (-N, 0, 0)$. A path of k ticks from x to $x - (k, 0, 0)$ must lower the first coordinate at every tick, since each tick moves ℓ^1-distance at most one; so only the

straight path contributes, its steps are posts of P inside B_N, and $P^{2N}_{B_N}(x,y) \le 0.3345^{2N}$. The total weight of B_N is at most φ^9, so $\pi_{B_N}(y) \ge \rho^N/\varphi^9$, and $\delta \le 0.3345^{2N}\varphi^9\rho^{-N} = \varphi^9(0.3345^2\varphi)^N$, with $0.3345^2\varphi = 0.18104$ and $\varphi^9 = 76.013$. At $N = 3$ the bound is 0.451.

(c) $P^M_{B_N}(x,y) = 0$ when $|x-y|_1 > M$, and $(N,0,0)$ and $(-N,0,0)$ are $2N$ apart while $\pi_{B_N} > 0$. □

So the walled form of Recognition Science's tick is strict on every inward-closed set (Theorem 26.23(b); its posts are positive by Theorem 26.21), and, given (T1), its Doeblin constant at window $2N$ decays exponentially in the radius. A rate that does not degrade with the radius needs a different tool, a spectral gap; it comes in Theorem 26.32. On $\mathbb{Z}^3$ itself the wall is never reached early.

Proposition 26.26 (On a ball the tick is a J-descent operator)**.** *Let P be a voxel tick, a a state and n, N natural numbers with $|a|_1 + n \le N$. Then $P^n_{B_N}(a,\cdot) = P^n(a,\cdot)$ and*

$$D\big(P^n(a,\cdot)\,\|\,\pi_{B_N}\big) = D_n(a) + \log\pi(B_N), \qquad \pi_{B_N} = \pi/\pi(B_N).$$

So on every ball the walled tick is a $\mathcal{J}$-descent operator with equilibrium π_{B_N} whose evolution from δ_a is the tick's own law for the first $N - |a|_1$ ticks.

Proof. After $k < n$ ticks the law lives on $B_{|a|_1+k} \subseteq B_{N-1}$, from which no post leaves B_N, so P_{B_N} and P act alike on it; induct on k. For the relative entropy, each term with $G(s) = P^n(a,s) > 0$ splits as $G\log(G/\pi) + G\log\pi(B_N)$, and $\sum G = 1$. □

Definition 26.27 (Poincaré gap)**.** For signed measures X, Y on $\mathbb{Z}^3$, one of them finitely supported, put $\langle X,Y\rangle_\pi = \sum_s X(s)Y(s)/\pi(s)$, and write XP for $(XP)(s') = \sum_s X(s)P(s,s')$. A voxel tick P has *Poincaré gap* γ on $\mathbb{Z}^3$ when every finitely supported X with $\sum_s X(s) = 0$ satisfies

$$\langle X,X\rangle_\pi - \langle X,XP\rangle_\pi \ge \gamma\langle X,X\rangle_\pi.$$

Theorem 26.28 (The rate from a point start)**.** *Let P be a voxel tick with every hold at least h and Poincaré gap γ, with $2h - 1 < 1 - \gamma$ and $(1-\gamma) + (2h-1) \ge 0$.*

(a) For every state a and every $n \ge 0$,

$$D_n(a) \le \log\Big(1 + (1-\gamma)^{2n}\big(\varphi^{9+|a|_1} - 1\big)\Big),$$

with equality at $n = 0$.

(b) For every finitely supported start law μ, $D(\mu P^n\,\|\,\pi) \le \log\big(1 + (1-\gamma)^{2n}\chi^2(\mu)\big)$, where $\chi^2(\mu) = \langle\mu,\mu\rangle_\pi - 1$.

(c) For all n_0 and n, $D_{n_0+n}(0) \le \log\big(1 + (1-\gamma)^{2n}(\varphi^9 P^{2n_0}(0,0) - 1)\big)$.

Proof. Step 1: relative entropy below the log of the energy. For a finitely supported law G, concavity of log, with the weights $G(s)$, gives $D(G\,\|\,\pi) = \sum_{G>0} G\log(G/\pi) \le \log\sum_{G>0} G\cdot(G/\pi) =$

$\log\langle G, G\rangle_\pi$. For $G = P^n(a,\cdot)$, detailed balance gives $\langle G, G\rangle_\pi = \sum_s P^n(a,s)P^n(s,a)/\pi(a) = P^{2n}(a,a)/\pi(a)$, which we call $E_n(a)$.

Step 2: one tick contracts the energy. Write $TX = XP$. On finitely supported measures T keeps finite support and total mass, and detailed balance makes it symmetric: $\langle X, TY\rangle_\pi = \langle TX, Y\rangle_\pi$. For every finitely supported Z, with $z = Z/\pi$,

$$\langle Z, Z\rangle_\pi + \langle Z, TZ\rangle_\pi = \frac{1}{2}\sum_{s,s'} \pi(s)P(s,s')\big(z(s) + z(s')\big)^2 \geq 2h\,\langle Z, Z\rangle_\pi,$$

keeping only the terms $s' = s$. So $\langle Z, TZ\rangle_\pi \geq a\langle Z, Z\rangle_\pi$ with $a = 2h - 1$. Let X be finitely supported with total mass 0, put $b = 1 - \gamma$, $c_k = \langle X, T^k X\rangle_\pi$, $Y = TX - aX$ and $Z = bX - TX$. Expanding with the symmetry of T gives the identity

$$(b-a)(b^2c_0 - c_2) = \big[b\langle Y, Y\rangle_\pi - \langle Y, TY\rangle_\pi\big] + \big[\langle Z, TZ\rangle_\pi - a\langle Z, Z\rangle_\pi\big] + (b^2 - a^2)(bc_0 - c_1).$$

The first bracket is nonnegative by the gap, since Y has total mass 0; the second by the hold bound; and the third term because $b > a$, $b + a \geq 0$ and $bc_0 - c_1 \geq 0$ by the gap. Since $b - a > 0$, $\langle TX, TX\rangle_\pi = c_2 \leq (1-\gamma)^2\langle X, X\rangle_\pi$, and by induction $\langle T^n X, T^n X\rangle_\pi \leq (1-\gamma)^{2n}\langle X, X\rangle_\pi$. No spectral theorem is used.

Step 3: truncation. $\delta_a - \pi$ is not finitely supported, so we truncate π. Let $Z_L = \pi(B_L)$ for $L \geq |a|_1 + 2n$, put $M = L - n$, and $X = \delta_a - \pi 1_{B_L}/Z_L$. Then $\langle X, X\rangle_\pi = 1/\pi(a) - 2/Z_L + 1/Z_L = 1/\pi(a) - 1/Z_L$. For $s \in B_M$, every state reachable from s in n ticks lies in B_L, so by detailed balance $(\pi 1_{B_L} P^n)(s) = \pi(s)\sum_x P^n(s,x) = \pi(s)$. Keeping in $\langle T^n X, T^n X\rangle_\pi$ only the terms with $s \in B_M$, where $P^n(a,\cdot)$ lives, Step 2 gives

$$E_n(a) - \frac{2}{Z_L} + \frac{Z_M}{Z_L^2} \leq (1-\gamma)^{2n}\Big(\frac{1}{\pi(a)} - \frac{1}{Z_L}\Big).$$

As $L \to \infty$, Z_L and Z_M tend to 1, so $E_n(a) - 1 \leq (1-\gamma)^{2n}\big(1/\pi(a) - 1\big)$, and $1/\pi(a) = \varphi^9\rho^{-|a|_1} = \varphi^{9+|a|_1}$.

Step 4. Combining, $D_n(a) \leq \log E_n(a) \leq \log\big(1 + (1-\gamma)^{2n}(\varphi^{9+|a|_1} - 1)\big)$. At $n = 0$ both sides are $-\log\pi(a)$.

(b) is the same argument with μ in place of δ_a: Step 1 bounds $D(\mu P^n \,\|\, \pi)$ by $\log\langle \mu P^n, \mu P^n\rangle_\pi$, and Step 3 with $X = \mu - \pi 1_{B_L}/Z_L$ gives $\langle \mu P^n, \mu P^n\rangle_\pi - 1 \leq (1-\gamma)^{2n}\chi^2(\mu)$. (c) is (b) for $\mu = P^{n_0}(0,\cdot)$, whose χ^2 is $\langle \mu, \mu\rangle_\pi - 1 = P^{2n_0}(0,0)/\pi(0) - 1$ by Step 1. □

Conditions and scope.

Base and premises

A voxel tick on $\mathbb{Z}^3$, a lower bound on its holds, a Poincaré gap, and the two inequalities linking them.

Conclusion

An explicit bound for the relative entropy to the T9 law at every tick, from every start, tight at the start.

Not claimed

That a tick is a unit of physical time, or that the T9 law is the Gibbs law of a J-cost; the latter holds only in the sense of Corollary 26.29(c).

Corollary 26.29 (The rate of Recognition Science's tick)**.** *Let P be Recognition Science's tick, and use (T1)–(T3).*

(a) For every state a and every n,
$D_n(a) \le \log\bigl(1 + (4961/5000)^{2n}(\varphi^{9+|a|_1} - 1)\bigr)$*, where* $4961/5000 = 0.9922$.

(b) $D_N(0) \le \log\bigl(1 + 15.26 \cdot (4961/5000)^{2(N-1)}\bigr)$ *for* $N \ge 1$*, and*
$D_N(0) \le \log\bigl(1 + 3.151 \cdot (4961/5000)^{2(N-4)}\bigr)$ *for* $N \ge 4$.

(c) On every ball B_N there is a $\mathcal{J}$-descent operator with equilibrium π_{B_N} whose n-fold evolution from δ_a is $P^n(a,\cdot)$ and stays within the bound of (a) for $|a|_1 + n \le N$. For a recognition system at temperature T_R, there are costs X on B_N whose Gibbs law is π_{B_N}, and the free-energy excess along this evolution is at most T_R times the bound of (a).

Proof. With $h = 0.135$ and $\gamma = 39/5000$: $2h - 1 = -0.73 < 1 - \gamma = 0.9922$ and $0.9922 - 0.73 \ge 0$, so Theorem 26.28 applies. (b) is part (c) of that theorem at $n_0 = 1$ and $n_0 = 4$, with (T3). For (c), Proposition 26.26 turns the walled evolution into the tick's law, and $D(P^n(a,\cdot) \,\|\, \pi_{B_N}) = D_n(a) + \log \pi(B_N) \le D_n(a)$. Every positive law on a finite set is a Gibbs law: take X with $J(X(x)) = -T_R \log \pi_{B_N}(x)$, possible because J takes every value in $[0,\infty)$ and $\pi_{B_N} \le 1$; then $Z = 1$, and $F_R(q) - F_R(\pi_{B_N}) = T_R\, D(q \,\|\, \pi_{B_N})$ by Theorem 26.10. □

In numbers: from the vacuum the bound of (a) starts at $9 \log \varphi \approx 4.331$ nats, the value of $D_0(0)$, and falls below one nat from tick 242 on; the first bound of (b) does so from tick 141, and the second from tick 43. These are proved worst cases, computed from (T1)–(T3), not relaxation times. Part (c) is the rate that Recognition Science's second-law notes ask of their Lyapunov function, and Proposition 26.18 showed that it fails for J-descent operators in general; for the tick itself, given (T1)–(T3), it is a theorem, on every ball, in both its relative-entropy and its free-energy form.

26.5 The Metropolis tick on the line, and a gap for every ball

The Metropolis tick has entries in $\mathbb{Q}(\varphi)$, so $\mathbb{R}_\delta$ represents it exactly, and its second law with a rate can be proved there with no omniscience and no choice. The decisions the proof needs are all about integer triples.

Definition 26.30 (Enumerated sets and the walled Metropolis tick on the line)**.** An *enumerated set* E is a finite list $e_0, \dots, e_{n-1}$ of distinct voxel states that contains the vacuum and contains every state reached from a listed state by an inward move. Whether a state is listed is found by searching the list, which compares integer triples. Let ρ be the point $\varphi - 1$ of $\mathbb{R}_\delta$, so $\rho^2 = 1 - \rho$. The *walled Metropolis tick* K_E has, for $i \ne j$, the entry $\frac{1}{6}$ if e_j is e_i after an inward move, $\rho/6$ if it is e_i after an outward move, and 0 otherwise; the diagonal entry is 1 minus the rest of the row. Its law is $\pi_E(i) = \rho^{|e_i|_1} / \sum_k \rho^{|e_k|_1}$, with levels $\ell_i = \log \pi_E(i)$.

Theorem 26.31 (A second law with a rate on the line)**.** *Let E be an enumerated set with $|e_i|_1 \le R$ for every i, and put $c = \rho^2/6 \approx 0.063661$. Write $D = D_\eta(\cdot \,\|\, \ell)$.*

(a) Every diagonal entry of K_E is at least $\rho^2/2$.

(b) K_E is stochastic, $\pi_E(i)K_E(i,j) = \pi_E(j)K_E(j,i)$, and π_E is stationary.

(c) $D(qK_E) \le D(q)$ for every $q \ge 0$.

(d) $D(qK_E) < D(q)$ for every distribution q with some $q_i \# \pi_E(i)$.

(e) $D(qK_E^{2Rm}) \le (1 - c^{2R})^m D(q)$ for every distribution q and every m.

All five statements are free. On the ball of radius one, with seven states, the factor in (e) is $1 - c^2 \approx 0.995947$ per two ticks.

Proof. (a) Which entry a move gets is decided by comparing integer costs and searching the list. Along each axis at most one move is inward, so the two posts of an axis sum to at most $(1 + \rho)/6$, the six posts to at most $(1 + \rho)/2$, and the diagonal entry is at least $1 - (1 + \rho)/2 = (1 - \rho)/2 = \rho^2/2$. No decision about which posts are kept is needed.

(b) An inward move from x and the reverse, outward, move from its target are both kept, by inward closure, and $\rho^{|x|_1} \cdot \frac{1}{6} = \rho^{|x|_1 - 1} \cdot \frac{\rho}{6}$. So detailed balance holds entry by entry, and summing it gives stationarity.

(c) is Theorem 26.7 with the stationary weights $e^{\ell_i} = \pi_E(i)$.

(d) By (a) the tick is lazy, and every index reaches the vacuum through inward moves inside E, so it is connected; Theorem 26.17(b) applies.

(e) As in Theorem 26.24, follow the path from e_i to the vacuum by inward moves, hold at the vacuum, and reach e_j by the reverse of its inward path. It has $2R$ steps, each with probability at least c: $\frac{1}{6} \ge c$, $\rho/6 \ge \rho^2/6$, and $\rho^2/2 \ge c$. Since $\pi_E(j) \le 1$, $K_E^{2R}(i,j) \ge c^{2R}\pi_E(j)$, and Theorem 26.17(a) gives the rate. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$, the golden point ρ, and a finite list of integer triples closed under inward moves.

Conclusion

Relative entropy to the walled T9 law never rises, falls strictly from every law apart from equilibrium, and falls geometrically over windows of $2R$ ticks; no omniscience and no choice.

Not claimed

The same for Recognition Science's own tick on $\mathbb{R}_\delta$: its entries solve a maximum-entropy equation and are not represented here. Under the reading, K_E is the classical walled Metropolis tick, entry for entry.

The Doeblin route gives a factor that decays with the radius. The next theorem gives a rate that does not: a Poincaré inequality for the walled tick with one constant for every inward-closed set. It is proved in classical mathematics, by canonical paths through the vacuum, a method of Jerrum and Sinclair and of Diaconis and Stroock [183, 179], here with weights along the path.

Theorem 26.32 (A spectral gap for every inward-closed set)**.** *Let P be a voxel tick whose inward posts are all at least $e > 0$, and let S be a finite inward-closed set containing the vacuum. Then every function f on S satisfies*

$$\operatorname{Var}_{\pi_S}(f) \le \frac{1030}{e}\,\mathcal{E}_S(f), \qquad \mathcal{E}_S(f) = \tfrac{1}{2}\sum_{x,y\in S} \pi_S(x)P_S(x,y)\big(f(x)-f(y)\big)^2,$$

so the walled tick has spectral gap at least $e/1030$, whatever the size of S. For Recognition Science's tick, with (T1), the constant is $10300000/1061 \approx 9707.8$ and the gap exceeds $1.03\cdot 10^{-4}$; for the Metropolis tick it is 6180, a gap of at least $1/6180 \approx 1.618\cdot 10^{-4}$; both on every ball B_N.

Proof. Let $L(u)$ be u after lowering its first nonzero coordinate by one in absolute value, and $L(0) = 0$. Inward closure keeps the path $x, Lx, L^2x, \dots, 0$ inside S; it has $|x|_1$ steps. Write w for the weight and $W = \sum_{s\in S} w(s)$.

(1) Mean. $\operatorname{Var}_{\pi_S}(f) \le \sum_x \pi_S(x)\big(f(x)-f(0)\big)^2$, since the mean minimises the mean square deviation.

(2) Weighted Cauchy–Schwarz along the path. With $g_k = f(L^kx) - f(L^{k+1}x)$ and $s = \frac{9}{10}$,

$$\big(f(x)-f(0)\big)^2 = \Big(\sum_{k<|x|_1} g_k\Big)^2 \le \Big(\sum_k s^k\Big)\Big(\sum_k \frac{g_k^2}{s^k}\Big) \le 10 \sum_{k<|x|_1} \frac{g_k^2}{s^k}.$$

(3) Exchange of sums. Put $G(u) = (f(u)-f(Lu))^2$ and $F(u) = \sum_{x\in S}\sum_{k<|x|_1} [L^kx = u]\, w(x)/s^k$. Then $\sum_x w(x)\sum_k G(L^kx)/s^k = \sum_{u\ne 0} G(u)F(u)$.

(4) The load on a state. A path through $u \ne 0$ either starts at u or passed one step earlier through a state $v \in S$ with $Lv = u$, so $F(u) \le w(u) + \frac{10}{9}\sum_{v\in S,\,Lv=u} F(v)$. The predecessors are explicit. If $u_1 \ne 0$, the only one is $u + \operatorname{sgn}(u_1)e_1$. If $u_1 = 0 \ne u_2$, there are three: $u \pm e_1$ and $u + \operatorname{sgn}(u_2)e_2$. If $u_1 = u_2 = 0 \ne u_3$, there are five: $u \pm e_1$, $u \pm e_2$ and $u + \operatorname{sgn}(u_3)e_3$. Each has cost $|u|_1 + 1$ and weight $\rho\, w(u)$. Give the three types of u the constants $C = \frac{7}{2}$, 19 and 103. With $\frac{10}{9}\rho < \frac{10}{9}\cdot 0.6181 < 0.68678$,

$$\begin{aligned} 1 + 0.68678\cdot\tfrac{7}{2} &= 3.404 \le \tfrac{7}{2},\\ 1 + 0.68678\cdot\big(\tfrac{7}{2}+\tfrac{7}{2}+19\big) &= 18.857 \le 19,\\ 1 + 0.68678\cdot\big(7+38+103\big) &= 102.64 \le 103. \end{aligned}$$

Induction from the states of largest cost in S, which have no predecessor in S, inward, gives $F(u) \le C(u)\, w(u) \le 103\, w(u)$.

(5) Edges. The maps $u \mapsto (u, Lu)$ and $u \mapsto (Lu, u)$ on $S \setminus \{0\}$ are injective with disjoint images, and detailed balance gives the two families equal weight; so $\sum_{u\ne 0} w(u)P(u,Lu)G(u) \le \frac{1}{2}\sum_{x,y\in S} w(x)P(x,y)(f(x)-f(y))^2$.

(6) Combine. $P(u, Lu) \geq e$, because Lu is an inward move. Dividing by W,

$$\mathrm{Var}_{\pi_S}(f) \leq \frac{10}{W} \sum_{u \neq 0} G(u)F(u) \leq \frac{10 \cdot 103}{eW} \sum_{u \neq 0} w(u)P(u, Lu)G(u) \leq \frac{1030}{e}\, \mathscr{E}_S(f),$$

where in $\mathscr{E}_S$ the walled tick may replace P, because the two agree off the diagonal and diagonal terms vanish. For Recognition Science's tick every post, inward ones included, is at least 0.1061 (Proposition 26.25(a)), and for the Metropolis tick the inward posts equal $\frac{1}{6}$. □

Conditions and scope.

Base and premises
A voxel tick with inward posts bounded below, and a finite inward-closed set containing the vacuum.

Conclusion
One Poincaré constant, $1030/e$, for every such set.

Not claimed
The size of the true gap: $1030/e$ is a proved worst case, not an estimate of the actual relaxation.

So the Doeblin constant of Proposition 26.25 decays like 0.18^N, while the gap does not degrade at all. Two statements remain open: a contraction of χ^2 at every tick that is uniform in the ball, and a form of the gap on $\mathbb{R}_\delta$. Some dependence on the start, however, cannot be removed.

Theorem 26.33 (No rate is uniform in the start)**.** *For every voxel tick P, every number of ticks n and every level M there is a c such that $D_n(a) \geq M$ for every start a with $|a|_1 \geq c$. Quantitatively, if $L + n < |a|_1$ then $D_n(a) \geq -\log\bigl(1 - \pi(B_L)\bigr)$. So the factor $\varphi^{9+|a|_1} - 1$ in Theorem 26.28 cannot be dropped.*

Proof. (i) A finitely supported law G carried by a set T has $D(G \,\|\, \pi) \geq -\log \pi(T)$: the inequality $\log y \geq 1 - 1/y$ at $y = G\pi(T)/\pi$ gives $G\log(G/\pi) \geq G - \pi/\pi(T) - G\log\pi(T)$ for each term with $G > 0$, and summing over T gives $D \geq 1 - 1 - \log\pi(T)$. (ii) After n ticks from a the law lives on $\{s : |s|_1 \geq |a|_1 - n\}$, since each tick changes the cost by at most one; if $L + n < |a|_1$, this set misses B_L, so its π-mass is at most $1 - \pi(B_L)$. (iii) $\pi(B_L) \to 1$, so $-\log(1 - \pi(B_L)) \to \infty$. □

26.6 The pace of the spine

A *spine* is a finite set of voxels. Started from the empty record, every voxel at the vacuum, each voxel relaxes toward the T9 law. The bound of Corollary 26.29 is a worst case. This section finds the exact pace, shows how a spine of many voxels settles, and shows what couplings between voxels can do. Everything here is proved in classical mathematics.

Definition 26.34 (The even-return excess and the exact rate)**.** For a voxel tick P the *even-return excess* is $e_n = P^{2n}(0,0) - \pi(0)$, and the *exact rate* of P is $r(P) = \sup_n e_{n+1}/e_n$.

Lemma 26.35 (The excess decays at exactly the rate $r(P)$)**.** *For every voxel tick P:*

(a) $e_n/\pi(0) = \sum_s \pi(s)\big(P^n(0,s)/\pi(s) - 1\big)^2 > 0$;

(b) $e_{n+1}^2 \le e_n e_{n+2}$, *so the ratios* e_{n+1}/e_n *are nondecreasing; they are at most* 1 *and tend to* $r(P)$, *and* $0 < r(P) \le 1$;

(c) $e_n \le e_0\, r(P)^n$, *and* $e_n \ge e_m (e_{m+1}/e_m)^{n-m}$ *for* $n \ge m$;

(d) if every hold is at least h *and* P *has Poincaré gap* γ, *with* $2h-1 < 1-\gamma$ *and* $(1-\gamma)+(2h-1) \ge 0$, *then* $r(P) \le (1-\gamma)^2$.

Proof. (a) With $G_n = P^n(0,\cdot)$, detailed balance gives $P^{2n}(0,0) = \sum_s G_n(s) P^n(s,0) = \pi(0)\sum_s G_n(s)^2/\pi(s)$, and since G_n and π both sum to 1, $\sum_s G_n^2/\pi - 1 = \sum_s \pi (G_n/\pi - 1)^2$. The terms outside B_n, where $G_n = 0$, equal $\pi(s) > 0$.

(b) With $u_n = G_n/\pi - 1$, the same computation gives $\sum_s \pi(s) u_n(s) u_{n+2}(s) = P^{2n+2}(0,0)/\pi(0) - 1 = e_{n+1}/\pi(0)$, and the Cauchy–Schwarz inequality for the weights π gives $e_{n+1}^2 \le e_n e_{n+2}$. If some ratio were $q > 1$, the later e_n would grow like q^n, but $e_n \le 1$. So the ratios increase to their supremum.

(c) Write e_n as e_0, or e_m, times a product of consecutive ratios, and bound each ratio by $r(P)$, or below by e_{m+1}/e_m.

(d) Step 3 of the proof of Theorem 26.28 at $a = 0$ gives $e_n/\pi(0) \le (1-\gamma)^{2n}(\varphi^9 - 1)$. A ratio $q > (1-\gamma)^2$ would give $e_n \ge e_m q^{n-m}$, which is too large for large n. □

Theorem 26.36 (The pace of one voxel)**.** *For every voxel tick P and every n,*

$$2e_n^2 \le D_{2n}(0) \qquad \text{and} \qquad D_n(0) \le \varphi^9 e_n.$$

Consequently $D_N(0)^{1/N} \to r(P)$ *as* $N \to \infty$, *and for* $m \le n$, $D_{2n}(0) \ge 2(e_m/q^m)^2 (q^2)^n$ *with* $q = e_{m+1}/e_m$.

Proof. Lower bound. Let $G = P^{2n}(0,\cdot)$ and $g = G(0) = e_n + \pi(0) \ge \pi(0)$. The log-sum inequality $\sum_i a_i \log(a_i/b_i) \ge A \log(A/B)$, with $A = \sum a_i$ and $B = \sum b_i$, follows by summing $a_i \log \frac{a_i B}{b_i A} \ge a_i - b_i A/B$, which is $\log y \ge 1 - 1/y$. Applied to the states other than the vacuum, whose π-mass is at most $1 - \pi(0)$, it gives

$$D_{2n}(0) \ge g \log \frac{g}{\pi(0)} + (1-g) \log \frac{1-g}{1-\pi(0)} \ge 2\big(g - \pi(0)\big)^2 = 2e_n^2.$$

The second inequality is the two-point case of Pinsker's inequality: for fixed $b \in (0,1)$ the function $\psi(a) = a \log \frac{a}{b} + (1-a)\log \frac{1-a}{1-b} - 2(a-b)^2$ has $\psi(b) = \psi'(b) = 0$ and $\psi''(a) = 1/a + 1/(1-a) - 4 \ge 0$.

Upper bound. Step 1 of the proof of Theorem 26.28 and $\log y \le y - 1$ give $D_n(0) \le P^{2n}(0,0)/\pi(0) - 1 = \varphi^9\big(e_n + \pi(0)\big) - 1 = \varphi^9 e_n$.

The pace. Write $u_N = D_N(0)$. By the upper bound and Lemma 26.35(c), $u_N \le \varphi^9 e_0\, r(P)^N$, so $\limsup u_N^{1/N} \le r(P)$. For $a < r(P)$ choose m with $q = e_{m+1}/e_m > a$. For $k \ge m$, $u_{2k} \ge 2e_k^2 \ge 2(e_m/q^m)^2 q^{2k}$. The relative entropy never rises from one tick to the next (apply Proposition 26.26 and Theorem 26.23(a) on a ball large enough), so $u_{2k+1} \ge u_{2k+2}$. Hence $u_N \ge c\,q^N$ for all $N \ge 2m$ with $c = 2(e_m/q^m)^2 q$, and $\liminf u_N^{1/N} \ge q > a$. The last statement is the lower bound with Lemma 26.35(c). □

The bound $2e_n^2 \le D_{2n}(0)$ uses the sharp constant 2 in Pinsker's inequality [188], due to Csiszár [172]. For Recognition Science's tick the bracket becomes a numerical interval. One part of it rests on a named hypothesis about a finite computation.

The return-probability hypothesis. We name one statement and use it only where it is named:

(R) a specified interval computation of the vacuum return probabilities of Recognition Science's tick returns, at tick 800, an upper end at most $h_{800} = 60670985342324649/2^{62}$ and, at tick 802, a lower end at least $\ell_{802} = 60670956941227723/2^{62}$.

The computation's enclosures contain the true values, so (R) gives $P^{800}(0,0) \le h_{800}$ and $\ell_{802} \le P^{802}(0,0)$, and these two inequalities are all we use. Statement (R) concerns the output of a finite computation; we state it as a hypothesis and do not prove it.

Corollary 26.37 (The pace of Recognition Science's tick)**.** *Let P be Recognition Science's tick and $r = r(P)$.*

(a) With (T1), (T2) and (T4), $0.879^2 \le r \le (4961/5000)^2$, that is $r \in [0.7726, 0.98447]$; in particular $r < 1$. Moreover $D_{2n}(0) \ge 2 \cdot 0.032^2 \cdot (0.879^2)^{2(n-5)}$ for every $n \ge 5$.

(b) Under hypothesis (R), $r \ge 0.9898^2 = 0.97970$, and for every $n \ge 400$

$$D_{2n}(0) \ge 2\,(1.525 \cdot 10^{-7})^2\,(0.9898^2)^{2(n-400)}.$$

(c) For every start a and every N, the entropy produced at all later ticks adds up to the relative entropy still present: $\sum_{i\ge 0}\big(D_{N+i}(a) - D_{N+i+1}(a)\big) = D_N(a)$, and with (T1), (T2) this is at most $\log\big(1 + (4961/5000)^{2N}(\varphi^{9+|a|_1} - 1)\big)$.

Proof. (a) The upper bound is Lemma 26.35(d) with $h = 0.135$ and $\gamma = 39/5000$. By (T4) and Lemma 26.35(b), $r \ge e_5/e_4 \ge 0.879^2$, and $e_6/e_5 \ge 0.879^2$ as well. Since $\pi(0) = 17\sqrt{5} - 38 < 0.013157$, (T4) gives $e_5 > 0.045166 - 0.013157 > 0.032$, so $e_n \ge 0.032\,(0.879^2)^{n-5}$ for $n \ge 5$, and Theorem 26.36 gives the floor.

(b) Hypothesis (R) gives $e_{400} \le h_{800} - \pi(0) < 3.0533 \cdot 10^{-7}$ and $e_{401} \ge \ell_{802} - \pi(0) > 2.9916 \cdot 10^{-7}$, so $e_{401}/e_{400} > 0.97979 > 0.9898^2$, and r is at least this ratio. The ratios are at most 1, so $e_{400} \ge e_{401} > 1.525 \cdot 10^{-7}$, and the floor follows as in (a).

(c) The partial sums telescope to $D_N(a) - D_{N+m}(a)$, and $D_{N+m}(a) \to 0$ by Corollary 26.29(a). □

So, given (T1), (T2) and (T4), the proved gap rate $(4961/5000)^2 = 0.9844608\ldots$ of Corollary 26.29 is the true pace to within a factor of 1.28, and to within half a percent under hypothesis (R) as well. A spine of independent voxels relaxes at the same pace, because relative entropy adds.

Theorem 26.38 (Relative entropy adds over independent voxels)**.** *Let V be a finite set of voxels and, for each v, let G_v be a law on a finite set of states. Then*

$$D\Big(\bigotimes_v G_v \,\Big\|\, \bigotimes_v \pi\Big) = \sum_v D(G_v \,\|\, \pi).$$

In particular, k voxels moving independently by a voxel tick P from starts a_v have joint relative entropy $\sum_v D_n(a_v)$ after n ticks, and from the empty record $k\,D_n(0)$. For Recognition Science's tick, with (T1)–(T4), for $N \geq 1$ and $n \geq 5$,

$$k\,D_N(0) \leq k \log\big(1 + 15.26 \cdot (4961/5000)^{2(N-1)}\big), \qquad k\,D_{2n}(0) \geq k \cdot 2 \cdot 0.032^2 \cdot (0.879^2)^{2(n-5)}.$$

Proof. At a joint state $p = (p_v)$ with $\prod_v G_v(p_v) > 0$,

$$\log \frac{\prod_v G_v(p_v)}{\prod_v \pi(p_v)} = \sum_v \log \frac{G_v(p_v)}{\pi(p_v)};$$

where some factor vanishes both sides of the term-by-term identity are 0. Summing the vth term against the product law leaves G_v, because every other factor sums to 1. The bounds are Corollary 26.29(b) and Corollary 26.37(a). □

Table 26.2 turns these bounds, and the second bound of Corollary 26.29(b), into windows for spines of Recognition Science's tick, proved from (T1)–(T4). A spine of k voxels is below 0.01 nats at every tick from the second column on: since $\log(1 + x) \leq x$, it suffices that $15.26 \cdot (4961/5000)^{2(N-1)} \leq 0.01/k$, the first bound of Corollary 26.29(b), and for $k = 10^6$ this holds once $N - 1 \geq \log(1.526 \cdot 10^9)/0.015661 \approx 1350.2$. The second bound of Corollary 26.29(b) gives the earlier ticks of the third column: it suffices that $3.151 \cdot (4961/5000)^{2(N-4)} \leq 0.01/k$, and for $k = 10^6$ this holds once $N - 4 \geq \log(3.151 \cdot 10^8)/0.015661 \approx 1249.5$. The spine is above 0.01 nats at every tick up to the fourth column: the floor of the theorem holds at the even tick $2n$, and $D_N(0) \geq D_{2n}(0)$ for $N \leq 2n$ because relative entropy never rises. Under hypothesis (R) the floor of Corollary 26.37(b) gives the fifth column; for $k = 10^6$ it adds nothing, since $10^6 \cdot 2\,(1.525 \cdot 10^{-7})^2 < 0.01$.

The second and third columns grow by about 63.85 ticks per nat of $\log k$, the fourth by about 3.9, and the fifth by about 48.8. These are the upper bound and the two lower bounds on $1/(-\log r)$ that Corollary 26.37 gives for the exact rate r, and Theorem 26.42 below shows that the true settling time grows by exactly $1/(-\log r)$ ticks per nat. The same pace governs the distance of the joint law from equilibrium in ℓ^1.

Table 26.2. Windows for a spine of k independent voxels of Recognition Science's tick from the empty record, proved from (T1)–(T4): the relative entropy $k\,D_N(0)$ is at most 0.01 nats at every tick N from the second column on, by the first bound of Corollary 26.29(b), and from the third column on, by its second bound; it is more than 0.01 nats at every tick up to the fourth column (fifth column: the same under the return-probability hypothesis (R)).

	below 0.01 from tick		above 0.01 through tick	
voxels k	first bound	second bound	proved	under (R)

10^{12}	2234	2136	110	874
10^{24}	3998	3900	218	2222
10^{80}	12232	12134	716	8510

Proposition 26.39 (The spine in ℓ^1)**.** *Let P be a voxel tick with every hold at least h and Poincaré gap γ, with $2h-1<1-\gamma$ and $(1-\gamma)+(2h-1)\geq 0$. Let voxels $v=1,\dots,k$ start from states s_v and move independently for m ticks, with joint law $Q(p)=\prod_v P^m(s_v,p_v)$, and put $\Pi(p)=\prod_v \pi(p_v)$. Then for every finite set B of joint states,*

$$\sum_{p\in B}\lvert Q(p)-\Pi(p)\rvert \leq \Big(\prod_{v=1}^{k}\big(1+(1-\gamma)^{2m}(\varphi^{9+\lvert s_v\rvert_1}-1)\big)-1\Big)^{1/2}.$$

Proof. Take $L\geq m+\max_v\lvert s_v\rvert_1$ so large that the box $\mathscr{B}=(B_L)^k$ contains B; it contains the support of Q. Write $E_m(a)=P^{2m}(a,a)/\pi(a)$. By Step 1 of the proof of Theorem 26.28, $\sum_{s\in B_L}P^m(a,s)^2/\pi(s)=E_m(a)$, and the sum over a product box of a product of functions is the product of the sums, so $\sum_{p\in\mathscr{B}}Q(p)^2/\Pi(p)=\prod_v E_m(s_v)$. Since Q sums to 1 on $\mathscr{B}$ and Π to at most 1,

$$\sum_{p\in\mathscr{B}}\frac{(Q(p)-\Pi(p))^2}{\Pi(p)}=\prod_v E_m(s_v)-2+\Pi(\mathscr{B})\leq\prod_v E_m(s_v)-1.$$

By the Cauchy–Schwarz inequality with the weights Π,

$$\sum_{p\in B}\lvert Q-\Pi\rvert=\sum_{p\in B}\frac{\lvert Q-\Pi\rvert}{\sqrt{\Pi}}\sqrt{\Pi}\leq\Big(\sum_{p\in B}\frac{(Q-\Pi)^2}{\Pi}\Big)^{1/2}\Big(\sum_{p\in B}\Pi\Big)^{1/2}\leq\Big(\prod_v E_m(s_v)-1\Big)^{1/2},$$

and Step 3 of the proof of Theorem 26.28 gives $E_m(a)\leq 1+(1-\gamma)^{2m}(\varphi^{9+\lvert a\rvert_1}-1)$. □

For k voxels of Recognition Science's tick from the empty record, with (T1) and (T2), the bound is at most $\big(\exp(75.02\,k\,(4961/5000)^{2m})-1\big)^{1/2}$, since $1+x\leq e^x$ and $\varphi^9-1<75.02$. It is below ε once $m\geq\big(\log k+\log(75.02/\log(1+\varepsilon^2))\big)/0.015661$, so in ℓ^1 as well the spine settles within 63.86 ticks per nat of $\log k$.

Independent voxels are the simplest joint law. Recognition Science also allows couplings, and they change the answer.

Definition 26.40 (Joint ticks, the target, and total correlation)**.** A *joint tick* of a spine V of k voxels assigns to each joint configuration reached from the empty record a probability law on joint moves, in which each voxel holds or makes one unit post, with the bookkeeping of Recognition Science's ledger: each post enters the journal as a reciprocal pair. It *meets Recognition Science's target* when, at every reached configuration, each voxel's own move law is the row of Recognition Science's tick at that voxel's imbalance. We write P_n for the law of the joint imbalance $p \in (\mathbb{Z}^3)^V$ after n ticks. The *product law* moves each voxel by its own row, independently. The *mirror law* of two voxels moves voxel 0 by its row and makes voxel 1 hold when voxel 0 holds and post the reverse move when voxel 0 posts. For a joint law P with marginals G_v, the *total correlation* is $\mathrm{TC}(\mathsf{P}) = \sum_p \mathsf{P}(p) \log\bigl(\mathsf{P}(p)/\prod_v G_v(p_v)\bigr)$.

Theorem 26.41 (Couplings add their total correlation)**.** *Let a joint tick of k voxels meet Recognition Science's target, and let n be a number of ticks.*

(a) Each voxel's marginal of P_n is $P^n(0,\cdot)$, and $\mathsf{P}_n(p) \le P^n(0, p_v)$ for every v.

(b) $D(\mathsf{P}_n \,\|\, \pi^{\otimes V}) = k\,D_n(0) + \mathrm{TC}(\mathsf{P}_n)$ and $\mathrm{TC}(\mathsf{P}_n) \ge 0$. So the joint relative entropy is at least $k\,D_n(0)$, and the product law attains this floor exactly.

(c) $D(\mathsf{P}_n \,\|\, \pi^{\otimes V}) \le C\,k\,D_n(0)$ exactly when $\mathrm{TC}(\mathsf{P}_n) \le (C-1)\,k\,D_n(0)$.

(d) The mirror law meets the target, carries all its mass on pairs $(s,-s)$, and has $D(\mathsf{P}_n \,\|\, \pi\otimes\pi) \ge 9\log\varphi \approx 4.331$ at every tick, while with (T1) and (T2) $2D_n(0) \to 0$. So for every constant C some tick n has $D(\mathsf{P}_n \,\|\, \pi\otimes\pi) > C \cdot 2D_n(0)$: not every joint tick that meets the target has an upper rate $C\,k\,D_n(0)$.

Proof. (a) By induction on n: at each reached configuration, voxel v moves by the row of the tick at its own imbalance, so its marginal is carried forward by P. A joint probability is at most each marginal.

(b) Where $\mathsf{P}_n(p) > 0$, every $G_v(p_v) \ge \mathsf{P}_n(p) > 0$, and $\log\frac{\mathsf{P}_n}{\prod\pi} = \log\frac{\mathsf{P}_n}{\prod G_v} + \sum_v \log\frac{G_v}{\pi}$. Summing against P_n and using (a) for each v gives the identity. For $\mathrm{TC} \ge 0$, $\log y \ge 1 - 1/y$ gives $\mathsf{P}_n \log(\mathsf{P}_n/\prod G_v) \ge \mathsf{P}_n - \prod_v G_v(p_v)$, and summing, $\mathrm{TC} \ge 1 - \sum_p \prod_v G_v(p_v) \ge 0$. Under the product law $\mathsf{P}_n = \prod_v G_v$, so $\mathrm{TC} = 0$.

(c) is (b) rearranged.

(d) Reflection $s \mapsto -s$ maps Recognition Science's tick to a voxel tick with positive holds and hold-return balance, hence to itself, since that tick is unique (Theorem 26.21); so the row at $-s$ is the reflected row at s, and voxel 1, which mirrors voxel 0, moves by its own row. Every reached configuration has $p_1 = -p_0$. A law carried by $T = \{(s,-s)\}$ has relative entropy at least $-\log(\pi\otimes\pi)(T)$, by part (i) of the proof of Theorem 26.33, and $(\pi\otimes\pi)(T) = \sum_s \pi(s)^2 \le \pi(0)\sum_s \pi(s) = \varphi^{-9}$, since $\pi(-s) = \pi(s) \le \pi(0)$. Finally $D_n(0) \to 0$ by Corollary 26.29(a), so for every C some n has $2C\,D_n(0) < 9\log\varphi$. □

Conditions and scope.

Base and premises

Recognition Science's tick, a spine of k voxels started from the empty record, and a joint tick that meets the target; (T1) and (T2) for (d).

Conclusion

The independent product law is the fastest joint law that meets the target; a coupling settles exactly as fast as its total correlation allows. The mirror law never settles to the product law: it stays at least $9\log\varphi$ from it, while it settles to its own anti-diagonal law (Proposition 26.43).

Identification

That the product law is Recognition Science's joint law rests on its joint-entropy premise. On two voxels, cross-voxel double entry together with the target forces the joint law of the mirror law (Proposition 26.43); which coupling nature uses is not claimed.

Total correlation is Watanabe's measure of multivariate dependence [189]. For independent voxels the spine settles at a sharp time. The phenomenon, a cutoff, was found by Aldous and Diaconis for card shuffling [175, 178].

Theorem 26.42 (The spine's sharp cutoff)**.** *Let P be a voxel tick with exact rate $r = r(P) < 1$, put $t^*(k) = \log k/(-\log r)$, and consider k independent voxels started from the empty record, with relative entropy $k\,D_N(0)$ after N ticks.*

(a) For every $\varepsilon > 0$, $k\,D_N(0) \le \varepsilon$ at every tick $N \ge t^*(k) + \log(\varphi^9/\varepsilon)/(-\log r)$.

(b) For every $\delta \in (0,1)$ and every level M there is K_0 such that $k\,D_N(0) \ge M$ for all $k \ge K_0$ and every tick $N \le (1-\delta)\,t^*(k)$.

(c) The settling time $T_\varepsilon(k) = \min\{N : k\,D_N(0) \le \varepsilon\}$ satisfies $T_\varepsilon(k)/\log k \to 1/(-\log r)$ as $k \to \infty$.

For Recognition Science's tick, with (T1), (T2) and (T4), $r < 1$ and $1/(-\log r)$ lies between 3.87 and 63.86 ticks per nat of $\log k$, and between 48.76 and 63.86 under hypothesis (R); for $\varepsilon = 0.01$ the window in (a) beyond $t^*(k)$ is at most 571 ticks.

Proof. (a) By Theorem 26.36 and Lemma 26.35(c), $D_N(0) \le \varphi^9 e_0\, r^N \le \varphi^9 r^N$, since $e_0 = 1-\pi(0) \le 1$. And $k\varphi^9 r^N \le \varepsilon$ exactly when $\log k + \log(\varphi^9/\varepsilon) \le N(-\log r)$.

(b) Put $a = r^{(1-\delta/2)/(1-\delta)}$, so $a < r$, since the exponent exceeds 1. The proof of Theorem 26.36 gives $c > 0$ and $q \in (a, 1]$ with $D_N(0) \ge c\,q^N$ for all large N, and, shrinking c, for all N, because every $D_N(0) \ge D_{2N}(0) \ge 2e_N^2 > 0$. For $N \le (1-\delta)t^*(k)$,

$$q^N \ge a^N \ge a^{(1-\delta)t^*(k)} = r^{(1-\delta/2)t^*(k)} = k^{-(1-\delta/2)},$$

because $r^{t^*(k)} = 1/k$. So $k\,D_N(0) \ge c\,k^{\delta/2}$, which exceeds M for all large k.

(c) By (a), $T_\varepsilon(k) \le t^*(k) + |\log(\varphi^9/\varepsilon)|/(-\log r) + 1$. By (b) with the level $M = 2\varepsilon$, $T_\varepsilon(k) > (1-\delta)t^*(k)$ for all large k. Divide by $\log k$ and let $\delta \to 0$.

For Recognition Science's tick, $0.879^2 \le r \le (4961/5000)^2$ by Corollary 26.37(a), so $-\log r \ge 0.015661$, giving $1/(-\log r) \le 63.86$ and a window of at most $\log(7602)/0.015661 \le 571$ ticks; and $1/(-\log 0.879^2) = 3.877$, $1/(-\log 0.9898^2) = 48.77$. □

Conditions and scope.

Base and premises

A voxel tick with exact rate $r < 1$, and k independent voxels from the empty record.

Conclusion

Settling at $\log k/(-\log r)$ ticks, with a window of bounded width above and a window of width $o(\log k)$ below.

Not claimed

A window of bounded width below $t^*(k)$; that would need a pure geometric lower bound $e_n \ge c r^n$ at the exact pace, which is open. A tick is not identified with a unit of physical time.

Theorem 26.41 leaves the coupling open. One coupling comes from the ledger's own double entry, read across voxels: a post at one voxel is matched, in the same tick, by the reverse post at another. A joint tick is *paired*, or keeps *cross-voxel double entry*, when at every reached configuration each joint move of positive probability matches every posting voxel with another voxel, matched back to it, that posts the reverse move: the same account, the opposite side. On two voxels a paired move is a joint hold, or a post of voxel 0 together with the reverse post of voxel 1; so the mirror law is paired. On two voxels double entry, together with the target, fixes the joint law completely, and we can compute everything about it.

Write $G_n = P^n(0,\cdot)$ for one voxel's law after n ticks, $m_n = \sum_s G_n(s)\,|s|_1$ for its mean imbalance cost, and $H(G) = -\sum_{G(s)>0} G(s)\log G(s)$ for the Shannon entropy of a law. On pairs of states (s,t) let Π_A and Π_c vanish off the anti-diagonal $t=-s$, and put

$$\Pi_A(s,-s) = \pi(s), \qquad \Pi_c(s,-s) = \frac{\pi(s)\,\pi(-s)}{Z}, \qquad Z = \sum_s \pi(s)\,\pi(-s).$$

Π_A is the *anti-diagonal T9 law*, and Π_c is the product law $\pi\otimes\pi$ conditioned on a zero total imbalance.

Proposition 26.43 (Double entry fixes the pair's law)**.** *The following is proved in classical mathematics. Let P be Recognition Science's tick with exact rate $r = r(P)$, and let a joint tick of two voxels meet the target and be paired, with joint law P_n after n ticks from the empty record.*

(a) For every n, $\mathsf{P}_n(s,t) = G_n(s)$ if $t=-s$ and 0 otherwise: voxel 1's imbalance is minus voxel 0's, and the pair's law is one voxel's law placed on the anti-diagonal. Its relative entropy to its own equilibrium is one voxel's: $D(\mathsf{P}_n\,\|\,\Pi_A) = D_n(0)$.

(b) $Z = (1+\varphi^{-2})^3/\varphi^{15}$, and for every n

$$D(\mathsf{P}_n\,\|\,\Pi_c) = D_n(0) + \log Z + (9+m_n)\log\varphi.$$

(c) $\mathrm{TC}(\mathsf{P}_n) = H(G_n) = (9+m_n)\log\varphi - D_n(0)$*, and for every* n

$$\big|15\log\varphi - \mathrm{TC}(\mathsf{P}_n)\big| \le C r^{n/2}, \qquad C = \log\varphi\sqrt{\varphi^9-1}\Big(\sum_s \pi(s)\,|s|_1^2\Big)^{1/2} + \varphi^9 - 1.$$

(d) For every n, $D(\mathsf{P}_n \,\|\, \pi\otimes\pi) = D(\mathsf{P}_n \,\|\, \Pi_c) - \log Z$*, so*

$$D(\mathsf{P}_n \,\|\, \pi\otimes\pi) \ge 15\log\varphi - 3\log(1+\varphi^{-2}) \approx 6.248.$$

(e) With (T1) and (T2), as $n\to\infty$*:* $D(\mathsf{P}_n \,\|\, \Pi_A)$ *never rises and tends to* 0*;* $D(\mathsf{P}_n \,\|\, \Pi_c)$ *tends to* $3\log(1+\varphi^{-2}) \approx 0.9705$*, not to* 0*; and* $\mathrm{TC}(\mathsf{P}_n)$ *and* $D(\mathsf{P}_n \,\|\, \pi\otimes\pi)$ *tend to* $15\log\varphi \approx 7.218$*, the entropy of the T9 law.*

(f) Let k *disjoint pairs of voxels move independently, each by the mirror law, with joint law* Q_n *on the* $2k$ *voxels. Then* $D(\mathsf{Q}_n \,\|\, \Pi_A^{\otimes k}) = k\,D_n(0)$*, the relative entropy of* k *independent voxels, so with (T1) and (T2) parts (a) and (b) of Theorem 26.42 hold for it verbatim; and* $D(\mathsf{Q}_n \,\|\, \pi^{\otimes 2k}) = k\,D(\mathsf{P}_n \,\|\, \pi\otimes\pi) \ge k\big(15\log\varphi - 3\log(1+\varphi^{-2})\big)$ *at every tick, where* P_n *is the mirror law's joint law.*

Proof. (a) A paired move of two voxels adds m to one imbalance and $-m$ to the other, or holds both, so it keeps the total imbalance p_0+p_1. The empty record has total 0, so every reached configuration has $p_1 = -p_0$, and $\mathsf{P}_n(s,t) = 0$ unless $t=-s$. By Theorem 26.41(a) voxel 0's marginal is G_n, so $G_n(s) = \sum_t \mathsf{P}_n(s,t) = \mathsf{P}_n(s,-s)$. Then $D(\mathsf{P}_n \,\|\, \Pi_A) = \sum_s G_n(s)\log\big(G_n(s)/\pi(s)\big) = D_n(0)$.

(b) The T9 law is a product over the three axes, $\pi(s) = \prod_i \rho^{|s_i|}/\varphi^3$, because $\sum_{j\in\mathbb{Z}} \rho^{|j|} = \varphi^3$ (the computation after Definition 26.19). So $\pi(-s) = \pi(s)$ and

$$Z = \sum_s \pi(s)^2 = \frac{1}{\varphi^{18}}\Big(\sum_{j\in\mathbb{Z}} \rho^{2|j|}\Big)^3 = \frac{1}{\varphi^{18}}\Big(\frac{1+\rho^2}{1-\rho^2}\Big)^3.$$

Since $\rho^2+\rho=1$, we have $1-\rho^2=\rho$, and $(1+\rho^2)/\rho = \varphi(1+\varphi^{-2})$; so $Z = \varphi^3(1+\varphi^{-2})^3/\varphi^{18} = (1+\varphi^{-2})^3/\varphi^{15}$. By (a),

$$D(\mathsf{P}_n \,\|\, \Pi_c) = \sum_s G_n(s)\log\frac{G_n(s)\,Z}{\pi(s)^2} = D_n(0) + \log Z - \sum_s G_n(s)\log\pi(s),$$

and $-\log\pi(s) = (9+|s|_1)\log\varphi$; summing against G_n, which has total mass 1, gives $(9+m_n)\log\varphi$.

(c) By (a), voxel 1's marginal at $-s$ is $\sum_{s'} \mathsf{P}_n(s',-s) = \mathsf{P}_n(s,-s) = G_n(s)$. So the term of $\mathrm{TC}(\mathsf{P}_n)$ at $(s,-s)$ is $G_n(s)\log\big(G_n(s)/(G_n(s)\,G_n(s))\big) = -G_n(s)\log G_n(s)$, and $\mathrm{TC}(\mathsf{P}_n) = H(G_n)$. The last computation of (b), with π in place of π^2/Z, gives $D_n(0) = -H(G_n) + (9+m_n)\log\varphi$.

For the bound we need the mean imbalance cost of the T9 law. Along one axis $\sum_{j\in\mathbb{Z}} |j|\rho^{|j|} = 2\rho/(1-\rho)^2$, and dividing by $\varphi^3 = (1+\rho)/(1-\rho)$ gives $2\rho/(1-\rho^2) = 2$; so $\sum_s \pi(s)|s|_1 = 6$, and the entropy of the T9 law is $\sum_s \pi(s)(9+|s|_1)\log\varphi = 15\log\varphi$. Hence

$$15\log\varphi - H(G_n) = (6-m_n)\log\varphi + D_n(0).$$

Since G_n vanishes outside B_n, $6-m_n = \sum_s \big(\pi(s)-G_n(s)\big)|s|_1$, and the Cauchy–Schwarz inequality with the weights π gives

$$|6-m_n| \le \Big(\sum_s \frac{(G_n(s)-\pi(s))^2}{\pi(s)}\Big)^{1/2}\Big(\sum_s \pi(s)|s|_1^2\Big)^{1/2} = \big(\varphi^9 e_n\big)^{1/2}\Big(\sum_s \pi(s)|s|_1^2\Big)^{1/2}$$

by Lemma 26.35(a) and $\pi(0) = \varphi^{-9}$. The last sum is finite: it has at most $4N^2 + 2$ states with $|s|_1 = N$, each of weight ρ^N/φ^9. By Lemma 26.35(c), $\varphi^9 e_n \le \varphi^9 e_0\, r^n = (\varphi^9 - 1)\, r^n$, since $e_0 = 1 - \pi(0)$; and $D_n(0) \le \varphi^9 e_n$ by Theorem 26.36. As $r \le 1$, $r^n \le r^{n/2}$, and the two bounds add up to $C r^{n/2}$.

(d) By Theorem 26.41(b) and part (c), $D(\mathsf{P}_n \,\|\, \pi \otimes \pi) = 2D_n(0) + H(G_n) = D_n(0) + (9 + m_n)\log\varphi$, which is $D(\mathsf{P}_n \,\|\, \Pi_c) - \log Z$ by (b). The masses of Π_c sum to 1, so $D(\mathsf{P}_n \,\|\, \Pi_c) \ge 0$: the inequality $\log y \ge 1 - 1/y$ gives $D(\mathsf{P}_n \,\|\, \Pi_c) \ge \sum_{\mathsf{P}_n > 0} (\mathsf{P}_n - \Pi_c) \ge 0$. Finally $-\log Z = 15\log\varphi - 3\log(1+\varphi^{-2})$ by (b).

(e) With (T1) and (T2), Lemma 26.35(d) gives $r \le (4961/5000)^2 < 1$, as in Corollary 26.37(a). So $D_n(0) \le (\varphi^9 - 1) r^n \to 0$, and $D_n(0)$ never rises from one tick to the next (the proof of Theorem 26.36); by (a) this is $D(\mathsf{P}_n \,\|\, \Pi_A)$. The bound in (c) gives $m_n \to 6$. Then (b) gives $D(\mathsf{P}_n \,\|\, \Pi_c) \to \log Z + 15\log\varphi = 3\log(1 + \varphi^{-2}) > 0$, and (c) and (d) give the limit $15\log\varphi$ of $\mathrm{TC}(\mathsf{P}_n)$ and of $D(\mathsf{P}_n \,\|\, \pi \otimes \pi)$.

(f) The mirror law meets the target (Theorem 26.41(d)) and is paired, so (a)–(e) apply to it. The k pairs move independently, so Q_n is the product over the pairs of P_n, and relative entropy adds over the factors of a product law, by the computation in the proof of Theorem 26.38, against $\Pi_A^{\otimes k}$ and against $\pi^{\otimes 2k}$ alike. So $D(\mathsf{Q}_n \,\|\, \Pi_A^{\otimes k}) = k\, D(\mathsf{P}_n \,\|\, \Pi_A) = k\, D_n(0)$ by (a), and $D(\mathsf{Q}_n \,\|\, \pi^{\otimes 2k}) = k\, D(\mathsf{P}_n \,\|\, \pi \otimes \pi)$, which (d) bounds below. The proof of Theorem 26.42(a) and (b) uses only the quantity $k\, D_N(0)$ and $r < 1$. □

Conditions and scope.

Base and premises

Recognition Science's tick; two voxels started from the empty record; a joint tick that meets the target and is paired at every reached configuration; (T1) and (T2) for the limits in (e) and the cutoff in (f).

Conclusion

Double entry and the target fix the pair's joint law: one voxel's law on the anti-diagonal. The pair settles to its own equilibrium at exactly one voxel's pace, while the information the coupling puts between the two voxels is 0 at the empty record and tends to the T9 law's entropy $15\log\varphi$, within $C r^{n/2}$ at tick n; and the pair stays at least 6.247 nats from the product T9 law at every tick. This sharpens the floor $9\log\varphi \approx 4.331$ of Theorem 26.41(d).

Identification

Cross-voxel double entry is a hypothesis of the proposition, not identified with a physical process. A tick is not identified with a unit of physical time.

Not claimed

That double entry fixes the joint law of more than two voxels; the smallest value of $D(\mathsf{P}_n \,\|\, \pi \otimes \pi)$ over the ticks, of which $-\log Z$ is only a lower bound; and that the exponent $r^{1/2}$ in (c) is sharp, which Proposition 26.44 reduces to two unproved statements about one voxel's walk.

Part (c) of Proposition 26.43 bounds the approach of the total correlation to its limit by $C r^{n/2}$. Is $r^{1/2}$ the true rate? By part (c) the gap is

$$g_n = 15\log\varphi - \mathrm{TC}(\mathsf{P}_n) = (6 - m_n)\log\varphi + D_n(0),$$

and $D_n(0)$ falls at the full pace r (Theorem 26.36), so the answer turns on how fast one voxel's mean imbalance cost m_n approaches the T9 value 6. Write $G_n(B_j) = \sum_{s\in B_j} G_n(s)$ for the mass of a cost ball after n ticks, and $\pi(B_j)$ for its equilibrium mass. We name two statements about one voxel's walk from the empty record:

(B) *ball dominance*: $G_n(B_j) \geq \pi(B_j)$ for every tick n and every radius j, that is, at every tick each cost ball keeps at least its equilibrium mass;

(M) *monotone mean*: $m_n \leq m_{n+1}$ for every n, that is, the mean imbalance never falls.

Neither statement is proved. A floating-point computation of the walk on the ball B_{80} finds (M) at every tick up to 1200, and (B) at every tick up to 1200 for every radius up to 65. This is evidence, not proof, and nothing below uses it.

Proposition 26.44 (The coupling's sharp rate, reduced to two statements)**.** *The following is proved in classical mathematics. Let P be Recognition Science's tick with exact rate $r = r(P)$.*

(a) For all $n \leq N$,

$$6 - m_n \geq \sum_{j=0}^{N-1} \big(G_n(B_j) - \pi(B_j)\big).$$

(b) If (B) holds, then $G_n(0) - \pi(0) \leq 6 - m_n$ for every $n \geq 1$.

(c) If (B) and (M) hold, then for every q with $0 < q < r^{1/2}$ there are $c > 0$ and n_0 with $c\,q^n \leq 6 - m_n$ for every $n \geq n_0$; and for every joint tick of two voxels that meets the target and is paired,

$$\big|15 \log \varphi - \mathrm{TC}(\mathsf{P}_n)\big|^{1/n} \longrightarrow r^{1/2} \qquad (n \to \infty).$$

(d) With (T5), $P^2(0,0) > P(0,0)$. So the statement that no ball ever gains mass, $G_{n+1}(B_j) \leq G_n(B_j)$ for every n and j, is false: the ball $B_0 = \{0\}$ gains mass from tick 1 to tick 2.

Proof. (a) A state s of B_N has $|s|_1$ equal to the number of $j < N$ with $j < |s|_1$, so for every law f on states

$$\sum_{s\in B_N} f(s)\,|s|_1 = \sum_{j=0}^{N-1} \big(f(B_N) - f(B_j)\big).$$

G_n lives on $B_n \subseteq B_N$, so $m_n = \sum_{j<N}\big(1 - G_n(B_j)\big)$. Every state outside B_N has $|s|_1 > N$, so, with the T9 mean 6 from the proof of Proposition 26.43(c) and the identity for $f = \pi$,

$$6 = \sum_s \pi(s)\,|s|_1 \geq \sum_{s\in B_N} \pi(s)\,|s|_1 + N\big(1 - \pi(B_N)\big) = \sum_{j<N}\big(1 - \pi(B_j)\big).$$

Subtracting the expression for m_n gives (a).

(b) Under (B) every term of the sum in (a) is nonnegative. Take $N = n \geq 1$ and keep the term $j = 0$, which is $G_n(0) - \pi(0)$.

(c) Since $q^2 < r$ and the ratios e_{k+1}/e_k increase to r (Lemma 26.35(b)), some ℓ has $\theta = e_{\ell+1}/e_\ell > q^2$. By Lemma 26.35(c), for every $k \geq \ell$, $e_k \geq e_\ell\,\theta^{k-\ell} \geq c'q^{2k}$ with $c' = e_\ell\,\theta^{-\ell} > 0$. Let $n \geq 2\ell + 2$. At an even tick $n = 2k$, part (b) gives $6 - m_{2k} \geq G_{2k}(0) - \pi(0) = e_k \geq c'q^{2k}$. At an odd tick $n = 2k + 1$, (M) gives $m_{2k+1} \leq m_{2k+2}$, so $6 - m_{2k+1} \geq e_{k+1} \geq c'q \cdot q^{2k+1}$. As $q < 1$, the constant $c = c'q$ serves at every tick $n \geq n_0 = 2\ell + 2$.

For the second claim, Proposition 26.43(c) gives $g_n = (6 - m_n)\log\varphi + D_n(0)$ and $|g_n| \leq C(r^{1/2})^n$, so $\limsup_n |g_n|^{1/n} \leq r^{1/2}$. Since $D_n(0) \geq 0$, the floor gives $g_n \geq c\log\varphi \cdot q^n > 0$ for $n \geq n_0$, so $\liminf_n |g_n|^{1/n} \geq q$. This holds for every q in $(0, r^{1/2})$, which is not empty because $r > 0$ (Lemma 26.35(b)).

(d) Let $h = P(0,0)$. Then $G_1(0) = h$ and $G_2(0) = h^2 + \sum_m P(0,m)P(m,0)$, the sum over the six moves. The six posts at the vacuum are equal, so each is $(1-h)/6$, and detailed balance $w(0)P(0,m) = w(m)P(m,0)$, with $w(0) = 1$ and $w(m) = \rho$, gives $P(m,0) = \varphi(1-h)/6$. Hence

$$G_2(0) - G_1(0) = h^2 + \frac{\varphi(1-h)^2}{6} - h = \frac{(1-h)\big(\varphi - (6+\varphi)h\big)}{6}.$$

By (T5), $h < 0.19 < 1.6/7.6 < \varphi/(6+\varphi)$, so both factors are positive. □

Part (d) closes the most natural route to (B) and (M). If no ball ever gained mass, (M) would follow from the identity $m_n = \sum_{j<N}\big(1 - G_n(B_j)\big)$ in the proof of (a), and (B) as well, since $G_n(B_j) \to \pi(B_j)$ by Pinsker's inequality once $D_n(0) \to 0$ (Corollary 26.29(a), with (T1)–(T3)). But the vacuum ball already gains mass at the second tick. With (B) and (M), part (c) and Proposition 26.43(c) together say that $r^{1/2}$, which lies between 0.879 and 0.9922 with (T1), (T2) and (T4), is the exact pace at which the coupling's information approaches $15\log\varphi$.

Conditions and scope.

Base and premises

Recognition Science's tick from the empty record; for (b) the statement (B); for (c) the statements (B) and (M), and a joint tick of two voxels that meets the target and is paired; for (d) the stated input (T5).

Conclusion

Under (B) the mean imbalance gap is at least the return excess; under (B) and (M) the information the coupling carries approaches the T9 law's entropy at exactly the square root of one voxel's pace; the stronger statement that no ball ever gains mass is false.

Not claimed

(B) and (M) themselves: both are open, and the computation reported before the proposition is evidence for them, not a proof. A tick is not identified with a unit of physical time.

26.7 Fields on the lattice

The voxels of Recognition Science form a cubic lattice. This section places the fields of classical physics on such a lattice, as functions on sites, edges and faces, and puts Maxwell's and Schrödinger's equations on it with the numbers of $\mathbb{R}_\delta$; identifying these lattice fields with Recognition Science's own fields is not claimed. Everything in it is free; the lattice

identities hold over every commutative ring. Amplitudes are pairs of points, $a = (\operatorname{Re} a, \operatorname{Im} a)$, multiplied as complex numbers, with $e^{i\theta} = (\cos\theta, \sin\theta)$ for the functions of Definition 21.6, and $\operatorname{sz}(a) = |\operatorname{Re} a| + |\operatorname{Im} a|$. A matrix U *is* $\exp(zH)$ when each entry of U is the limit of the corresponding entries of the partial sums $\sum_{k<M} z^k H^k/k!$. The quarter period q is the point with $0 \le q \le 2$ and $\cos q = 0$; by Theorem 21.8, $4q = 2\pi_\delta$.

Definition 26.45 (Lattice fields and the Maxwell generator)**.** Let $\Lambda = (\mathbb{Z}/(N+1))^3$ be the periodic cubic lattice with $N+1$ sites per side and unit vectors e_0, e_1, e_2; axis indices are read modulo 3. Over a commutative ring, a *scalar field* f is a function on sites, an *edge field* A gives $A_i(x)$ on the edge from x to $x + e_i$, and a *face field* B gives $B_k(x)$ on the face at x normal to e_k. Put

$$\begin{aligned}
(\nabla f)_i(x) &= f(x+e_i) - f(x),\\
(\operatorname{curl} A)_k(x) &= \big[A_{k+2}(x+e_{k+1}) - A_{k+2}(x)\big] - \big[A_{k+1}(x+e_{k+2}) - A_{k+1}(x)\big],\\
\operatorname{div}_F B(x) &= \textstyle\sum_i \big[B_i(x+e_i) - B_i(x)\big],\\
(\operatorname{curl}^* B)_i(x) &= \big[B_{i+1}(x-e_{i+2}) - B_{i+1}(x)\big] - \big[B_{i+2}(x-e_{i+1}) - B_{i+2}(x)\big],\\
\operatorname{div}_E E(x) &= \textstyle\sum_i \big[E_i(x-e_i) - E_i(x)\big].
\end{aligned}$$

A *Maxwell field* is a pair $\psi = (E, B)$ of an edge field and a face field with values in $\mathbb{R}_\delta$. The *Maxwell generator* is $\mathfrak{A}\psi = (\operatorname{curl}^* B, -\operatorname{curl} E)$, and the *energy* is $\|\psi\|^2 = \sum_x \sum_i \big(E_i(x)^2 + B_i(x)^2\big)$.

The evolution $\dot E = \operatorname{curl}^* B$, $\dot B = -\operatorname{curl} E$ is the vacuum Maxwell system on Yee's staggered lattice [190], with the electric field on edges and the magnetic field on faces. Summation by parts on the periodic lattice shows that curl^* is the adjoint of curl and div_E that of ∇ for the counting inner product.

Theorem 26.46 (The lattice Maxwell flow is free)**.**

(a) Over every commutative ring, $\operatorname{curl}\nabla f = 0$, $\operatorname{div}_F \operatorname{curl} A = 0$ *and* $\operatorname{div}_E \operatorname{curl}^* B = 0$.

(b) On $\mathbb{R}_\delta$*, for every point* t *there is a map* $U(t) = \exp(t\mathfrak{A})$ *on Maxwell fields, the limit of its exponential series with an explicit modulus, such that* $U(0)$ *is the identity,* $U(t+s) = U(t)U(s)$*,* $\|U(t)\psi\| = \|\psi\|$*, and the Gauss residuals* $\operatorname{div}_E E$ *and* $\operatorname{div}_F B$ *of* $U(t)\psi$ *do not depend on* t*.*

Proof. (a) Shifts along different axes commute. Expanding, $(\operatorname{curl}\nabla f)_k(x)$ is $[f(x+e_{k+1}+e_{k+2}) - f(x+e_{k+1}) - f(x+e_{k+2}) + f(x)]$ minus the same expression with the two shifts in the other order, which is 0; the other two identities expand in the same way.

(b) *The series.* In the basis of unit fields $\mathfrak{A}$ is a finite integer matrix with at most four entries ± 1 in each row, since each component of curl and of curl^* has four terms. So every entry of $\mathfrak{A}^m$ is an integer of absolute value at most 4^m. Let V be a natural number with $|t| \le V$, and let $S_M(t) = \sum_{m<M} t^m \mathfrak{A}^m/m!$. Once $M \ge 8V$ consecutive terms of $\sum_m (4V)^m/m!$ at least halve, so every entry of $S_{M'}(t) - S_M(t)$, for $M' \ge M \ge 8V$, is at most $2(4V)^M/M!$ in absolute value, which tends to 0 with an explicit rate. The diagonal limit (Theorem 12.25) computes each entry of $U(t) = \lim_M S_M(t)$ from a regular sequence naming t, and limits are unique, so $U(t)$ depends only on the point t. Then $U(t)\psi = \sum_b \psi_b U(t) e_b$ is a finite combination over the unit fields e_b, and no regular sequence of ψ is ever chosen. Clearly $U(0)$ is the identity.

The group law. For $|t|, |s| \le V$, expanding $(t+s)^n$ by the binomial theorem gives

$$S_M(t)S_M(s) - S_M(t+s) = \sum_{\substack{a,b<M \\ a+b\ge M}} \frac{t^a s^b}{a!\,b!}\,\mathfrak{A}^{a+b},$$

and since $\sum_{a+b=n} 1/(a!\,b!) = 2^n/n!$, every entry of the right side is at most $\sum_{n\ge M}(8V)^n/n! \le 2(8V)^M/M!$ once $M \ge 16V$. Products and sums of finitely many limits are limits, so $U(t)U(s) = U(t+s)$.

Energy. Summation by parts on the periodic lattice, $\sum_x f(x+e_j)g(x) = \sum_x f(x)g(x-e_j)$, shows that curl^* is the adjoint of curl, so $\langle \mathfrak{A}\phi, \chi\rangle = -\langle \phi, \mathfrak{A}\chi\rangle$ for the counting inner product. Hence $\langle \mathfrak{A}^m\phi, \chi\rangle = (-1)^m\langle \phi, \mathfrak{A}^m\chi\rangle$, and summing the series, $\langle U(t)\phi, \chi\rangle = \langle \phi, U(-t)\chi\rangle$. So $\|U(t)\psi\|^2 = \langle \psi, U(-t)U(t)\psi\rangle = \langle \psi, U(0)\psi\rangle = \|\psi\|^2$.

Gauss. A term of order $m \ge 1$ is $\mathfrak{A}(\mathfrak{A}^{m-1}\psi)$, whose electric part is a curl^* and whose magnetic part is a curl; by (a), div_E and div_F vanish on them. So the Gauss residuals of every partial sum $S_M(t)\psi$ are those of ψ, and they pass to the limit. □

Proposition 26.47 (Gauss's law: sources and prices)**.**

(a) For a static current J, an edge field, put $W(t) = \sum_m t^{m+1}\mathfrak{A}^m/(m+1)!$ and $U_J(t)\psi = U(t)\psi - W(t)(J,0)$. Then $U_J(t)\psi = \psi + W(t)\big(\mathfrak{A}\psi - (J,0)\big)$, the integrated form of $\dot E = \mathrm{curl}^*\, B - J$, $\dot B = -\mathrm{curl}\, E$; $U_J(t+s) = U_J(t)U_J(s)$; and at every site $\mathrm{div}_E E(t) = \mathrm{div}_E E(0) - t\,\mathrm{div}_E J$. A charge $Q(t)$ satisfies Gauss's law $\mathrm{div}_E E(t)(x) + Q(t) = 0$ at every t exactly when it does at $t = 0$ and $Q(t) = Q(0) + t\,\mathrm{div}_E J(x)$.

(b) On a lattice with at least two sites per side, at a fixed site x_0, with no choice principle: "every field satisfies $\mathrm{div}_E E(x_0) = 0$ or does not" is equivalent to WLPO; "every field that violates it violates it visibly, with $\mathrm{div}_E E(x_0)\ \#\ 0$" to $\mathrm{MP}_{\mathrm{bin}}$; and "every field satisfies it or violates it visibly" to LPO. The same holds for $\mathrm{div}_F B(x_0) = 0$.

The flow keeps Gauss's law at no price; deciding it carries the price.

Proof. (a) Termwise, $U(t) = 1 + W(t)\mathfrak{A}$, which gives the integrated form. The divergence kills every term of $W(t)(J,0)$ except the first, $t(J,0)$, by Theorem 26.46(a). The series identity $W(t+s) = W(t) + U(t)W(s)$ gives the flow property, and the continuity statement follows from the formula for $\mathrm{div}_E E(t)$.

(b) With two or more sites per side, $x_0 - e_0 \ne x_0$. For a point a, the edge field with $E_0(x_0) = -a$ and all other entries 0 has $\mathrm{div}_E E(x_0) = a$, so the three statements for all fields are the statements $a = 0 \vee a \ne 0$, $a \ne 0 \to a\ \#\ 0$ and $a = 0 \vee a\ \#\ 0$ for all points, which cost WLPO, $\mathrm{MP}_{\mathrm{bin}}$ and LPO by Corollary 12.18. The face field with $B_0(x_0) = -a$ does the same for div_F. □

Light on the lattice is exact, and its error against the continuum is explicit.

Theorem 26.48 (Standing light and its dispersion)**.** *Let m be a natural number, $\theta = 4qm/(N+1) = 2\pi_\delta m/(N+1)$ and $\omega = 2\sin(\theta/2)$.*

(a) The standing wave with $E_1(x) = \cos(\theta x_0)$, where $x_0 \in \{0, \dots, N\}$ is the first coordinate of x, and all other components 0, evolves under the Maxwell flow exactly as $E_1(t,x) = \cos(\theta x_0)\cos(\omega t)$, with $E_0 = E_2 = 0$ at every time.

(b) For every $\theta \geq 0$ and every point t, with $\omega = 2\sin(\theta/2)$, $|\cos(\omega t) - \cos(\theta t)| \leq |t|\theta^3/24$.

(c) For $\theta > 0$ the phase speed satisfies $1 - \theta^2/24 \leq \omega/\theta \leq 1$, and the group speed $\cos(\theta/2)$ satisfies $1 - \theta^2/8 \leq \cos(\theta/2) \leq 1$.

Proof. (a) Fields whose only components are E_1 and B_2, both depending on x_0 alone, form an invariant space: $\mathfrak{A}$ sends $E_1 = f$ to $B_2 = -(f(x_0+1) - f(x_0))$ and $B_2 = g$ to $E_1 = g(x_0 - 1) - g(x_0)$, and all other components of the image vanish because nothing depends on x_1 or x_2. So $\mathfrak{A}^2$ acts on E_1 as the periodic second difference $f(x_0+1) - 2f(x_0) + f(x_0 - 1)$. Since $\theta(N+1) = 2\pi_\delta m$, the function $\cos(\theta x_0)$ is periodic with period $N+1$, and the addition formula gives $\cos(\theta(x_0+1)) + \cos(\theta(x_0-1)) = 2\cos\theta\cos(\theta x_0)$. So $\mathfrak{A}^2$ multiplies the standing wave by $-(2 - 2\cos\theta) = -\omega^2$. The even terms of the exponential series give $E_1 = \cos(\theta x_0)\sum_k (-\omega^2 t^2)^k/(2k)! = \cos(\theta x_0)\cos(\omega t)$, and the odd terms contribute only to B_2.

(b) For $y \geq 0$, $y - y^3/6 \leq \sin y \leq y$. From the series, for $0 \leq y^2 \leq 20$ the terms of $1 - \mathrm{S}(y^2)$ pair into nonnegative brackets, and for $0 \leq y^2 \leq 42$ so do those of $\mathrm{S}(y^2) - 1 + y^2/6$; for $y \geq 1$, $\sin y \leq 1 \leq y$, and for $y^2 \geq 12$, $y - y^3/6 \leq -y < -1 \leq \sin y$. The overlapping ranges cover all $y \geq 0$. At $y = \theta/2$ this gives $\theta - \theta^3/24 \leq \omega \leq \theta$. The cosine is 1-Lipschitz, since $\cos a - \cos b = -2\sin\frac{a+b}{2}\sin\frac{a-b}{2}$ and $|\sin y| \leq |y|$; so $|\cos(\omega t) - \cos(\theta t)| \leq |t|\,|\omega - \theta| \leq |t|\theta^3/24$.

(c) The phase speed is (b) divided by θ. The group speed bound is $\cos y \geq 1 - y^2/2$ at $y = \theta/2$, proved from the series like the sine bounds. □

So lattice light travels at the continuum speed up to a relative error of $\theta^2/24$ in the phase speed, where θ is the wave number times the lattice spacing. In every direction the same computation gives plane waves of frequency Ω with $\Omega^2 = \sum_j 4\sin^2(\theta_j/2)$, and for $0 \leq \theta_j$ with $\theta_j^2 \leq 48$, $\sum_j(\theta_j^4/12 - \theta_j^6/360) \leq |\theta|^2 - \Omega^2 \leq \sum_j \theta_j^4/12$: the lattice is anisotropic at fourth order only.

Schrödinger's equation on a lattice has a light cone too, and a continuum limit with an error of order h^2. Let V be a potential with ratio values, $|V(x)| \leq K$ for a natural number K. The *box Hamiltonian* on the sites $-L, \dots, L$ is $(H_L\psi)(x) = V(x)\psi(x) - \psi(x+1) - \psi(x-1)$, with the terms outside the box omitted, and its *propagator* at time t is $\exp(-\mathrm{i}tH_L)$.

Theorem 26.49 (A light cone and convergent propagators)**.**

(a) Let U be a square matrix of amplitudes and d a function on pairs of indices with $d(x,x) = 0$ and $d(x,z) \leq d(x,y) + d(y,z)$, and suppose $U_{xy} = 0$ whenever $d(x,y) > 1$. Then $(U^k)_{xy} = 0$ whenever $k < d(x,y)$. If moreover the sizes $\mathrm{sz}(U_{rk})$ in each column of U sum to at most B, and $\mathrm{sz}(z) \leq S$ for natural numbers B, S, then every entry of $\exp(zU)$ at a pair with $d = d(x,y) \geq 2BS$ has real and imaginary part at most $4(BS)^d/d!$ in absolute value.

(b) Let $|t| \le T$ for a natural number T, put $c = (2+K)T$, let $R \le L \le L'$ and $m = L - R + 1$, and let $|x|, |y| \le R$. If $m \ge 2c$, the entries (x, y) of the propagators of H_L and $H_{L'}$ agree to within $4c^m/m!$ in real and in imaginary part. If only $c \le m$, they agree to within $4c^{2m}/(2m)!$.

(c) For $|x|, |y| \le R$ the box amplitudes converge, as $L \to \infty$, to an amplitude $A(x, y)$ within $4c^m/m!$ of every box amplitude with $m \ge 2c$. The columns of A are orthonormal, and A preserves the inner product of every pair of finitely supported states.

(d) Deciding, for all potentials, boxes and times, whether a propagator entry is exactly 0 is equivalent to WLPO, with no choice principle.

Parts (a) to (c) are free.

Proof. (a) By induction on k: $(U^{k+1})_{xy} = \sum_r (U^k)_{xr} U_{ry}$, and for each r either $k < d(x, r)$, so the first factor vanishes, or $d(r, y) > 1$ by the triangle inequality, so the second does. For the bound, the series of $\exp(zU)$ at (x, y) starts at order d, its jth term is at most $2(BS)^j/j!$ in each part, and the tail estimate of (b) below applies.

(b) Compare two exponential series whose coefficients agree below order m. The entries of H_L^k satisfy the three-term recursion of the Hamiltonian; $(H_L^k)_{xy} = 0$ for $|x - y| > k$ by (a); $|(H_L^k)_{xy}| \le (2 + K)^k$; and $(H_L^k)_{xy} = (H_{L'}^k)_{xy}$ when $|x| + k \le L$, because a site just outside the smaller box is beyond the cone of x. So the two series agree below order m, and from order $j \ge m$ each term of the difference is at most $2c^j/j!$ in real and imaginary part. Once $2c \le j + 1$ consecutive terms at least halve, so the tail is at most $2 \cdot 2c^m/m!$; bounds at every stage pass to the limits. For the sharp form, the boxes agree on every order k with $k + |x| + |y| < 2L + 2$, a round trip from x to the wall and back to y, so agreement holds below order $2m$.

(c) By (b) the box amplitudes form a Cauchy sequence in L with an explicit modulus, and the diagonal limit gives A. Each box propagator is unitary: H_L is real and symmetric, so the conjugate transpose of $\exp(-\mathrm{i}tH_L)$ is $\exp(\mathrm{i}tH_L)$, and their product is 1 by the group law. By the bound in (a), with $B = 2 + K$, the entries of every box propagator in column y decay like $4c^d/d!$ at distance $d \ge 2c$ from y, uniformly in the box; so the sums of products of columns over $|x| \le M$ converge uniformly, and orthonormality passes to the limit, and with it the preservation of inner products of finitely supported states.

(d) With WLPO, decide whether the real and the imaginary part are 0. Conversely, for $L = 1$ and $V = 0$ the entry between the sites -1 and 0 is $\mathrm{i}\sin(\sqrt{2}\,t)/\sqrt{2}$, because the odd powers of H_1 have that entry -2^j and the even powers have it 0. For $|t| \le 1$, $\sin(\sqrt{2}t) = 0$ exactly when $t = 0$, since $\mathrm{S}(y^2) \ge \frac{2}{3}$ for $y^2 \le 2$. So the decision gives $t = 0 \vee t \ne 0$ for every $|t| \le 1$, which is WLPO by Corollary 12.18 after scaling. □

Part (a) is the exact form, for range-one steps, of the finite group velocity of Lieb and Robinson [185].

Theorem 26.50 (The continuum limit of the ring, with error of order h^2)**.** *Let $n \geq 3$, let H be the matrix of $2\psi_j - \psi_{j+1} - \psi_{j-1}$ on a ring of n sites, and put $\theta_m = 4qm/n = 2\pi_\delta m/n$ for integers m. For finitely many amplitudes a_m let $\psi(j) = \sum_m a_m e^{\mathrm{i}\theta_m j}$. For every point s and every matrix $U = \exp(-\mathrm{i}sH)$, at every site j the amplitude $(U\psi)(j)$ is within*

$$\frac{|s|}{12} \sum_m \mathrm{sz}(a_m)\, \theta_m^4$$

of the continuum value $\sum_m a_m e^{-\mathrm{i}\theta_m^2 s} e^{\mathrm{i}\theta_m j}$, in real and in imaginary part. Such a matrix U exists for every s, and it is unitary. In physical units, with spacing $h = 2\pi_\delta/n$, time $t = h^2 s$ and position $x = hj$, the continuum value is $\Psi(t,x) = \sum_m a_m e^{\mathrm{i}(mx - m^2 t)}$, which solves $\mathrm{i}\,\partial_t \Psi = -\partial_x^2 \Psi$, and the bound is $|t|\, h^2 \sum_m \mathrm{sz}(a_m) m^4/12$. On the voxel lattice $(\mathbb{Z}/n)^3$ the same holds with m^4 replaced by $m_1^4 + m_2^4 + m_3^4$. All of this is free.

Proof. Eigenvectors. Since $\theta_m n = 2\pi_\delta m$, the plane wave $v(j) = e^{\mathrm{i}\theta_m j}$ is periodic around the ring, and $v(j+1) + v(j-1) = 2\cos\theta_m\, v(j)$, so $Hv = \lambda v$ with $\lambda = 2 - 2\cos\theta_m$. The partial sums of the exponential series act on v as the scalar partial sums, whose even and odd parts are the cosine and sine series; limits are unique, so $Uv = e^{-\mathrm{i}s\lambda} v$, and by linearity $(U\psi)(j) = \sum_m a_m e^{-\mathrm{i}s\lambda_m} e^{\mathrm{i}\theta_m j}$. The matrix U exists because H has integer entries, at most three in each row, so its exponential series converges entrywise with an explicit modulus, as in the proof of Theorem 26.46(b); it is unitary because H is real and symmetric, so the conjugate transpose of $\exp(-\mathrm{i}sH)$ is $\exp(\mathrm{i}sH)$, and the group law makes their product 1.

The error of one mode. Cosine and sine are 1-Lipschitz, so each part of $a\,e^{\mathrm{i}A} - a\,e^{\mathrm{i}B}$ is at most $\mathrm{sz}(a)|A - B|$, here with $|A - B| = |s|\,|\theta^2 - \lambda(\theta)|$.

The dispersion gap. $1 - \theta^2/2 \leq \cos\theta \leq 1 - \theta^2/2 + \theta^4/24$ for every θ: with $u = \theta^2$, the terms of $\mathrm{C}(u) - 1 + u/2$ pair into nonnegative brackets for $u \leq 30$, and $1 - u/2 \leq -1$ for $u \geq 4$; those of $1 - u/2 + u^2/24 - \mathrm{C}(u)$ pair into nonnegative brackets for $u \leq 56$, and $1 - u/2 + u^2/24 \geq 1$ for $u \geq 12$. So $0 \leq \theta^2 - \lambda(\theta) \leq \theta^4/12$. Summing over the modes gives the bound. With $\theta_m = mh$ and $s = t/h^2$, $|s|\theta_m^4/12 = |t|h^2 m^4/12$, and Ψ solves the equation mode by mode. On $(\mathbb{Z}/n)^3$ the Laplacian is the sum of three ring Laplacians and the gaps add. □

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$, its cosine, sine and π_δ, a lattice, and a finite trigonometric initial state.

Conclusion

The lattice evolution exists and differs from the free continuum Schrödinger evolution by at most $|t|h^2 \sum \mathrm{sz}(a_m) m^4/12$.

26.8 Laws and their prices

A physical law classifies states by comparisons: an orbit is bound when its energy is negative, a field obeys Gauss's law when a divergence is zero, a displacement is causal when $E \geq |p|$. On $\mathbb{R}_\delta$ each comparison has a price (Corollary 12.18), and a law combines them. This section computes the exact price of whole classes of laws by programs that read only the thresholds, and then prices the lattice premises that Recognition Science uses for an inverse-square field. The prices are proved with no choice principle. As equivalences with omniscience principles they are trivial in classical mathematics, so their content is that each price is exact without choice. Theorem 25.59(4) of Chapter 25 lists the prices a sign law on an observable that takes every value can have; Theorem 26.52 below computes, by an explicit rule on the thresholds, which of them each such law has.

Definition 26.51 (Sign laws and their germs)**.** A *sign law* in one quantity x is built from *atoms* $x < c$, $x \leq c$, $x = c$, $c < x$, $c \leq x$, with ratio thresholds c, by "and" and "or". It *holds* at a point as written. It is *visibly refuted* at x when its failure is witnessed by strict comparisons: $x < c$ and $x \leq c$ are refuted when $c < x$, $c < x$ and $c \leq x$ when $x < c$, and $x = c$ when $x \# c$; "and" is refuted when one part is, "or" when both are. Write the law in disjunctive normal form; its *cells* are conjunctions of atoms. At a threshold p of the law record six bits, each saying whether some cell holds on the whole of a germ at p: the point p itself (P), an open interval just left of p (L), just right of p (R), an interval $(p - \varepsilon, p]$ (LC), an interval $[p, p + \varepsilon)$ (RC), and an open interval around p (N), for all small $\varepsilon > 0$. The *local decision price* at p is the first row of Table 26.3 that applies. The *decision class* of the law is the join of its local prices in the order free $<$ LLPO $<$ WLPO $<$ LPO. Its *holds class* is *refuted* if P, L or R fails at some threshold, and otherwise free if N holds at every threshold, LLPO if LC and RC hold at every threshold, and LPO in the remaining case. With a seventh bit F, whether the law is visibly refuted at p itself, its *refutation class* is false if some threshold has neither P nor F, otherwise free if every threshold has N, F, or both L and R, and $\mathrm{MP}_{\mathrm{bin}}$ in the remaining case; its *settling class* is false in the same case, and otherwise the join over the thresholds of: free if N or F, LLPO if L, R, LC and RC, and LPO otherwise.

For example, Kepler's trichotomy of an energy, $E < 0 \vee E = 0 \vee E > 0$, has holds class LPO; the closed dichotomy $E \leq 0 \vee 0 \leq E$ has holds class and decision class LLPO; the overlapping cover $x < 1 \vee -1 < x$ has holds class free; deciding $E < 0$ costs LPO, and deciding $E = 0$ or $E \leq 0$ costs WLPO.

Theorem 26.52 (One program prices every sign law)**.** *For every sign law φ, with no choice principle:*

(a) "φ holds at every point" is equivalent to the meaning of its holds class: false, true, LLPO or LPO;

(b) "φ holds or fails at every point" is equivalent to the meaning of its decision class: true, LLPO, WLPO or LPO;

(c) "wherever φ fails it is visibly refuted" is equivalent to the meaning of its refutation class: false, true or $\mathrm{MP}_{\mathrm{bin}}$; and "$\varphi$ holds or is visibly refuted at every point" to the meaning of its settling class: false, true, LLPO or LPO;

(d) (a)–(c) hold as well for sign laws whose thresholds lie in $\mathbb{Z}[\varphi]$.

Proof. Windows. Between two consecutive thresholds every atom is constant. List the thresholds in order, which is decided by comparing ratios, and apply cotransitivity of $<$ once at each gap between consecutive values: every point x lies in the *window* of some threshold p, on the same strict side as p of every other threshold, and for each p every point lies in its window or strictly on one side of p. In the window of p the law at x agrees with its germ at p: if N, it holds at x; if LC and $x \le p$, it holds; if L and $x < p$, it holds; if P and $x = p$, it holds. Each bit that fails confines where it holds: without R to $x \le p$, without P to points apart from p, without N to $x \le p$ or $p \le x$, without LC to $x < p$ or $p \le x$ (symmetrically for L and RC). Visible refutation is read atom by atom, then through "and" and "or": an atom whose threshold is not p is visibly refuted at x exactly when it is at p, and one with threshold p never is at p but holds or is visibly refuted at each $x < p$ and $x > p$. So the law is visibly refuted throughout the window if F, at each $x < p$ there if L fails (each $x > p$ if R fails), and, if F fails, nowhere else.

Upper bounds. With the principle named by a row, the position of x relative to p is decided as finely as the row's bits require: LLPO gives $x \le p \vee p \le x$; WLPO decides $x = p$ and $x \le p$; LPO decides $x < p$, $x = p$ or $x > p$. In the rows marked free, either a cell holds on a whole neighbourhood of p, or the law fails at p and on both sides, and then $\neg\varphi(x)$ follows by refuting each way it could hold. A point in a different window is strictly on one side of p, so a local decision spreads to the whole line, and the join of the local principles decides the law. For (c): if some threshold has neither P nor F, the law there neither holds nor is visibly refuted, and both statements fail. Otherwise take x in the window of p. With F the law is visibly refuted at x, with N it holds, and with P, L and R it cannot fail, since $\neg(x < p)$ and $\neg(p < x)$ give $x = p$. Otherwise P holds, and a failure at x gives $x \neq p$, which $\mathrm{MP}_{\mathrm{bin}}$ turns into $x < p$ or $p < x$ (Table 12.2), a side whose bit fails, where the law is visibly refuted. For settling, LLPO places x where LC or RC makes the law hold, and LPO places x below, at or above p.

Lower bounds. At a threshold p whose row names a principle, the confinements turn a decision of the law at each x of the window into one comparison with p: $x = p \vee x \neq p$ (row 5), $x \le p \vee \neg(x \le p)$ (row 6 with LC; mirrored, row 7 with RC), $x \le p \vee p \le x$ (row 3 with LC and RC), and $x < p \vee \neg(x < p)$ or its mirror image in the other rows; for instance, in row 4 with L the law holds only apart from p and fails only where $\neg(x < p)$. Points outside the window are strictly on one side of p. As $x < y$ exactly when $x - y + p < p$, and likewise

for $\leq$ and $=$, the comparison with p at every point is the same comparison for all pairs of points, priced WLPO, LLPO or LPO in Table 12.2. For (a), a law whose holds class is refuted fails at a threshold or at a point just beside one, found inside its window by density of the ratios; otherwise it holds everywhere under the principle named, and a threshold without N (or without one of LC, RC) is in row 3 and yields LLPO (or LPO). For (c), where refutation is not free, P holds, N and F fail, and so does L or R. If both do, the law fails at each $x \neq p$ of the window, so it is visibly refuted, at a point $x < p$ or $p < x$; if only L does, it fails where $\neg(p \leq x)$ and is visibly refuted, at a point $x < p$. This is $x \neq p \to x < p \vee p < x$, or $\neg(p \leq x) \to x < p$, at every point, which costs $\mathrm{MP}_{\mathrm{bin}}$. For settling, with P and neither N nor F: if L fails, the law holds only where $p \leq x$ and is visibly refuted only where $x < p$, or $p < x$ with R failing, so settling decides $x < p$, which is LPO; if L and R hold, it is never visibly refuted in the window, and settling is holding, priced as in (a). For (d), the proof uses of the thresholds only that their strict and weak order is decided by a computation, and in $\mathbb{Z}[\varphi]$ the sign of $a + b\varphi$ is decided by integer arithmetic: $a + b\varphi > 0$ exactly when $2a + b > -b\sqrt{5}$, which compares the integers $(2a + b)^2$ and $5b^2$ once the signs of $2a + b$ and b are known. □

Laws in two quantities are priced by the same idea, after a reduction to lines through finitely many points.

Theorem 26.53 (Linear laws of two quantities)**.** *Consider the laws built by "and" and "or" from atoms $ax + by < c$, $ax + by \leq c$ and $ax + by = c$ in two quantities x, y, with integers a, b and ratio thresholds c. There are programs, reading the coefficients, that assign to each law two classes such that, with no choice principle, "the law holds at every point of the plane" is equivalent to the meaning of the first, which is false, true, LLPO or LPO, and "the law holds or fails at every point" to the meaning of the second, which is true, LLPO, WLPO or LPO. The class is the join, over finitely many* centres*, of the class of the law's* fan *at the centre, and the class of a fan is the join of the one-quantity classes of Theorem 26.52 along finitely many lines through its vertex. The* critical heights *are 0, the ratio c/b of each atom with $b \neq 0$, and the heights where two non-parallel lines that are not horizontal cross; the centres at a critical height h are $(0, h)$ and the points where the non-horizontal lines meet the height h. They include every crossing point of the law's lines. For laws in $k \geq 3$ quantities the corresponding statement is open.*

Proof. Fans. At a centre v keep the atoms whose lines pass through v; near v the others are constant. Such a law depends only on the direction of $d = (d_1, d_2) = (x, y) - v$. Its lines through v, with the horizontal line through v, cut the plane into open sectors and open rays, each with an integer sample point, and on each piece every atom's form has the sign it has at the sample (strict or zero on the open piece, weak on its closure). So the fan law holds on an open piece exactly when it holds at the sample, and a cell holding at v and at the sample holds on the closed piece. Along the line through v in a sample direction the fan law is a one-quantity sign law at the threshold 0, priced by Table 26.3; the lower bounds come from these lines. For the upper bounds the table gives, on each sample line: a price at most WLPO forces, without P, neither L nor R (rows 2, 4), and with P and R, RC (rows 1, 3, 7); at most LLPO with P forces N, or R and RC (rows 1, 3); free with P forces N (row 1). Without P the law fails at v and on every open piece, so at every d, which cannot lie outside all pieces. With P: if the class is free, a cell holds at w, 0 and $-w$ for the sample w of an open sector, where every non-constant form is nonzero, with opposite signs at $\pm w$; so the cell's atoms are constants true at v, and it holds everywhere. If LLPO, every closed piece carries a cell holding

on it, and LLPO places d in a closed sector, by the weak sign of d_2 and then of each offset $d_1 - \kappa d_2$ from a line $d_1 = \kappa d_2$ of the law, in increasing order of κ. If WLPO, zero tests place d at v, or in a closed ray or sector C with d not excluded from its open part; if the law holds at the sample of C, RC gives a cell on C, and otherwise it fails on the open part, hence at d. LPO decides every atom. For holding everywhere, a fan law that fails at v or at a sample is refuted, and one that holds at both cannot fail at any d, so it holds wherever it is decided. Three closed half-planes meeting at a point and covering the plane cost exactly LLPO, since a line through the vertex in a generic direction already carries the dichotomy.

Centres. The critical heights are ratios, and they include the heights of the horizontal lines. For a point (x, y), the one-quantity window argument places y strictly between the critical heights next to some critical height h, so (x, y) is strictly on the side of h of every horizontal line at another height. If the law has no non-horizontal line, the centre is $v = (0, h)$. Otherwise, in that band two lines that meet the height h at different points do not cross, so their order at y is their order at h, and cotransitivity places x next to one group of lines, whose point at height h is a centre v. Either way (x, y) lies in the window of v, strictly on v's side of every line not through v, and there the law is its fan law at $(x, y) - v$. Every direction from a centre enters its window after scaling, and fan laws are invariant under scaling, so "holds everywhere" and "decided everywhere" for the law are the conjunctions of the same statements for its fans. □

For example, the light-cone law $E \geq |p|$, in units with $c = 1$, is decided everywhere exactly under WLPO, and the strict cone $E > |p|$ exactly under LPO. The program never needs a principle outside the chain free, LLPO, WLPO, LPO.

Theorem 26.54 (Laws on a half-line, and the oscillator's energy)**.**

(a) For every sign law φ and every ratio c there is a sign law φ_c with $\varphi_c(x)$ exactly when $\varphi(\max(x, c))$, for every point x.

(b) Let a quantity $\mathcal{O}$ on a set of states have range exactly $[c, \infty)$: $\mathcal{O}(s) \geq c$ for every state, and every point $a \geq c$ is $\mathcal{O}(s)$ for some state. Then "$\varphi(\mathcal{O}(s))$ at every state" costs exactly the holds class of φ_c, and "$\varphi(\mathcal{O}(s))$ is decided at every state" exactly its decision class.

(c) The energy of the harmonic oscillator, a positive quadratic form in position and momentum, has range exactly $[0, \infty)$. So $E \leq 0 \vee E \geq 0$ holds and is decided at every state with no principle; Kepler's trichotomy $E < 0 \vee E = 0 \vee E > 0$ holds at every state exactly under LPO and is decided at every state exactly under LPO; and deciding whether the oscillator is at rest, $E = 0$, costs exactly WLPO.

(d) Clamping does not carry visible refutation: for no ratio c is there a sign law ψ such that, at every point y, ψ holds exactly when the atom $\max(y, c) < c$ holds and ψ is visibly refuted exactly when that atom is visibly refuted.

All of this is proved with no choice principle.

Proof. (a) Replace each atom by its clamped form, decided by comparing q with c: $\max(x, c) < q$ is false if $q \leq c$ and is $x < q$ if $c < q$; $\max(x, c) \leq q$ is false if $q < c$ and $x \leq q$ otherwise; $\max(x, c) = q$ is false if $q < c$, is $x \leq c$ if $q = c$, and is $x = q$ if $c < q$; $q < \max(x, c)$ is true if

$q < c$ and $q < x$ otherwise; $q \le \max(x, c)$ is true if $q \le c$ and $q \le x$ otherwise. Constants are sign laws, such as $x < 1 \vee -1 < x$ and $x < -1 \wedge 1 < x$. Each equivalence holds on $\mathbb{R}_\delta$ with no case split on x; for instance, if $\max(x, c) = q > c$ then $x < q$ is impossible, so $x \ge q$, and $x \le \max(x, c) = q$.

(b) The values $\mathcal{O}(s)$ and the values $\max(x, c)$ are the same set of points, so the statements about states are the statements of Theorem 26.52 for φ_c.

(c) The energy is at least 0, and every $a \ge 0$ is attained with zero momentum at the position given by the square root on the line. Then apply (b) with $c = 0$: the clamped dichotomy holds at every point, the clamped trichotomy is $x \le 0 \vee 0 < x$, with holds and decision class LPO, and the clamped rest law is $x \le 0$, with decision class WLPO.

(d) Suppose ψ existed, and take a ratio y below c and below every threshold of ψ. At y every atom of ψ holds or is visibly refuted: $y < q$ makes $x < q$ and $x \le q$ hold, and refutes $x = q$, $q < x$ and $q \le x$ with the strict witness $y < q$. "And" and "or" keep this property, so ψ holds or is visibly refuted at y. But $\max(y, c) = c$, and the atom $c < c$ neither holds nor is visibly refuted, since a refutation would need $c < c$. □

So on a half-line the program prices holding and deciding a law, and the refutation prices of Theorem 26.52(c) do not transfer by clamping.

Recognition Science's lattice premises

Recognition Science obtains an inverse-square field on its lattice from a current with three properties. On $\mathbb{Z}^D$ a *current* assigns a rate $j(x, i)$ to the edge from x to $x + e_i$, and its divergence at x is $\operatorname{div} j(x) = \sum_i \big(j(x, i) - j(x - e_i, i)\big)$.

Definition 26.55 (Balanced, shell-uniform and sourced currents)**.** A current is *balanced off the origin* when $\operatorname{div} j(x) = 0$ for every $x \ne 0$, and *sourced* when $\operatorname{div} j(0) \ne 0$. It is *shell-uniform* with rates $f(0), f(1), \ldots$ when, for every radius r and axis i, every edge leaving the box $\|x\|_\infty \le r$ through its face $x_i = r$ carries $f(r)$, $j(x, i) = f(r)$, and every edge leaving through the face $x_i = -r$ carries the outward flow $f(r)$, $j(x - e_i, i) = -f(r)$.

Shell uniformity is Recognition Science's isotropy premise: the flux leaves every box equally through every boundary edge. The box of radius r has $2D(2r + 1)^{D-1}$ outward edges, and summing the divergence over the box, all interior edges cancel; so for a balanced shell-uniform current

$$2D\,(2r + 1)^{D-1} f(r) = \operatorname{div} j(0) \qquad \text{for every } r, \tag{26.4}$$

which is the lattice form of Gauss's law with $f(r)(2r + 1)^{D-1} = f(0)$.

Theorem 26.56 (The inverse-square premises are satisfiable in every dimension)**.** *The following is proved in classical mathematics. Let $D \ge 1$.*

(a) There is a current on $\mathbb{Z}^D$ with rational rates that is balanced off the origin and shell-uniform with $f(r) = 1/(2r + 1)^{D-1}$; in three dimensions the rates are the inverse squares $1/(2r + 1)^2$.

(b) *A profile f admits a balanced, shell-uniform current exactly when $f(r)(2r+1)^{D-1} = f(0)$ for every r.*

(c) *If $D \geq 2$, a current of potential form, $j(x,i) = \phi(x) - \phi(x+e_i)$ for a function ϕ on sites, that is balanced off the origin and shell-uniform with rates f has $f(r) = 0$ for every r, and so source 0.*

Proof. (b) Necessity is (26.4); sufficiency follows from (a), since a multiple of a current is a current.

(a) Give every outward edge of every box the rate it must carry, $1/(2r+1)^{D-1}$ outward on the boundary of the box of radius r. The edges from the origin carry 1, so the source is $2D$. The sites of the shell $\|x\|_\infty = r+1$ receive $2D$ in total through the boundary of the box of radius r and send $2D(2r+3)^{D-1}/(2r+3)^{D-1} = 2D$ out through the boundary of the next box, and every edge between two shells is one of these. So the net supply on each shell sums to 0. For $D \geq 2$ the shell is connected by its own edges, and a spanning tree routes any supply of total 0 with rational rates; for $D = 1$ each shell site has one edge in and one out, both carrying 1. This current has $f(r) = 1/(2r+1)^{D-1}$, and $f(0)$ times it has any profile with $f(r)(2r+1)^{D-1} = f(0)$.

(c) For a current of potential form, $\operatorname{div} j(x) = \sum_i \big(2\phi(x) - \phi(x+e_i) - \phi(x-e_i)\big)$. Put $a = e_0$ and $b = 2e_0$. The sites 0, e_0 and $2e_0$ lie on the faces $x_0 = 0, 1, 2$ of the boxes of radii $0, 1, 2$, so $\phi(0) - \phi(e_0) = f(0)$, $\phi(e_0) - \phi(2e_0) = f(1)$ and $\phi(2e_0) - \phi(3e_0) = f(2)$; the term of axis 0 in $\operatorname{div} j$ is $f(1) - f(0)$ at a and $f(2) - f(1)$ at b. For an axis $k \neq 0$, the sites $e_0 \pm e_k$ lie on the face $x_0 = 1$ of the box of radius 1, so $\phi(2e_0 \pm e_k) = \phi(e_0 \pm e_k) - f(1)$, and also $\phi(2e_0) = \phi(e_0) - f(1)$; so the term of axis k, $2\phi(x) - \phi(x+e_k) - \phi(x-e_k)$, is the same at b as at a. Both divergences vanish, and their difference is $f(0) - 2f(1) + f(2) = 0$. By (26.4), $f(1) = f(0)/A$ and $f(2) = f(0)/B$ with $A = 3^{D-1}$ and $B = 5^{D-1}$, so $f(0)(AB - 2B + A) = 0$. For $D \geq 2$, $A \geq 3$ and $AB - 2B + A = B(A-2) + A > 0$, so $f(0) = 0$, and then $f(r) = f(0)/(2r+1)^{D-1} = 0$ for every r. □

For $D = 1$ part (c) has no force: there $A = B = 1$, and the potential $\phi(x) = -|x|$ gives the balanced shell-uniform current with every rate 1. In two or more dimensions a lattice potential obeys the boundary-averaged law behind (26.4), that the flux out of every box equals the source, but never the shell-uniform premise with a source.

Theorem 26.57 (No integer current is balanced, shell-uniform and sourced)**.** *On $\mathbb{Z}^3$:*

(a) *every current with integer rates that is balanced off the origin and shell-uniform with integer rates has source 0; so no integer current is balanced, shell-uniform and sourced;*

(b) *on $\mathbb{Z}^D$, for every $D \geq 1$, every current with real rates that vanishes outside a box and is balanced off the origin and shell-uniform has source 0, and a balanced shell-uniform current with a nonzero source carries a nonzero rate on the axis edge leaving $(R+1)e_i$, for every R and every axis i, so it has infinitely many nonzero rates;*

(c) *deciding, for every integer current, whether it is balanced off the origin costs exactly WLPO, while for currents vanishing outside a given box it is decided with no principle;*

(d) at a state where every compared quantity lies in $\mathbb{Z}[\varphi]$, every exact law is decided, and a failing law without strict atoms is visibly refuted, with no principle.

Parts (a) and (b) concern integer and real currents in classical mathematics; (c) and (d) are proved with no choice principle.

Proof. (a) By (26.4), $6(2r+1)^2 f(r)$ is the source σ for every r. Take $r = |\sigma|$: then $6(2r+1)^2 > |\sigma|$, so the integer $f(r)$ has absolute value below 1, hence is 0, and $\sigma = 0$.

(b) A current that vanishes outside a box has $f(r) = 0$ for large r, so its source $2D(2r+1)^{D-1} f(r)$ is 0 by (26.4). If the source is not 0, then $f(r) \neq 0$ for every r, and the axis edge leaving $(R+1)e_i$ is an outward edge of the box of radius $R+1$, so it carries $f(R+1) \neq 0$.

(c) Balance off the origin is a conjunction, over all sites, of decidable integer equations. With WLPO, enumerate the sites $x_n \neq 0$ and decide whether the sequence $[\operatorname{div} j(x_n) \neq 0]$ is all zero. Conversely, for a binary sequence α let j carry the rate $\alpha(n)$ on the edge from $(2n+2)e_0$ to $(2n+3)e_0$ and 0 elsewhere; then j is balanced off the origin exactly when α is all zero. For a current vanishing outside a box, only finitely many sites can have nonzero divergence.

(d) $\mathbb{Z}[\varphi]$ has decidable equality and sign: $a+b\varphi$ with integers a, b is compared with 0 by integer arithmetic. So each atom is decided, hence each law; and a failing atom $x \leq y$ or $x = y$ fails strictly, which is a visible refutation. □

Conditions and scope.

Base and premises

Recognition Science's balance and isotropy premises for a lattice current.

Conclusion

The premises are consistent in every dimension, with rates fixed exactly to $f(0)/(2r+1)^{D-1}$. On $\mathbb{Z}^3$ they cannot be met with integer rates (on $\mathbb{Z}$ they can: the current of the potential $-|x|$ has every rate 1), and with a source they need infinitely many nonzero rates, an infinite posting history.

Not claimed

That a potential field meets them: in two or more dimensions Theorem 26.56(c) excludes it, and a pointwise inverse-square decay for a lattice potential is an open statement.

26.9 Thermal light on the lattice

Fill the cubic lattice of Section 26.7 with light at temperature T. How much energy does it hold? In the continuum the answer is the Stefan–Boltzmann law: energy density proportional to T^4, with the constant $\pi^2/15$ in natural units. On the lattice the photon's energy is not proportional to its wave number, so the law can hold only as $T \to 0$, and the first correction is of order T^2. This section proves the lattice law, its correction with exact coefficients, and the facts about the lattice photon behind them, on $\mathbb{R}_\delta$ with no omniscience principle and no choice principle. Three statements fail as first posed, for a reason worth seeing: they quantify over every zero of the cosine at which the sine is 1, rather than over the quarter period alone.

As in Section 26.7, q is the quarter period, $\pi = 2q$, and the *zone* is $[-\pi, \pi]^3$. For a function F on the zone, its *midpoint averages* are the averages of F over the $(N+1)^3$ centres of the cells of the grid with $N+1$ cells per axis, and v is its *zone average*, the continuum's $(2\pi)^{-3}\int F d^3k$, when the midpoint averages converge to v. Write $S(k) = \sum_j (1 - \cos k_j)$ and $|k|^2 = \sum_j k_j^2$.

Definition 26.58 (The lattice photon and the cold datum)**.** Let $r > 0$. The *Bose kernel* is the function K with $K(s)(e^s - 1) = s$ for every point s and $K(0) = 1$; there is exactly one. The *lattice photon energy* is the function E with $E(k) \geq 0$ and

$$\cosh E(k) - 1 = r\,S(k)$$

at every wave vector k, the shell equation of the lattice; its root is unique. A *cold datum* is $r > 0$, its square root $\sqrt{r}$, the functions E and K, a family $a(T)$, $T > 0$, of zone averages of $k \mapsto K(E(k)/T)$, and the Stefan–Boltzmann value $L = \pi^2/(15\sqrt{r}^3)$. The thermal energy density divided by T^4 is then $u(T)/T^4 = 2a(T)/T^3$, two polarizations times the average energy $TK(E/T)$ of a mode.

The parameter r sets the speed of long waves: $E(k)^2 = r|k|^2$ to leading order, as Proposition 26.59 shows.

Proposition 26.59 (The lattice photon)**.** *Let $r \geq 0$, and in the limits of parts 3 and 4 and the slope, $r > 0$.*

1. *$E(k)^2 \leq r|k|^2$ for every k; and if $|k_j| \leq 4$ for each j, then $r|k|^2 \leq 16(1+6r)E(k)^2$ and $r|k|^2 - E(k)^2 \leq C_4(r)|k|^4$, for a constant $C_4(r)$ given explicitly by the series of* cosh.
2. *At the zone edge $k = (\pi, 0, 0)$: $E^2 \leq 16/5$ when $r = 1$, and $E^2 \geq 19/5$ when $r = 4/3$.*
3. Long-wave limits. *Along a ray $k = \kappa n$ with $|n| = 1$, as $\kappa \to 0$: $E^2/\kappa^2 \to r$; with $v^2 = \sum_j (r \sin k_j / \sinh E)^2$ the squared group speed, $(1 - v^2/r)/\kappa^2 \to (\sum_j n_j^4 + r)/4$; and with $w = \sqrt{v^2/r}$, $(1-w)/E^2 \to (\sum_j n_j^4 + r)/(8r)$.*
4. Real time. *If $rS(k) \leq 2$, the real-time shell $1 - \cos\omega = rS(k)$ has a root ω with $0 \leq \omega \leq \pi$. Along a ray, for real-time roots in $[0, \pi]$, the limits of part 3 hold with $\sum_j n_j^4 - r$ in place of $\sum_j n_j^4 + r$ and ω in place of E. If $\omega(k)$ is such a root at every k with $rS(k) < 2$, then at every k with $S(k) > 0$, $rS(k) < 2$ and $\sin\omega(k)$ apart from 0, its derivative in k_j is $r \sin k_j / \sin\omega(k)$.*

Proof. (1) The series of cosh gives $E^2/2 \leq \cosh E - 1$, hence $E^2 \leq 2rS(k) \leq r|k|^2$, since $1 - \cos y \leq y^2/2$. The two other bounds compare both sides of the shell equation with their leading terms, using a lower bound for $1 - \cos y$ on $|y| \leq 4$ and the tail of the series of cosh beyond its quadratic and quartic terms on the range of E allowed by the first bound.

(2) At $k = (\pi, 0, 0)$, $S = 2$, so $\cosh E = 1 + 2r$. At $r = 1$, $\cosh E = 3$, and $E^2 \leq 16/5$ follows from $\cosh(\sqrt{16/5}) > 3$, checked on the series; at $r = 4/3$, $\cosh E = 11/3$, and $E^2 \geq 19/5$ from $\cosh(\sqrt{19/5}) < 11/3$. Each comparison is a finite computation with ratio bounds on the tail of the series.

(3) On the shell, $\sinh^2 E = (\cosh E - 1)(\cosh E + 1) = rS(2 + rS)$, and $\sum_j \sin^2 k_j = 2S - \sum_j (1 - \cos k_j)^2$, so $v^2 S(2 + rS) = r(2S - \sum_j (1 - \cos k_j)^2)$ exactly. Expanding $S = \kappa^2/2 - \kappa^4 \sum n_j^4/24 + \cdots$

along the ray, with the remainders of Proposition 12.98, gives each limit with an explicit modulus.

(4) The root is $\omega = \arccos(1 - rS(k))$, with the line's arccosine, which takes values in $[0, \pi]$ on $[-1, 1]$. On the real-time shell $\sin^2 \omega = rS(2 - rS)$, which gives the limits as in (3). The slope comes from an implicit-function argument with explicit constants: $\sin\omega\, d\omega = r \sin k_j\, dk_j$ on the shell. □

Theorem 26.60 (The lattice Stefan–Boltzmann law and its correction)**.** *Let $r > 0$. The zone averages $a(T)$ of Definition 26.58 exist for every $T > 0$, as one function of T. On every cold datum:*

1. *$u(T)/T^4 \to L = \pi^2/(15\sqrt{r}^3)$ as $T \to 0^+$;*
2. *for every $\varepsilon > 0$, eventually $L - \varepsilon T^2 \le u(T)/T^4$; for some $c > 0$, eventually $L + cT^2 \le u(T)/T^4$; and for some C, $u(T)/T^4 \le L + CT^2$ for every $T > 0$;*
3. *the coefficient $\big(u(T)/T^4 - L\big)/T^2$ converges as $T \to 0^+$, to*

$$\kappa\Big(\frac{\alpha}{r} + \beta\Big)L, \qquad \kappa = \frac{15}{\pi^2} \cdot \frac{2}{(2\pi)^3}, \quad 63\alpha = 4\pi^7, \quad 189\beta = 20\pi^7,$$

that is, to $\frac{5\pi^2}{21}\big(\frac{1}{r} + \frac{5}{3}\big)L$.

No omniscience principle and no choice principle is used.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; the quarter period; $r > 0$; the Bose kernel, the lattice photon energy and the zone averages of Definition 26.58.

Conclusion

Light on the cubic lattice obeys the Stefan–Boltzmann law as $T \to 0$, and its first correction is positive, of order T^2, with the exact coefficient $\frac{5\pi^2}{21}(\frac{1}{r} + \frac{5}{3})$ relative to the law, for the discrete-time shell $\cosh E - 1 = rS$ of Definition 26.58; the term $\frac{25\pi^2}{63}$ comes from the time step of that shell.

Not claimed

The identification of r, T or the lattice spacing with Recognition Science's own constants.

Proof. The zone averages. The integrand $K(E(k)/T)$ has a modulus of uniform continuity on the zone computed from T, and its midpoint averages form a sequence with an explicit Cauchy modulus. Such a presented sequence converges with no completeness and no choice, and the limit is a function of T because the modulus is computed, not chosen.

The law. Scale $k = Ty$. The midpoint average at temperature T becomes $T^3/(2\pi)^3$ times a box sum of $K(E(Ty)/T)$ over $[-\pi/T, \pi/T]^3$. By Proposition 26.59(1), $E(Ty)^2/T^2$ is within $C_4 T^2 |y|^4$ of $r|y|^2$ and at least $r|y|^2/(16(1 + 6r))$ on the scaled zone, so the integrand is dominated by

a separable product of functions $\operatorname{sech}^2(ay_j/2)$, whose box sums are bounded by telescoping, uniformly in the box and the grid. Every comparison is between two integrands on one box. As $T \to 0$ the box sums of $K(E(Ty)/T)$ approach the space value of $K(\sqrt{r}|y|)$. That value is $128q^5/(15\sqrt{r}^3) = 4\pi^5/(15\sqrt{r}^3)$: expand $K(s) = \sum_{n<M} se^{-(n+1)s} + K(s)e^{-Ms}$; each mode is the elementary integrand $|y|e^{-|y|}$ rescaled, whose space value is 24π (Theorem 12.96); the tail is bounded uniformly in the grid; and $\zeta(4) = \pi^4/90$ (Theorem 12.97) sums the modes. Multiplying by $2/(2\pi)^3$ gives L.

The T^2 coefficient. Write $b = \sqrt{r}|y|$ for the continuum photon energy at the scaled wave vector and $\sigma = E(Ty)/T$ for the lattice one. The shell equation, expanded to fourth order with the remainders of Proposition 12.98, gives

$$\sigma^2 = b^2 - \frac{T^2}{12}\Big(r\sum_j y_j^4 + r^2|y|^4\Big) + O(T^4|y|^6),$$

with an explicit constant, so the lattice photon lies just below light. Expand the kernel into its modes, $K(s) = \sum_{m\ge1} se^{-ms}$. For one mode $f(s) = se^{-ms}$, whose first two derivatives are explicit, the dispersion gives

$$f(\sigma) - f(b) = T^2\,\frac{\sqrt{r}}{24}\,(mb-1)e^{-mb}\Big[\big(\tfrac{3}{5}+r\big)|y|^3 + \frac{P_4(y)}{|y|}\Big]$$

up to explicit integrable majorants of order T^4, where $P_4(y) = \sum_j y_j^4 - \frac{3}{5}|y|^4$. The quartic P_4 is harmonic, so $P_4(y)W(|y|)/|y|$ is the divergence of $k(|y|)\nabla P_4$ with $k' = W/4$, and its box sums are fluxes through the faces of the box, which vanish as the box grows: this is how the angular average $\frac{1}{5}$ of n_1^4 enters, with no rotation symmetry of the cubic box. The radial part integrates exactly by Theorem 12.96, through $\int_0^\infty t^2(at-1)e^{-at}t^3\,dt = 600/a^6$, so mode m contributes $\sqrt{r}^{-3}(120q/r + 200q)/m^6$. Summing over the modes, with a tail bound uniform in T and $\zeta(6) = \pi^6/945$ (Theorem 12.97), the excess divided by T^2 tends to $\sqrt{r}^{-3}(\alpha/r + \beta)$ with $\alpha = 120q\,(2q)^6/945$, that is $63\alpha = 4\pi^7$, and $\beta = 200q\,(2q)^6/945$, that is $189\beta = 20\pi^7$. Multiplying by $2/(2\pi)^3$ and writing $\sqrt{r}^{-3} = 15L/\pi^2$ gives part 3; then $\kappa\alpha = \frac{20}{21}q^2$ and $\kappa\beta = \frac{100}{63}q^2$, which is the stated relative coefficient. The Bose value

$$\int_0^\infty s^2K(cs)\,ds = \frac{16q^4}{15c^3} = \frac{\pi^4}{15c^3},$$

proved on midpoint grids by the same splitting into modes, each a rescaled $\int t^3e^{-t}\,dt = 6$ (Proposition 12.98), with a tail uniform in the grid, is the one-dimensional form of the law's constant.

Part 2. The coefficient of part 3 is positive. So, eventually, $u(T)/T^4$ lies above $L + cT^2$ for c half the coefficient, and above $L - \varepsilon T^2$ for every $\varepsilon > 0$. The upper bound holds at every temperature, not only small ones: the kernel decreases, with $K(a) - K(b) \le (b-a)(1+b)K(a)$ for $0 \le a \le b$, which gives the pointwise bound $K(\sigma) \le K(b) + T^2m_1(y)$ with m_1 below an explicit separable majorant; and the box sums of $K(b)$ never exceed its space value by more than any given ε on fine grids, since the integrand is nonnegative, so a box holds no more than all of space. □

Corollary 26.61 (The correction depends on the parameter r). *The relative T^2 coefficient times the squared photon energy at the zone edge is strictly smaller at $r = 1$ than at $r = 4/3$: $\kappa(\alpha+\beta)E_1^2 < \kappa(\frac{3}{4}\alpha+\beta)E_{4/3}^2$, where E_r is the lattice photon energy at $(\pi,0,0)$.*

Proof. Since $0 < \alpha \le \beta$ (indeed $\beta = \frac{5}{3}\alpha$), $\kappa(\alpha+\beta)E_1^2 \le \frac{16}{5}\kappa(\alpha+\beta)$ and $\kappa(\frac{3}{4}\alpha+\beta)E_{4/3}^2 \ge \frac{19}{5}\kappa(\frac{3}{4}\alpha+\beta)$ by Proposition 26.59(2), and $16(\alpha+\beta) < 19(\frac{3}{4}\alpha+\beta)$ because $\frac{7}{4}\alpha < 3\beta$. □

So the size of the correction, measured against the photon energy at the zone edge, is not the same at $r = 1$ and at $r = 4/3$: it depends on the parameter r, not on the lattice alone.

Modes of a box, and two statements that needed the quarter period

On a periodic box with $N+1$ sites per side the field's own modes have wave numbers $2\pi m/(N+1)$. Theorem 12.101(3) shows that for a periodic integrand with a modulus of uniform continuity the averages over these modes converge to the zone average, with no principle; applied to $K(E(k)/T)$, the thermal energy summed over the box's own modes, divided by the number of modes, converges to $a(T)$. The characters of the box are then the plane waves.

Proposition 26.62 (Roots of unity and plane waves). *Let z be a pair of points, multiplied as a complex number, with $z^{N+1} = 1$. Then $z = e^{\mathrm{i}\,2\pi m/(N+1)}$ for exactly one natural number $m \le N$. Consequently every character ψ of the periodic box of side $N+1$, a map to the complex pairs with $\psi(0) = 1$, $\psi(x+y) = \psi(x)\psi(y)$ and period $N+1$ in each direction, is a plane wave $\psi(x) = e^{\mathrm{i}k\cdot x}$ with $k = 2\pi m/(N+1)$ for some $m \in \{0,\dots,N\}^3$. The first statement is false when $\pi = 2q$ is read with q any point having $q > 0$, $\cos q = 0$ and $\sin q = 1$: for $q' = 5q$, $N = 4$ and $z = e^{\mathrm{i}\,2\pi/5}$, no $m \le 4$ has $z = e^{\mathrm{i}\,4q'm/5}$.*

Proof. The points $\zeta_m = e^{\mathrm{i}2\pi m/(N+1)}$, $m \le N$, are roots of $z^{N+1} - 1$, pairwise at distance at least $2\sin(\pi/(N+1))$, so $z^{N+1} - 1 = \prod_m (z - \zeta_m)$. Given z with $z^{N+1} = 1$, $|z| = 1$. Let d be the least distance. Since $\prod_m |z - \zeta_m| = 0$, a finite comparison finds an m with $|z - \zeta_m| < d/2$: for each m decide, by approximation, whether $|z - \zeta_m| < d/2$ or $|z - \zeta_m| > d/4$; they cannot all exceed $d/4$, since then the product would be at least $(d/4)^{N+1} > 0$. This singles out one ζ_m near z. The product of the other factors is bounded away from 0 near ζ_m, and the whole product is 0, so $z = \zeta_m$. Uniqueness of m follows from the distances. A character with $\psi(0) = 1$ is determined by its values on the three unit steps, $\psi(x) = \prod_j \psi(e_j)^{x_j}$, each a root of unity of order $N+1$, since $\psi(e_j)^{N+1} = \psi((N+1)e_j) = \psi(0) = 1$. Without $\psi(0) = 1$ the zero map is a counterexample. For $q' = 5q$, $4q'm/5 = 4qm$, so $e^{\mathrm{i}4q'm/5} = 1$ for every m, while $e^{\mathrm{i}2\pi/5} \ne 1$. □

The same reading, every zero of the cosine with sine 1, also falsified two statements about real time, and the corrected forms are those of Proposition 26.59(4). As posed, the real-time ray limits and the real-time slope asked for them at roots in $[0, 2q']$ for every such q'. For $q' = 5q$ the root $4q - \kappa$ lies in $[0, 2q']$, satisfies the real-time shell, and has $\omega^2/\kappa^2 \ge 4/\kappa^2$, so the limit of ω^2/κ^2 fails; and a root function that jumps from ω_0 to $4q - \omega_0$ off one coordinate plane has no derivative there, which, asked for at every such function, would decide whether a point equals 0. With $q' \le 2$, that is with the quarter period, both statements hold.

26.10 Kepler's motion for all time

The rest of the chapter leaves the lattice of light: a polynomial field with a coercive first integral, the Kepler field, has a motion on the whole time line, and the lattice gauge expansions of Remark 26.64 state what is still missing below countable choice.

Theorem 26.63 (Kepler on the whole line)**.** *Let s be a physical state of the Kepler field (Definition 25.8) whose eight coordinates are ratios, with negative energy $E < 0$ and $|L|^2 > 0$. Then there is a motion $X : \mathbb{R}_\delta \to \mathbb{R}_\delta^8$ of the field, uniformly differentiable on bounded intervals, with $X(0) = s$. No omniscience principle and no choice principle is used.*

Proof. The motion is built explicitly, with no case split: no decision between a circle and an ellipse, no perihelion direction, no polar form of a vector. Write $\Lambda = |L|^2$ and $\ell = \sqrt{\Lambda}$. In the polar angle θ measured from the initial position the inverse radius is $U(\theta) = U_c + C\cos\theta + S'\sin\theta$, the solution of Binet's equation $U'' + U = m/\Lambda$, with $U_c = m/\Lambda$, $C = u - U_c$ and $S' = -u(x\cdot v)/\ell$ read from the state. The exact identity

$$2(mU + E) = \Lambda\big((U_c + C\cos\theta + S'\sin\theta)^2 + (C\sin\theta - S'\cos\theta)^2\big)$$

gives $mU \geq -E > 0$, so U has a positive lower bound. The polar angle as a function of time solves $\dot\Theta = \ell U(\Theta)^2$, $\Theta(0) = 0$; its rate is bounded above and below, and the clock construction of Theorem 25.40 (Lemma 25.22) gives Θ on the whole line. With the orthonormal pair $e_1 = ux$, $e_2 = u(L\times x)/\ell$ spanning the orbital plane, put $A = \cos\Theta\, e_1 + \sin\Theta\, e_2$ and $B = \cos\Theta\, e_2 - \sin\Theta\, e_1$, and

$$x(t) = A/U(\Theta), \quad v(t) = -\ell U'(\Theta)A + \ell U(\Theta)B, \quad u(t) = U(\Theta), \quad m(t) = m.$$

Differentiating, this is a motion of the Kepler field on the whole line, because $\Lambda U_c = m$, and at $t = 0$ it is the state s. □

Remark 26.64 (What the lattice expansions still need)**.** Six expansions of lattice gauge quantities hold given countable choice of natural numbers and are not known with no choice: the rate of a face phase, $|\Phi(h) - ch^2(g_y(0) - g_x(0))| \leq 2|c|M|h|^3$, and the cubic bounds for a face defect, for a plaquette and for a covariant difference, together with their two rates. Each follows from Taylor's step of Proposition 12.99, whose price with pointwise derivatives is open (Remark 12.104); with uniform derivatives each holds with no choice.

Questions to work through

1. (Theorem 26.11 and Theorem 26.15.) For the chain K of the opening, list the predecessor sets of the three configurations and the merging classes of K and of K^2. Find every distribution q with $D(qK \,\|\, p) = D(q \,\|\, p)$, and check that q_0 is one of them. Why does K^2 lower D strictly from every $q \neq p$, although K^2 has a zero entry?

2. (Theorem 26.16.) For the same chain, compute the largest δ with $(K^4)_{ij} \geq \delta\, p_j$ for all i, j, and the bound the theorem gives for $D(q_0K^8 \,\|\, p)$. Compare it with the true value.

3. (Theorem 26.23 and Theorem 26.24.) Let S be the ball of radius one, the vacuum and the six unit vectors, and P the Metropolis tick. Write down the walled tick P_S, check that it keeps π_S, and find its merging classes. Which Doeblin constant does Theorem 26.24 give at window 2, and what is the true largest one?

4. (Lemma 26.4 and Theorem 26.6.) Show that $g(\ell, q)$ is convex in q, and use the two-level system of the proof of Theorem 26.6 to show directly that "the free energy is $-\log Z$ or strictly above it" implies LPO.

5. (Proposition 26.43.) For two voxels under double entry, compute $D(\mathsf{P}_0 \,\|\, \Pi_c)$, $\mathrm{TC}(\mathsf{P}_0)$ and $D(\mathsf{P}_0 \,\|\, \pi \otimes \pi)$ at the empty record exactly, and check part (d) there. Show that the limit in part (e) is $D(\Pi_A \,\|\, \Pi_c)$, and write it with $\log 5$ and $\log \varphi$. By how much does the floor of part (d) exceed the floor $9 \log \varphi$ of Theorem 26.41(d)?

6. (Theorem 26.57.) Construct, for $D = 2$, a current with rational rates that is balanced off the origin and shell-uniform with $f(r) = 1/(2r + 1)$, by routing the flow around the shell $\|x\|_\infty = 1$ explicitly. Why can no integer multiple of it have integer rates?

Chapter 27

Gravity: the long-wave form of the cost and Regge's action

A geometry close to flat space is a metric $g = 1 + \varepsilon h$, with 1 the flat metric, h a symmetric strain and ε small. A ledger that compares the two geometries compares them through the matrix ratio $1^{-1}g = 1 + \varepsilon h$, whose eigenvalues are the stretches along the principal axes. When the ledger charges the cost $J(x) = \frac{1}{2}(x + x^{-1}) - 1$ of Chapter 21 for each stretch, what does it charge for the geometry, and is that charge the graviton?

Here is one wave. Use four coordinates, the zeroth read as time, take the wave covector $K = e_0$, and take the strain $h = e_1 e_2^{\mathsf{T}} + e_2 e_1^{\mathsf{T}}$, which shears the plane of the first two space axes. The matrix $1 + \varepsilon h$ has eigenvalues $1 + \varepsilon$, $1 - \varepsilon$, 1, 1, so the ledger charges

$$J(1+\varepsilon) + J(1-\varepsilon) = \frac{\varepsilon^2}{2(1+\varepsilon)} + \frac{\varepsilon^2}{2(1-\varepsilon)} = \frac{\varepsilon^2}{1-\varepsilon^2}.$$

Divided by ε^2 this tends to 1, which is $\frac{1}{2}\operatorname{tr}(h^2)$: the long-wave form of J. Linearized gravity charges a strain h at the wave K the Fierz–Pauli form [87]

$$\mathrm{FP}(h, K) = |K|^2 \operatorname{tr}(h^2) - 2|hK|^2 + 2 \operatorname{tr} h \, (K^{\mathsf{T}} h K) - |K|^2 (\operatorname{tr} h)^2,$$

which here is $2 - 0 + 0 - 0 = 2$. That is $|K|^2$ times twice the long-wave form of J. Two other strains at the same wave show where the agreement ends:

strain at $K = e_0$	$\frac{1}{2}\operatorname{tr}(h^2)$	$\mathrm{FP}(h, K)$	what it is
$e_1 e_2^{\mathsf{T}} + e_2 e_1^{\mathsf{T}}$	1	2	transverse and traceless
$e_0 e_1^{\mathsf{T}} + e_1 e_0^{\mathsf{T}}$	1	0	a change of coordinates
$\operatorname{diag}(0, 1, 1, 1)$	$\frac{3}{2}$	-6	the conformal mode

The ledger charges a mere change of coordinates, which gravity does not, and it charges the conformal mode positively, where gravity's form is negative. So the ledger's charge is not the gravitational action. On the strains that are transverse and traceless, however, the two agree exactly, at every wave, and the factor between them is the dispersion $|K|^2$.

This chapter proves that agreement and finds its scope. On transverse-traceless strains the graviton is J's long-wave form, in $D \geq 3$ space dimensions only, and J's calibration fixes the factor (Section 27.1); the identity holds over every commutative ring, hence on $\mathbb{R}_\delta$ with no choice, where the decisions about a wave have exact prices (Section 27.2). J allows every trace completion, locality selects Fierz–Pauli, locality itself rests on a depth bound for records or on taking the long-wave limit at a fixed stage, and J fixes neither the background nor Newton's constant (Section 27.3). Curvature, lattice deficits and Regge's table see exactly the non-gauge part, and no nonzero local two-derivative invariant form is nonnegative (Section 27.4).

Regge's action and J's odd hinge cost agree to second order only: J's cubic vertex breaks gauge invariance, so for a static field built from two harmonic modes the second-order equation has no solution and J's post-Newtonian parameter β_{PN} does not exist; a hinge cost linear in the deficit matches Regge's derivatives exactly when its area factor is linear to second order (Section 27.5). Schläfli's identity holds for every nondegenerate Euclidean 4-simplex, and Regge's Hessian is $\sqrt{|\det g_\kappa|}$ times one rational family of tables, with true second derivatives for every $\kappa < \frac{1}{4}$ and at $\kappa = 1$ (Sections 27.6 and 27.7); the near-flat chain from Regge's action to Fierz–Pauli, and its cubic term, run on $\mathbb{R}_\delta$, free, and at $\kappa = 1$ a wave with no deficits is a vertex displacement or, at zero wave, a constant metric strain (Section 27.7). The background $\kappa = 1$ is equivalent to the purity of one posting's lattice record and is not derived (Section 27.8); the locality clause can be a world's rule and is a named premise (Section 27.9); and reading J's comparison as the graviton's action needs two numbers at one wave, each resting on a named premise whose exact content we state (Section 27.10). Sections 27.11–27.16 go beyond linear gravity: Regge's long-wave vertices are one half of Einstein's through quartic order, with Regge's own derivatives on every Euclidean background g_κ, $\kappa < \frac{1}{4}$, and for the continued tables on every background off the poles; among hinge charges built from one function of the area, gauge consistency selects Regge's action through cubic order, and for shape costs it fixes Regge's action up to its coupling; J's cubic vertex is one quarter of Einstein's plus a part Δ that no redefinition removes; hinge shape costs cannot complete a changed coupling at quartic order; four gravitons scatter at tree level and long wavelength as in general relativity on every flat background g_κ off the poles; at order K^4 the graviton's two branch values are known on every Lorentzian background other than $\kappa = \frac{1}{2}$, and every background with $\kappa > \frac{1}{2}$, $\kappa = 1$ included, is birefringent; and each named premise of reading the cost as the graviton's action is separated from the foundation or reduced to one named reading.

Polynomial identities hold over every commutative ring and are free on $\mathbb{R}_\delta$; the native chain is proved on $\mathbb{R}_\delta$ directly, with δ's own π, cosine and square root, and its decisions carry the prices of Chapter 12. Statements about real matrices, limits, complex exponentials and records are proved in classical mathematics, and we claim no price on $\mathbb{R}_\delta$ for them; each section and scope box says which kind it states. Reading a strain as a spacetime metric, the Kuhn lattice as discretized spacetime and Regge's action as the gravitational action are identifications, named where they enter. The full treatment of linear gravity on the ledger is the preprint [95] (Zenodo, 2026); the vertices through quartic order are treated in [196], and the gravity program as a whole in [197]. Each result stated here has its proof here, in one of three forms that the proof makes plain: complete; resting on a long finite computation that the proof describes, with its inputs, without reproducing it; or, for Theorems 27.32 and 27.33, a route whose steps and constants the proof names without carrying the estimates out.

27.1 The long-wave form of J is the Fierz–Pauli form on transverse strains

We first fix the objects. Indices of four-dimensional vectors and matrices run over 0, 1, 2, 3; e_a is the ath unit vector and $E_{ab} = e_a e_b^{\mathsf{T}}$.

Definition 27.1 (Matrix cost, long-wave form, Fierz–Pauli form)**.**

1. For an invertible real $n \times n$ matrix A, the *cost of the ratio* A is $J(A) = \frac{1}{2}(\operatorname{tr} A + \operatorname{tr} A^{-1}) - n$. For a real $n \times n$ matrix X, *J's long-wave form* is $J_2(X) = \frac{1}{2}\operatorname{tr}(X^2)$.

2. A *strain* is a real symmetric 4×4 matrix h, and a *wave* is a covector $K \in \mathbb{R}^4$ with $|K|^2 = K \cdot K$. The *Fierz–Pauli form* $\mathrm{FP}(h, K)$ is the form displayed in the opening. A *gauge mode* at K is $K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}}$ with $\xi \in \mathbb{R}^4$.

3. For $K \neq 0$ the *transverse projector* is $\Pi_K = 1 - KK^{\mathsf{T}}/|K|^2$, and the *transverse strain* of h is $\Pi_K h \Pi_K$. The strain h is *transverse-traceless* (TT) at K when $hK = 0$ and $\operatorname{tr} h = 0$.

If A is diagonalizable with positive eigenvalues λ_i, then $J(A) = \sum_i J(\lambda_i)$: the cost of a ratio of metrics is J summed over the principal stretches. Π_K satisfies $\Pi_K^2 = \Pi_K$, $\Pi_K K = 0$ and $\operatorname{tr} \Pi_K = 3$. Reading $g_0^{-1} g$ as the comparison of two spacetime metrics, and FP as the action of linearized gravity, are identifications. The results of this section are proved in classical mathematics over the classical real numbers.

Theorem 27.2 (The exact expansion of the cost of a ratio)**.** *Let X be a real $n \times n$ matrix and ε a real number with $1 + \varepsilon X$ invertible. Then*

$$J(1 + \varepsilon X) = \frac{\varepsilon^2}{2} \operatorname{tr}\big(X^2 (1 + \varepsilon X)^{-1}\big),$$

and $J(1 + \varepsilon X)/\varepsilon^2 \to J_2(X)$ as $\varepsilon \to 0$ with $\varepsilon \neq 0$.

Proof. $(1 - \varepsilon X)(1 + \varepsilon X) = 1 - \varepsilon^2 X^2$, so $(1 + \varepsilon X)^{-1} = 1 - \varepsilon X + \varepsilon^2 X^2 (1 + \varepsilon X)^{-1}$. Take traces, add $\operatorname{tr}(1 + \varepsilon X) = n + \varepsilon \operatorname{tr} X$ and halve. The determinant of $1 + \varepsilon X$ is continuous with value 1 at $\varepsilon = 0$, so the matrix is invertible near 0, and inversion is continuous at the identity; hence $\frac{1}{2}\operatorname{tr}(X^2(1 + \varepsilon X)^{-1}) \to J_2(X)$. □

Theorem 27.3 (Fierz–Pauli is the dispersion times *J*'s long-wave form)**.** *Let h be a strain, $K \neq 0$ a wave and $A = \Pi_K h \Pi_K$ its transverse strain.*

(a) $\mathrm{FP}(h, K) = |K|^2\big(\operatorname{tr}(A^2) - (\operatorname{tr} A)^2\big) = |K|^2\big(2J_2(A) - (\operatorname{tr} A)^2\big)$.

(b) If h is TT at K, then $\mathrm{FP}(h, K) = |K|^2 \cdot 2J_2(h)$.

(c) A gauge mode $h = K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}}$ has $\mathrm{FP}(h, K) = 0$, *while $J_2(h) = (K \cdot \xi)^2 + |K|^2|\xi|^2$, which is positive when $\xi \neq 0$.*

(d) The conformal mode $h = \Pi_K$ has $\mathrm{FP}(\Pi_K, K) = -6|K|^2 < 0$, *while $J_2(\Pi_K) = \frac{3}{2} > 0$.*

Conditions and scope.

Base and premises

Real symmetric 4×4 matrices and real waves, with the Euclidean dot product, all four axes treated alike. Proved in classical mathematics.

Conclusion

On transverse-traceless strains, linearized gravity's form is exactly the dispersion times twice J's long-wave form; off them the two differ in gauge and in sign.

Not claimed

That the graviton's action is J's cost of comparing metrics: by (c) that cost is not gauge invariant. The Lorentzian form is Theorem 27.6.

Identification

h as a metric strain and FP as the action of linearized gravity.

Proof. (a) Put $s = |K|^2$ and $\Pi = \Pi_K$. Since $\Pi^2 = \Pi$, $\operatorname{tr} A = \operatorname{tr}(\Pi h) = \operatorname{tr} h - s^{-1} K^{\mathsf{T}} h K$ and $\operatorname{tr}(A^2) = \operatorname{tr}((\Pi h)^2)$. Expanding $\Pi h = h - s^{-1} K K^{\mathsf{T}} h$ and using $\operatorname{tr}(K K^{\mathsf{T}} h^2) = |hK|^2$ and $\operatorname{tr}((K K^{\mathsf{T}} h)^2) = (K^{\mathsf{T}} h K)^2$ gives $\operatorname{tr}(A^2) = \operatorname{tr}(h^2) - 2s^{-1}|hK|^2 + s^{-2}(K^{\mathsf{T}} h K)^2$. Hence

$$s\big(\operatorname{tr} A^2 - (\operatorname{tr} A)^2\big) = s \operatorname{tr} h^2 - 2|hK|^2 - s(\operatorname{tr} h)^2 + 2 \operatorname{tr} h\, K^{\mathsf{T}} h K = \mathrm{FP}(h, K),$$

the two terms $\pm s^{-1}(K^{\mathsf{T}} h K)^2$ cancelling. (b) If $hK = 0$ then $\Pi h \Pi = h$, so $A = h$ and $\operatorname{tr} A = 0$. (c) $\Pi K = 0$ gives $\Pi(K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}})\Pi = 0$, so $A = 0$ and (a) gives FP $= 0$. Also $\operatorname{tr}((K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}})^2) = 2(K \cdot \xi)^2 + 2|K|^2|\xi|^2$. (d) $A = \Pi$, $\operatorname{tr} A = \operatorname{tr} A^2 = 3$, so FP $= |K|^2(3 - 9)$, and $J_2(\Pi) = \frac{3}{2}$. □

Symmetry alone leaves the factor in front of FP free. J fixes it. To say this precisely we use the nine invariants of a strain and a wave under the symmetries of the cube (permutations and sign changes of the axes), which contain every two-derivative form a lattice of cubes can produce:

$$\begin{aligned} I_1 &= (\operatorname{tr} h)^2 |K|^2, & I_2 &= \operatorname{tr}(h^2)|K|^2, & I_3 &= \operatorname{tr} h\, K^{\mathsf{T}} h K, & I_4 &= |hK|^2, \\ A_1 &= \operatorname{tr} h \textstyle\sum_x h_{xx} K_x^2, & A_2 &= \textstyle\sum_{x,y} h_{xy}^2 K_x^2, & A_3 &= \textstyle\sum_x h_{xx} K_x (hK)_x, & A_4 &= |K|^2 \textstyle\sum_x h_{xx}^2, \end{aligned}$$

and $A_5 = \sum_x h_{xx}^2 K_x^2$, so that FP $= I_2 - 2I_4 + 2I_3 - I_1$. A form $\mathcal{Q}(h, K)$ is *gauge invariant* when $\mathcal{Q}(h + K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}}, K) = \mathcal{Q}(h, K)$ for every strain h and all K, ξ.

Theorem 27.4 (J's calibration fixes the factor)**.** *Let $\mathcal{Q} = \gamma_1 I_1 + \gamma_2 I_2 + \gamma_3 I_3 + \gamma_4 I_4 + \alpha_1 A_1 + \cdots + \alpha_5 A_5$ with real coefficients. If $\mathcal{Q}$ is gauge invariant, then $\mathcal{Q} = \gamma_2$ FP. Hence a gauge-invariant $\mathcal{Q}$ satisfies $\mathcal{Q}(h, K) = |K|^2 \cdot 2J_2(h)$ for every strain h that is TT at K if and only if $\mathcal{Q} =$ FP.*

Proof. Write the strain with independent entries h_{ab}, $a \le b$, and expand $\mathcal{Q}(h + K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}}, K) - \mathcal{Q}(h, K)$ as a polynomial in the h_{ab}, K_a and ξ_a. Gauge invariance makes every coefficient vanish. The coefficients of eight monomials are, by direct expansion of the nine invariants,

$$\begin{aligned} K_1^2 K_2 h_{00} \xi_2 &: \ 4\gamma_1 + 2\gamma_3, & K_0 K_1 K_2 h_{01} \xi_2 &: \ 4\gamma_3 + 4\gamma_4, \\ K_0 K_2^2 h_{01} \xi_1 &: \ 4\gamma_2 + 2\gamma_4, & K_0^4 \xi_1^2 &: \ 2\gamma_2 + \gamma_4 + \alpha_2, \\ K_1^3 h_{00} \xi_1 &: \ 4\gamma_1 + 2\gamma_3 + 2\alpha_1, & K_0^2 K_1 h_{00} \xi_1 &: \ 4\gamma_1 + 4\gamma_3 + 2\gamma_4 + 2\alpha_1 + \alpha_3, \\ K_0 K_1^2 h_{00} \xi_0 &: \ 4\gamma_1 + 4\gamma_2 + 2\gamma_3 + 2\gamma_4 + \alpha_3 + 4\alpha_4, & K_0^3 h_{00} \xi_0 &: \ 4(\gamma_1 + \cdots + \gamma_4 + \alpha_1 + \cdots + \alpha_5). \end{aligned}$$

Setting them to zero in this order gives $\gamma_3 = -2\gamma_1$, $\gamma_4 = 2\gamma_1$, $\gamma_2 = -\gamma_1$, $\alpha_2 = 0$, $\alpha_1 = 0$, $\alpha_3 = 0$, $\alpha_4 = 0$ and $\alpha_5 = 0$. So $(\gamma_1, \gamma_2, \gamma_3, \gamma_4) = \gamma_2(-1, 1, 2, -2)$ and $\mathcal{Q} = \gamma_2$FP. At the TT strain $h = E_{12} + E_{21}$ and $K = e_0$ we have $|K|^2 \cdot 2J_2(h) = 2 = \mathrm{FP}(h, K)$, so the calibration on TT strains forces $\gamma_2 = 1$. Conversely FP is gauge invariant (Theorem 27.3(a), since A does not change) and calibrated on TT strains (Theorem 27.3(b)). □

"J's calibration" is the normalization $J(x) = (x-1)^2/2 + O((x-1)^3)$ of Theorem 21.14. It fixes the factor that symmetry leaves free; it does not fix the physical strength of the action, which Proposition 27.14 takes up.

How many independent transverse-traceless strains are there? Take $D+1$ coordinates and read time along the all-ones vector $\mathbf{1} = (1, \dots, 1)$, as the lattice of Section 27.7 does. A strain H is *TT at the wave m* when it is symmetric and $H\mathbf{1} = 0$, $Hm = 0$ and $\operatorname{tr} H = 0$.

Theorem 27.5 (A graviton exactly in three or more space dimensions)**.** *Let $D \geq 0$ and let $m \in \mathbb{R}^{D+1}$ be a wave that is not a multiple of $\mathbf{1}$.*

(a) The strains TT at m form a real vector space of dimension $(D+1)(D-2)/2$, with $D-2$ read as 0 when $D < 2$.

(b) $J_2(H) > 0$ for every nonzero strain H that is TT at m.

(c) A nonzero TT strain exists at some wave that is not a multiple of $\mathbf{1}$ if and only if $D \geq 3$. For $D = 3$ there are two polarizations; for $D = 4$, five.

Proof. (a) Choose coordinates $i \neq j$ with $m_i \neq m_j$ and let R be the other $D-1$ coordinates. For $k \in R$ solve $a_k + b_k = 1$, $a_k m_i + b_k m_j = m_k$ (determinant $m_j - m_i \neq 0$) and put $r_k = e_k - a_k e_i - b_k e_j$, so that $r_k \cdot \mathbf{1} = 0 = r_k \cdot m$. For symmetric B on R, $H_B = \sum_{k,l \in R} B_{kl} r_k r_l^{\mathsf{T}}$ is symmetric with $H_B\mathbf{1} = 0 = H_B m$ and block B on R; and a symmetric H with $H\mathbf{1} = 0 = Hm$ equals H_B for its block B, since $H - H_B$ vanishes on $R \times R$ and its rows solve the same 2×2 system with zero right side. So these strains form a space of dimension $(D-1)D/2$, on which the trace is a nonzero functional when $D \geq 2$ ($\operatorname{tr} r_k r_k^{\mathsf{T}} = |r_k|^2 > 0$); for $D = 1$, R is empty. (b) $\operatorname{tr}(H^2) = \sum_{r,c} H_{rc}^2$ for symmetric H. (c) If $D \geq 3$, the wave e_0 is not a multiple of $\mathbf{1}$ and (a) gives dimension at least 2. If $D \leq 2$, (a) gives dimension 0 at every admissible wave, and when $D = 0$ there is no admissible wave. □

This is a lower bound: J gives no upper bound $D \leq 3$, and the three dimensions of Chapter 23 come from linking, not from this count.

27.2 The Lorentzian identity on $\mathbb{R}_\delta$

The identity of Theorem 27.3 is a polynomial identity once the inverse of the dispersion is given as data, and then it holds over every commutative ring. On $\mathbb{R}_\delta$ that inverse exists exactly when the dispersion is apart from 0.

For a commutative ring R, a symmetric 4×4 matrix S over R (an inverse metric), a wave $u \in R^4$ and symmetric X, Y, put $\eta = u^{\mathsf{T}} S u$ and

$$\begin{aligned} \mathrm{FP}_S(u; X, Y) = {} & \eta \operatorname{tr}(SXSY) - 2\, u^{\mathsf{T}} SXSYSu + \operatorname{tr}(SY)\, u^{\mathsf{T}} SXSu \\ & + \operatorname{tr}(SX)\, u^{\mathsf{T}} SYSu - \eta \operatorname{tr}(SX) \operatorname{tr}(SY). \end{aligned}$$

For $S = 1$ and $X = Y = h$ this is $\mathrm{FP}(h, u)$. The lattice of Recognition Science's gravity sector is taken at the cell metric $g_1 = 1 - \mathbf{1}\mathbf{1}^{\mathsf{T}}$ (the background $\kappa = 1$, a named premise; Section 27.8), in which each axis step is light-like; its inverse is $g_1^{-1} = 1 - \frac{1}{3}\mathbf{1}\mathbf{1}^{\mathsf{T}}$, and its dispersion is

$$m \cdot m = m^{\mathsf{T}} g_1^{-1} m = \sum_a m_a^2 - \tfrac{1}{3}\Big(\sum_a m_a\Big)^2.$$

We write $\mathrm{FP}_{g_1}(m; X, Y)$ for FP_S with $S = g_1^{-1}$. A strain H is TT at u when it is symmetric and $H\mathbf{1} = 0$, $Hu = 0$, $\operatorname{tr} H = 0$.

Theorem 27.6 (The Lorentzian graviton identity, over every ring)**.** *Let R be a commutative ring, S, X, Y symmetric and $u \in R^4$.*

(a) If $w\eta = 1$ for some $w \in R$, put $P = 1 - w(Su)u^{\mathsf{T}}$ and $A_X = P^{\mathsf{T}} X P$. Then

$$\mathrm{FP}_S(u; X, Y) = \eta\big(\operatorname{tr}(SA_XSA_Y) - \operatorname{tr}(SA_X)\operatorname{tr}(SA_Y)\big).$$

(b) $\mathrm{FP}_S(u; u\xi^{\mathsf{T}} + \xi u^{\mathsf{T}}, Y) = 0$ for every $\xi \in R^4$.

(c) For every $t \in R$, if X and Y are TT at u, then with $S = 1 - t\mathbf{1}\mathbf{1}^{\mathsf{T}}$, $\operatorname{tr}(SXSY) = \operatorname{tr}(XY)$ and $\operatorname{tr}(SX) = 0$.

(d) If $3t = 1$, then $(1 - \mathbf{1}\mathbf{1}^{\mathsf{T}})(1 - t\mathbf{1}\mathbf{1}^{\mathsf{T}}) = 1$, and with $S = 1 - t\mathbf{1}\mathbf{1}^{\mathsf{T}}$ the conformal mode g_1 has $\mathrm{FP}_S(u; g_1, g_1) = -6\eta$ while $\operatorname{tr}(Sg_1Sg_1) = 4$.

(e) On $\mathbb{R}_\delta$, every wave u whose dispersion $u \cdot u$ is apart from 0 has an inverse w of its dispersion.

So on $\mathbb{R}_\delta$, at every wave off the cone, $\mathrm{FP}_{g_1}(u; H, H) = (u \cdot u) \cdot 2J_2(H)$ for every TT strain H. All of this is free.

Conditions and scope.

Base and premises

Any commutative ring; on $\mathbb{R}_\delta$ the ring of Proposition 12.19. No omniscience principle and no choice principle.

Conclusion

The Lorentzian graviton form is the dispersion times J's polarized long-wave form of the transverse strain; gauge modes are null; on the lattice metric the conformal mode has the sign opposite to J's.

Not claimed

Anything on the cone $u \cdot u = 0$, where the projector P does not exist; deciding whether a wave is on the cone has a price (Theorem 27.8).

Proof. (a) Put $v = Su$ and $S_\perp = S - wvv^{\mathsf{T}}$. Using $w\eta = 1$ and $u^{\mathsf{T}}S = v^{\mathsf{T}}$: $SP^{\mathsf{T}} = S - wvv^{\mathsf{T}} = S_\perp$, and $PS_\perp = S_\perp - wvv^{\mathsf{T}} - wvv^{\mathsf{T}} + w^2\eta vv^{\mathsf{T}} = S_\perp$. Hence $\operatorname{tr}(SA_XSA_Y) = \operatorname{tr}(PS_\perp XS_\perp Y) = \operatorname{tr}(S_\perp XS_\perp Y)$ and $\operatorname{tr}(SA_X) = \operatorname{tr}(S_\perp X)$. Expanding,

$$\operatorname{tr}(S_\perp XS_\perp Y) = \operatorname{tr}(SXSY) - 2wv^{\mathsf{T}}XSYv + w^2(v^{\mathsf{T}}Xv)(v^{\mathsf{T}}Yv),$$
$$\operatorname{tr}(S_\perp X)\operatorname{tr}(S_\perp Y) = \operatorname{tr}(SX)\operatorname{tr}(SY) - w\operatorname{tr}(SX)v^{\mathsf{T}}Yv - w\operatorname{tr}(SY)v^{\mathsf{T}}Xv + w^2(v^{\mathsf{T}}Xv)(v^{\mathsf{T}}Yv).$$

The w^2 terms cancel in the difference; multiplying by η and using $w\eta = 1$ gives the five terms of FP_S, since $v^{\mathsf T}XSYv = u^{\mathsf T}SXSYSu$. (b) With $X = u\xi^{\mathsf T} + \xi u^{\mathsf T}$, $\zeta = S\xi$ and $a = \xi^{\mathsf T}Su$: $SXS = v\zeta^{\mathsf T} + \zeta v^{\mathsf T}$, so the five terms are $2\eta\,\zeta^{\mathsf T}Yv$, $-2(\eta\,\zeta^{\mathsf T}Yv + a\,v^{\mathsf T}Yv)$, $2\eta a\,\mathrm{tr}(SY)$, $2a\,v^{\mathsf T}Yv$ and $-2\eta a\,\mathrm{tr}(SY)$, which add to 0. (c) $\mathbf{1}^{\mathsf T}X = (X\mathbf{1})^{\mathsf T} = 0$, so $SX = X$ and $SY = Y$. (d) $\mathbf{1}^{\mathsf T}\mathbf{1} = 4$ gives $(1 - \mathbf{1}\mathbf{1}^{\mathsf T})(1 - t\mathbf{1}\mathbf{1}^{\mathsf T}) = 1 - (1 - 3t)\mathbf{1}\mathbf{1}^{\mathsf T}$. With $Sg_1 = 1$ the five terms are 4η, -2η, 4η, 4η and -16η. (e) is Proposition 12.19, item 3. The final sentence combines (a), (c) and (d): for TT H, $A_H = H$ because $Hu = 0$, and $\mathrm{tr}(SHSH) = \mathrm{tr}(H^2)$. □

The same identity shows that J's transverse form cannot see the background. Let $g_\kappa = 1 - \kappa\mathbf{1}\mathbf{1}^{\mathsf T}$; $\kappa = 0$ is the Euclidean metric, $\kappa = 1$ the lattice metric, and $\det g_\kappa = 1 - 4\kappa$, so $\kappa = \frac{1}{4}$ is degenerate. This κ is the background parameter of the lattice, not the Einstein coupling of Chapter 22.

Proposition 27.7 (Fierz–Pauli is affine in the background; J is blind to it)**.** *Over every commutative ring, with $S_t = 1 + t\mathbf{1}\mathbf{1}^{\mathsf T}$:*

(a) for every wave u and symmetric H, $\mathrm{FP}_{S_t}(u; H, H) = \mathrm{FP}_1(u; H, H) + t\,B(u, H)$, where, with $o = \mathbf{1}$,

$$B(u,H) = (o\cdot u)^2\big(\mathrm{tr}\,H^2 - (\mathrm{tr}\,H)^2\big) - 2|u|^2(o^{\mathsf T}Ho)\,\mathrm{tr}\,H + 2|u|^2|Ho|^2 + 4(o\cdot u)\,\mathrm{tr}\,H(o^{\mathsf T}Hu) - 4(o\cdot u)(o^{\mathsf T}H^2u) + 2(o^{\mathsf T}Ho)(u^{\mathsf T}Hu) - 2(o^{\mathsf T}Hu)^2;$$

(b) $g_\kappa S_t = 1$ whenever $t(1 - 4\kappa) = \kappa$;

(c) for symmetric X, Y with $X\mathbf{1} = 0 = Y\mathbf{1}$, $\mathrm{tr}(S_tXS_tY) = \mathrm{tr}(XY)$ and $\mathrm{tr}(S_tX) = \mathrm{tr}\,X$, whatever t.

The proofs are free on $\mathbb{R}_\delta$.

Proof. (a) Each of the five terms of FP_{S_t} is a polynomial in t of degree at most four. Expanding with $S_t = 1 + t\,oo^{\mathsf T}$ and $o^{\mathsf T}o = 4$, the coefficients of t^2, t^3 and t^4 cancel and the coefficient of t is $B(u, H)$; the expansion is a finite computation with integer coefficients. (b) $g_\kappa S_t = 1 + (t - \kappa - 4\kappa t)oo^{\mathsf T}$. (c) $o^{\mathsf T}X = 0$ removes every t. □

So the background enters Fierz–Pauli linearly and J's transverse form not at all: J does not fix κ. Section 27.8 shows what does.

On $\mathbb{R}_\delta$ the questions one asks about a wave have exact prices. The *spatial part* of a wave m is $n = m - \frac{1}{4}(\sum_a m_a)\mathbf{1}$, and when its squared length $|n|^2$ has an inverse r, the projector $\Pi = 1 - \frac{1}{4}\mathbf{1}\mathbf{1}^{\mathsf T} - r\,nn^{\mathsf T}$ and the map $\Lambda_m(H) = \Pi H\Pi - \frac{1}{2}\,\mathrm{tr}(\Pi H)\Pi$ are defined. The principles are those of Definition 7.8.

Theorem 27.8 (Cone, sign and projector on $\mathbb{R}_\delta$)**.** *On $\mathbb{R}_\delta$, with no choice principle:*

(a) $g_1 g_1^{-1} = 1 = g_1^{-1} g_1$, and the dispersion is $m\cdot m = \sum_a m_a^2 - \frac{1}{3}(\sum_a m_a)^2$;

(b) if $|n|^2$ is apart from 0, then Λ_m sends every symmetric strain to a strain TT at m, satisfies $\Lambda_m \circ \Lambda_m = \Lambda_m$ and fixes every strain TT at m; all free;

(c) deciding $m\cdot m = 0 \vee m\cdot m \neq 0$ for every wave m is equivalent to WLPO;

(d) deciding $m \cdot m > 0 \vee m \cdot m = 0 \vee m \cdot m < 0$ for every wave is equivalent to LPO;

(e) "if $|n|^2 \neq 0$, then $|n|^2$ has an inverse", for every wave, is equivalent to $\mathrm{MP}_{\mathrm{bin}}$*;*

(f) for integer waves, $m \cdot m = 0$ exactly when $3\sum_a m_a^2 = (\sum_a m_a)^2$, which is decided free.

Proof. (a) is Theorem 27.6(d) with $t = \frac{1}{3}$. (b) is a polynomial computation in r using $r|n|^2 = 1$, $\Pi\mathbf{1} = 0$, $\Pi n = 0$, $\Pi^2 = \Pi$ and $\operatorname{tr}\Pi = 2$. For (c)–(e): every point x is the dispersion of a wave, namely $m = \frac{1}{2}(1+x)\hat{n} + \frac{\sqrt{3}}{4}(1-x)\mathbf{1}$ with $\hat{n} = (e_0 - e_1)/\sqrt{2}$, since then $m \cdot m = \frac{1}{4}(1+x)^2 - \frac{1}{4}(1-x)^2 = x$; and every point $x \geq 0$ is $|n|^2$ for the wave $m = y(e_0 - e_1)$ with $y = \sqrt{x/2}$. Conversely each dispersion and each $|n|^2$ is a point. So each statement is equivalent to the corresponding statement for all points, or for all nonnegative points, and Corollary 12.18 prices those; its proofs of the WLPO and $\mathrm{MP}_{\mathrm{bin}}$ cases use only nonnegative points, and a point has an inverse exactly when it is apart from 0 (Proposition 12.19). (f) Multiply by 3. □

27.3 Completions, locality and the scale

J fixes the graviton's form on transverse-traceless strains. A full quadratic form must also say what to charge for the trace of the transverse strain, and J allows every answer. Locality decides.

Definition 27.9 (Completions and local lattice costs)**.**

1. For real β, the *completion* C_β is $C_\beta(h, K) = |K|^2\big(\operatorname{tr} A^2 + \beta(\operatorname{tr} A)^2\big)$ with $A = \Pi_K h \Pi_K$, and $C_\beta(h, 0) = 0$.
2. A *completion of J's transverse form* is a function $C(h, K)$ of strains and waves that is gauge invariant, invariant under every orthogonal R ($C(RhR^{\mathsf{T}}, RK) = C(h, K)$), homogeneous ($C(h, tK) = t^2 C(h, K)$), a quadratic form in h for each K, and equal to $|K|^2 \cdot 2J_2(h)$ whenever h is TT at K.
3. A *local lattice cost* is a finite list of terms j, each with two lattice offsets $p_j, q_j \in \mathbb{Z}^4$ and a real coefficient $c_j(H_0, H_1)$ depending on two strains. On the plane-wave pair $H_0 e^{iK\cdot x}$, $H_1 e^{-iK\cdot x}$ its cost at the site $x \in \mathbb{Z}^4$ is $\sum_j c_j e^{iK\cdot(x+p_j)} e^{-iK\cdot(x+q_j)}$. Its *symbol* is $\sum_j c_j \cos(K \cdot d_j)$ with $d_j = p_j - q_j$, and its *long-wave symbol* is $-\frac{1}{2}\sum_j c_j (K \cdot d_j)^2$.

The parameter β is DeWitt's [86]: $\beta = -1$ is Fierz–Pauli (Theorem 27.3(a)) and $\beta = 0$ is J's own long-wave form of the transverse strain. A local cost compares strains at lattice sites a fixed distance apart, with signed coefficients; the lattice actions of Section 27.4 are of this kind. The results of this section are proved in classical mathematics.

Theorem 27.10 (J allows every completion)**.**

(a) Every C_β is a completion of J's transverse form; $C_{-1} =$ FP on strains, and $C_{-1} \neq C_0$.

(b) Every completion C equals C_β on strains, with $\beta = (C(\Pi_{e_0}, e_0) - 3)/9$.

(c) Each C_β is built from J: for every strain h and wave $K \neq 0$, with $A = \Pi_K h \Pi_K$,

$$2|K|^2 \, \frac{J(1+\varepsilon A) + \beta\, J\big(\det(1+\varepsilon A)\big)}{\varepsilon^2} \longrightarrow C_\beta(h,K) \qquad (\varepsilon \to 0,\ \varepsilon \neq 0),$$

and the volume cost obeys J's composition law: for real matrices M, N with $\det M, \det N > 0$, $J(\det MN) + J(\det MN^{-1}) = 2J(\det M)J(\det N) + 2J(\det M) + 2J(\det N)$.

(d) For $\beta \geq 0$, $C_\beta(h,K) \geq 0$ for every strain, while $C_{-1}(1,K) = -6|K|^2$ for $K \neq 0$.

So no property that J imposes on the strain selects β, and J's positivity points away from Fierz–Pauli.

Proof. (a) $\Pi_K(K\xi^{\mathsf T} + \xi K^{\mathsf T})\Pi_K = 0$ gives gauge invariance; $\Pi_{RK} = R\Pi_K R^{\mathsf T}$ gives orthogonal invariance; $\Pi_{tK} = \Pi_K$ for $t \neq 0$ gives homogeneity; A is linear in h; and on TT strains $A = h$ and $\operatorname{tr} A = 0$. $C_{-1} = \mathrm{FP}$ is Theorem 27.3(a). $C_{-1} - C_0 = -|K|^2(\operatorname{tr} A)^2$ is -1 at $h = E_{00}$, $K = e_1$. (b) First take $K = e_0$. Adding the gauge mode $e_0\xi^{\mathsf T} + \xi e_0^{\mathsf T}$ with $\xi = -(\frac{1}{2}h_{00}, h_{01}, h_{02}, h_{03})$ clears the zeroth row and column, so $C(h, e_0)$ depends only on the spatial block a of h, a symmetric 3×3 matrix, through a quadratic form invariant under permutations and sign changes of the three space axes. Write $a = a_0 + \frac{1}{3}(\operatorname{tr} a)1$ with a_0 traceless. The polarization of the form between a_0 and 1 is a linear functional of a_0 invariant under the sign changes, so it ignores the off-diagonal entries, and under the permutations, so it is a multiple of $\operatorname{tr} a_0 = 0$. A traceless a, padded with zeros, is TT at e_0, so the form equals $\operatorname{tr}(a_0^2)$ there. Hence $C(h, e_0) = \operatorname{tr}(a_0^2) + \frac{1}{9}(\operatorname{tr} a)^2 C(1) = \operatorname{tr}(a^2) + \beta(\operatorname{tr} a)^2$ with $\beta = (C(1) - 3)/9$, and a is the transverse strain at e_0. For $K \neq 0$ a reflection R maps $K/|K|$ to e_0, and invariance and homogeneity give $C(h,K) = |K|^2 C(RhR^{\mathsf T}, e_0) = C_\beta(h,K)$; at $K = 0$ both vanish. (c) Theorem 27.2 gives $J(1+\varepsilon A)/\varepsilon^2 \to \frac{1}{2}\operatorname{tr} A^2$, and $\det(1+\varepsilon A) = 1 + \varepsilon \operatorname{tr} A + O(\varepsilon^2)$ with $J(1+y) = y^2/(2(1+y))$ gives $J(\det(1+\varepsilon A))/\varepsilon^2 \to \frac{1}{2}(\operatorname{tr} A)^2$. The law is J's composition law $J(xy) + J(x/y) = 2J(x)J(y) + 2J(x) + 2J(y)$ of Chapter 21 at $x = \det M$, $y = \det N$, since $\det(MN^{-1}) = \det M / \det N$. (d) For $\beta \geq 0$ both terms are nonnegative, A being symmetric. At $h = 1$, $A = \Pi_K$. □

The trace part is fixed on the other side of the comparison: on the wave covector. Chapter 21's composition law, read in a vector variable, passes to its long-wave limit as the parallelogram law.

Theorem 27.11 (The parallelogram law selects Fierz–Pauli)**.**

(a) Let F and q be real functions on $\mathbb{R}^m$ with $F(x+y) + F(x-y) = 2F(x)F(y) + 2F(x) + 2F(y)$ for all x, y and $F(\varepsilon x)/\varepsilon^2 \to q(x)$ for every x. Then $q(x+y) + q(x-y) = 2q(x) + 2q(y)$ for all x, y. No regularity of F is assumed.

(b) C_β obeys the parallelogram law in K for every strain h if and only if $\beta = -1$.

Proof. (a) Replace x, y by $\varepsilon x, \varepsilon y$ and divide by ε^2. The product term $2F(\varepsilon x)F(\varepsilon y)/\varepsilon^2 = 2\varepsilon^2 \cdot (F(\varepsilon x)/\varepsilon^2)(F(\varepsilon y)/\varepsilon^2)$ tends to 0, and the other terms tend to the parallelogram law. (b) $C_\beta = \mathrm{FP} + (1+\beta)|K|^2(\operatorname{tr} A)^2$, and FP is a quadratic polynomial in K, so it obeys the law.

The extra term is $(|K|^2 \operatorname{tr} h - K^{\mathsf{T}} h K)^2/|K|^2$. At $h = E_{00}$ it equals $(|K|^2 - K_0^2)^2/|K|^2$, with values $\frac{1}{2}$, $\frac{1}{2}$, 0, 1 at $e_0 + e_1$, $e_0 - e_1$, e_0, e_1. So the defect of the law for C_β at $K = e_0$, $K' = e_1$ is $(1+\beta)(\frac{1}{2} + \frac{1}{2} - 2 \cdot 0 - 2 \cdot 1) = -(1+\beta)$. □

Locality supplies the parallelogram law. A lattice-local cost compares strains at fixed offsets, and its symbol is built from J evaluated on unimodular record ratios. We extend J to nonzero complex z by $J(z) = \frac{1}{2}(z + z^{-1}) - 1$.

Theorem 27.12 (Locality selects the Fierz–Pauli completion)**.** *Let L be a local lattice cost, H_0, H_1 strains and K a wave.*

(a) The real part of the cost at every site x is the symbol $\sum_j c_j \cos(K \cdot d_j)$; it does not depend on x.

(b) The symbol equals $\sum_j c_j\big(1 + J(r_j)\big)$, where $r_j = e^{iK\cdot d_j}$ is the record ratio of term j, and $r_j(K+K') = r_j(K)\, r_j(K')$. Each $K \mapsto \cos(K \cdot d) - 1$ obeys the composition law in K.

(c) If $\sum_j c_j = 0$, the symbol at εK divided by ε^2 tends to the long-wave symbol, which obeys the parallelogram law in K.

(d) If for every strain h some local cost has long-wave symbol $C_\beta(h, \cdot)$ on the pair (h, h), then $\beta = -1$.

(e) Fierz–Pauli is realized: a local cost with 32 terms at the offsets $\pm(e_a \pm e_b)$ and coefficients bilinear in (H_0, H_1), with $\sum_j c_j = 0$, has long-wave symbol $\mathrm{FP}(h, K)$ on every pair (h, h).

Conditions and scope.

Base and premises
Classical real and complex numbers; Euclidean waves.

Conclusion
Every cost that compares strains at fixed lattice offsets has a long-wave symbol obeying the parallelogram law, and among the completions only Fierz–Pauli has that property; Fierz–Pauli is realized by such a cost.

Identification
That the graviton's long-wave action is the symbol of a local lattice cost (the Regge lattice of Sections 27.4 and 27.7).

Not claimed
That the realizing table of (e) is gauge null at every momentum; only its long-wave symbol is computed.

Proof. (a) $e^{iK\cdot(x+p)} e^{-iK\cdot(x+q)} = e^{iK\cdot(p-q)}$: the site drops out. (b) $\frac{1}{2}(z + z^{-1}) = \cos(K \cdot d)$ for $z = e^{iK\cdot d}$; exponents add; and $\cos(a+b) + \cos(a-b) = 2\cos a \cos b$ is the composition law for $\cos - 1$. (c) $|\cos t - 1 + t^2/2| \le t^4/24$, and $\sum c_j = 0$ removes the constant; the limit is a quadratic form in K. (d) (c) and Theorem 27.11(b). (e) Write the polarized form as $\mathrm{FP}(H_0, H_1; K) = \sum_{a,b} M_{ab}(H_0, H_1) K_a K_b$ with M bilinear. A term with coefficient c at offset d

contributes $-\frac{1}{2}c(K\cdot d)^2$ to the long-wave symbol, and $(K_a+K_b)^2-(K_a-K_b)^2=4K_aK_b$. So the coefficient $-\frac{1}{2}M_{ab}$ at offset e_a+e_b and $+\frac{1}{2}M_{ab}$ at e_a-e_b, for each ordered pair (a,b), give long-wave symbol $\sum M_{ab}K_aK_b$, and the coefficients sum to 0. □

Theorem 27.12 takes the cost to be local; a charge reads records, which reach as far as the rounds of events behind them. A *law* gives the next record (a finite bit string) of every finite list of records. The post on n records *depends on* position i when two lists of length n that differ only there get different posts; a *chain* from n is a list $i_1,\dots,i_m$ with the post on n records depending on i_1 and that on i_k records on i_{k+1}. The *flip law* posts the complement of the latest record's first bit (a missing bit read as 0), the *comparison law* whether the two latest records are equal. On $\mathbb{Z}^4$ with the sup distance, a *rule of radius r* writes each site's new record from the strains and records within r; *n rounds* from a constant record give records of depth n. A charge on strain fields has *strain range R* when its value at x depends only on strains within R of x, and *depth at most T* with radius r when it reads, within r of x, the strain and the records of T rounds of a rule of radius at most r. Charges Φ_n, one per stage n, have *stage depth*, or *uniform depth T*, when each Φ_n has depth at most n, or at most T. In the *potential world* sites keep the strain h and a potential $\psi\in\mathbb{R}$, and the cost P_β has terms at the offsets 0, e_a and e_a+e_b, coefficients bilinear in the two records and summing to zero, and long-wave symbol $\mathrm{FP}(h,K)+(1+\beta)(2s\psi-|K|^2\psi^2)$ on (r,r), $r=(h,\psi)$, $s=|K|^2\operatorname{tr}h-K^{\mathsf T}hK$; these fix its total coefficient at each offset on equal records (by the K_aK_b and K_a^2 terms). Its cost per site on plane waves of amplitude (h,ψ) is $P_\beta(h,\psi;K)=\mathscr{A}+\mathscr{B}\psi+\mathscr{C}\psi^2$, with *stationary potential* $\psi_*=-\mathscr{B}/(2\mathscr{C})$ (0 where $\mathscr{C}=0$). The *relaxation* with step ω, the rule of radius one $\psi\mapsto\psi-\omega(2\mathscr{C}\psi+\mathscr{B}h)$ with stencils $\mathscr{B}$, $\mathscr{C}$, writes on plane waves $\psi_0=0$, $\psi_{n+1}=(1-2\omega\mathscr{C})\psi_n-\omega\mathscr{B}$.

Theorem 27.13 (Locality rests on record depth and an order of limits)**.** *In classical mathematics:*

(a) every law's chains from n have length at most n; the flip law and the comparison law (which no single record decides from two records on, and which reads at most two records posted before any time t) have unbounded chains, of length n from n and from $n+1$ respectively;

(b) a charge of depth at most T with radius r has strain range $r+Tr$. So stage depth gives range $r+nr$ at stage n, and uniform depth T, or depth at most $f(n)\le T$, range $r+Tr$ at every stage;

(c) the running total $\sum_{k<n}h_{00}(x-ke_0)$ has stage depth with $r=1$, but at stage $n+1$ depends on the strain at $x-ne_0$: no strain range and no depth, for any radius, is uniform in the stage;

(d) if for every strain h some local cost L over records (h,x), $x\in\mathbb{R}^m$, with $\sum_j c_j(r,r)=0$ and each $c_j(r,r)$ continuous in r, read at $x_n(\varepsilon K)$, where $x_{k+1}=Mx_k+b$ with $M(K)$, $b(K)$ continuous in K and x_0, n fixed, has cost per site at the wave εK over ε^2 tending to $C_\beta(h,K)$ for every K, then $\beta=-1$. In the potential world, for all β, ω, n, the charge after n rounds of relaxation has strain range $1+n$, and $P_\beta(h,\psi_n(\varepsilon K);\varepsilon K)/\varepsilon^2\to\mathrm{FP}(h,K)$;

(e) in the potential world, if $\omega\ne0$ and $\mathscr{C}(K)\ne0$, then

$$P_\beta(h,\psi_n;K)=P_\beta(h,\psi_*;K)+\mathscr{C}(K)(1-2\omega\mathscr{C}(K))^{2n}\psi_*(K)^2$$

for every n, and for every β, strain h and wave K, $P_\beta(h,\psi_*(\varepsilon K);\varepsilon K)/\varepsilon^2\to C_\beta(h,K)$. If $\omega(1+\beta)<0$ and $|K|^2\ne0$, then for every $f:\mathbb{N}\to\mathbb{N}$ with $f(n)\to\infty$ and all small $\varepsilon\ne0$, $P_\beta(h,\psi_{f(n)}(\varepsilon K);\varepsilon K)\to P_\beta(h,\psi_*(\varepsilon K);\varepsilon K)$. If $\beta\ne-1$, $C_\beta(E_{00},e_1)\ne\mathrm{FP}(E_{00},e_1)$.

Proof. (a) Lists of length n that differ only at a position $i \geq n$ are equal, so the positions of a chain decrease. Changing the latest of $m+1$ records changes the flip law's post, and changing the latest of $m+2$ equal records the comparison law's, which gives the chains $n-1,\dots,0$ and $n,\dots,1$; the comparison law reads only the two latest records, each of which can change its post. (b) By induction a record of depth n at x reads only strain within nr of x. (c) The rule $\psi(x) \mapsto \psi(x-e_0)+h_{00}(x)$ writes the sum, and changing h_{00} at $x-ne_0$ alone changes it at stage $n+1$, which defeats a range $R<n$; a uniform depth would give a uniform range by (b). (d) The records $x_n(K)$ are continuous in K, so the coefficients at $(h, x_n(\varepsilon K))$ tend to those at $(h, x_n(0))$; as they sum to zero, $|\cos t - 1 + t^2/2| \leq t^4/24$ makes the limit the long-wave symbol of L at $(h, x_n(0))$, a quadratic form in K, which obeys the parallelogram law; Theorem 27.11(b) gives $\beta = -1$. In the potential world ψ_n is continuous with $\psi_n(0)=0$, as $\mathscr{B}(0)$ is a sum of coefficients, and the limit is the long-wave symbol at $\psi = 0$, $\mathrm{FP}(h,K)$. Both rules have radius one; apply (b). (e) For $\mathscr{C} \neq 0$, $P_\beta = \mathscr{A} - \mathscr{B}^2/(4\mathscr{C}) + \mathscr{C}(\psi-\psi_*)^2$ and $\psi_n - \psi_* = -(1-2\omega\mathscr{C})^n\psi_*$. As in (d), $\mathscr{A}, \mathscr{B}, \mathscr{C}$ at εK over ε^2 tend to $\mathrm{FP}(h,K)$, $2(1+\beta)s$, $-(1+\beta)|K|^2$, so for $1+\beta \neq 0 \neq |K|^2$ the stationary cost over ε^2 tends to $\mathrm{FP}+(1+\beta)s^2/|K|^2 = C_\beta(h,K)$ (proof of Theorem 27.11(b)); for $1+\beta = 0$, $\mathscr{B} = \mathscr{C} = 0$; at $K=0$ both sides vanish. If $\omega(1+\beta) < 0$, then $\omega\mathscr{C}(\varepsilon K)/\varepsilon^2 \to -\omega(1+\beta)|K|^2 > 0$ and $\mathscr{C}(\varepsilon K) \to 0$ give $0 < \omega\mathscr{C} < \frac{1}{2}$ for small $\varepsilon \neq 0$. Finally $s(E_{00}, e_1) = 1$, so there $C_\beta - \mathrm{FP} = 1+\beta$. □

Reading a round of the ledger's events as a stage is an identification. The potential world, local in its records, reaches every completion with the stage first, which for $\beta \neq -1$ no cost local in the strain does (Theorem 27.12(d)). Locality of the cost stays a named premise: the long-wave limit at a fixed stage, or a depth bound that does not grow with the stage.

Finally, the strength. J's calibration fixes the coefficient of FP in J's unit, and nothing in J converts that unit into Newton's constant. To see what would, scale the $\kappa = 1$ lattice action of Section 27.7 by s, so that its long-wave quadratic part on a wave u and amplitude h is $-(s\sqrt{3}/16)\,\mathrm{FP}_{g_1}(u;h,h)$, and read Newton's constant from Einstein's normalization, $G_s = 1/(8\pi s)$. Write $G = \varphi^5/(4\log 2)$ for the value of Newton's constant in Recognition Science's units, $\hbar = \varphi^{-5}$ for the action quantum and λ for the recognition length (Chapter 22). The *posting premise* states that one posting, a deficit of $\pi/6$, on a timelike hinge of area A carries the action $a(A) = s\,A\,\pi/6$; that a adds over area and does not decrease with it; and that a full turn of twelve postings on a face of area λ^2 counts the face's one bit, $\exp(12\,a(\lambda^2)/\hbar) = 2$.

Proposition 27.14 (J does not fix Newton's constant; the posting bit does)**.** *In classical mathematics:*

(a) if the coefficient of $-\mathrm{FP}_{g_1}$ is a number $v > 0$, then $s = 16v/\sqrt{3}$ and $G_s = \sqrt{3}/(128\pi v)$; this equals G if and only if $v = v^* = \sqrt{3}/(128\pi G) = \sqrt{3}\log 2/(32\pi\varphi^5)$;

(b) $928 < 1/v^* < 929$, so $v^* \approx 1/928.65$;

(c) the posting premise holds exactly at $s = \hbar\log 2/(2\pi\lambda^2) = 1/(8\pi G)$, that is, at $v = v^*$.

Proof. (a) $1/(8\pi\cdot 16v/\sqrt{3}) = \sqrt{3}/(128\pi v)$, and $128\pi G = 32\pi\varphi^5/\log 2$. (b) With $\varphi^5 = 11.0902$, $\pi = 3.14159$, $\sqrt{3} = 1.73205$ and $\log 2 = 0.693147$ to the digits shown, $32\pi\varphi^5/(\sqrt{3}\log 2) = 1114.89/1.20057 = 928.65$, and the errors of the rounded values move this by less than 0.1.

(c) The bit condition reads $12\,s\lambda^2\pi/6 = \hbar\log 2$, that is, $s = \hbar\log 2/(2\pi\lambda^2)$; conversely, at this s the action $a(A) = sA\pi/6$ meets every clause. Finally $\hbar\log 2/(2\pi\lambda^2) = 1/(8\pi G)$ because $G = \lambda^2/(4\hbar\log 2)$ in these units, and then $\nu = (\sqrt{3}/16)s = \nu^*$. □

No Newton constant is derived here. The number ν^* is the product of the face bit ($\log 2$ per full turn), the action quantum $\hbar = \varphi^{-5}$ and the cell factor $\sqrt{3}/16$ of the $\kappa = 1$ lattice; none of these is supplied by J. That the timelike hinge carries the posting action is a named premise.

27.4 Holonomies, deficits and the sign of the graviton term

A gauge mode is a change of coordinates, and a quantity that ignores gauge modes depends on the geometry only through what coordinates cannot remove: curvature in the continuum, holonomies around hinges on a lattice. This section proves that both descriptions see exactly the non-gauge part, that Regge's lattice action pairs a hinge's holonomy with its change of area, and that such a pairing must have both signs. All results are proved in classical mathematics.

In momentum space the linearized Riemann tensor of a strain H at the wave K is

$$R_{abcd}(H,K) = K_bK_cH_{ad} + K_aK_dH_{bc} - K_aK_cH_{bd} - K_bK_dH_{ac},$$

with Ricci tensor $R_{bd} = \sum_a R_{abad}$, scalar $R = \sum_b R_{bb}$ and Einstein tensor $G_{bd} = R_{bd} - \frac{1}{2}\delta_{bd}R$.

Theorem 27.15 (Zero curvature is gauge; Fierz–Pauli pairs a strain with its Einstein tensor)**.** *For every strain H and wave K:*

(a) $R_{abcd}(K\xi^{\mathsf T} + \xi K^{\mathsf T}, K) = 0$ *for every ξ, and* $R_{abcd}(H, tK) = t^2R_{abcd}(H,K)$*;*

(b) if $K \neq 0$*, then* $R_{abcd}(H,K) = 0$ *for all indices if and only if H is a gauge mode at K;*

(c) $\mathrm{FP}(H,K) = -\sum_{b,d} H_{bd}G_{bd}(H,K)$*;*

(d) $\sum_{b,d}(K\xi^{\mathsf T} + \xi K^{\mathsf T})_{bd}G_{bd}(H,K) = 0$ *for every ξ.*

Proof. (a) Substituting $H_{ad} = K_a\xi_d + \xi_aK_d$, the eight products cancel in pairs; homogeneity is visible. (b) Put $s = |K|^2$. Contracting $R_{abcd} = 0$ with K_c and then with K_b gives $s^2H_{ad} = sK_a(HK)_d + sK_d(HK)_a - K_aK_d(K^{\mathsf T}HK)$, so $H = K\xi^{\mathsf T} + \xi K^{\mathsf T}$ with $\xi = HK/s - (K^{\mathsf T}HK)K/(2s^2)$; the converse is (a). (c) $R_{bd} = K_b(HK)_d + K_d(HK)_b - sH_{bd} - K_bK_d\,\mathrm{tr}\,H$ and $R = 2K^{\mathsf T}HK - 2s\,\mathrm{tr}\,H$, so $\sum H_{bd}G_{bd} = 2|HK|^2 - s\,\mathrm{tr}\,H^2 - 2\,\mathrm{tr}\,HK^{\mathsf T}HK + s(\mathrm{tr}\,H)^2 = -\mathrm{FP}(H,K)$. (d) The pairing is $2\xi^{\mathsf T}GK$, and $GK = 0$ by the formulas in (c): the linearized Bianchi identity. □

On a lattice the curvature of a hinge is its holonomy: the boost or rotation acquired around it. J reads holonomies through its odd part.

Proposition 27.16 (J's odd part; every signed table is a J-built cost)**.** *For $x, y > 0$ put $J_{\mathrm{odd}}(x,y) = \frac{1}{2}\big(J(xy) - J(x/y)\big)$. Then*

(a) $J(xy) = J(x) + J(y) + J(x)J(y) + J_{\mathrm{odd}}(x,y)$ and $J(x/y) = J(x) + J(y) + J(x)J(y) - J_{\mathrm{odd}}(x,y)$;

(b) $J_{\mathrm{odd}}(x,y) = \frac{1}{4}(x - x^{-1})(y - y^{-1}) = \sinh u \sinh v$ for $x = e^u$, $y = e^v$; it is negative when $x > 1 > y$;

(c) for a real symmetric $n \times n$ table T, the cost $\sum_{i,j} T_{ij} J_{\mathrm{odd}}(r_i, r_j)$ equals $\sum_{i,j} T_{ij} \sinh u_i \sinh u_j$ at $r = e^u$; at $r_i = e^{\varepsilon u_i}$, divided by ε^2, it tends to $\sum T_{ij} u_i u_j$; and two symmetric tables give the same cost for all positive r only if they are equal.

So every quadratic table of couplings, Regge's included, is a cost built from J, and J's composition law fixes none of its weights.

Proof. (a) The law gives the even part $\frac{1}{2}(J(xy) + J(x/y)) = J(x)J(y) + J(x) + J(y)$. (b) $J(xy) - J(x/y) = \frac{1}{2}(xy + \frac{1}{xy} - \frac{x}{y} - \frac{y}{x}) = \frac{1}{2}(x - x^{-1})(y - y^{-1})$. (c) The first two claims follow from (b) and $\sinh t/t \to 1$. For the last, take u supported on $\{i, j\}$ and compare the coefficients of $\sinh u_i \sinh u_j$. □

A holonomy around a spacelike hinge is a boost, e^{ε}, and around a timelike hinge a rotation, $e^{i\varepsilon}$. J's even part treats them oppositely.

Proposition 27.17 (Rotation holonomies; on the lattice metric every hinge is timelike)**.**

(a) $J(e^{i\varepsilon}) = \cos\varepsilon - 1 \in [-2, 0]$, which equals the boost value $J(e^{\varepsilon}) = \cosh\varepsilon - 1 \geq 0$ only at $\varepsilon = 0$. $(\cos t\varepsilon - 1)/t^2 \to -\varepsilon^2/2$, and $(\cos t^2 c - 1)/t^4 \to -c^2/2$: the even part is of fourth order in a curvature of size t^2.

(b) $J_{\mathrm{odd}}(x, e^{i\varepsilon}) = \frac{i}{2}(x - x^{-1}) \sin\varepsilon$ for $x > 0$, with J_{odd} extended by (b) of Proposition 27.16, and the real part of $-i J_{\mathrm{odd}}(e^{t\alpha}, e^{it\varepsilon})$ divided by t^2 tends to $\alpha\varepsilon$, as $J_{\mathrm{odd}}(e^{t\alpha}, e^{t\varepsilon})/t^2$ does for boosts.

(c) Let $g_1(u, v) = u \cdot v - (\sum u)(\sum v)$. For nested $0/1$ vectors $d_1 \leq d_2$ with $k_1 \geq 1$ and $k_2 > k_1$ ones, $g_1(d_1, d_1) g_1(d_2, d_2) - g_1(d_1, d_2)^2 = k_1(1 - k_2)(k_2 - k_1) < 0$.

Proof. (a) $\frac{1}{2}(e^{i\varepsilon} + e^{-i\varepsilon}) = \cos\varepsilon$; $\cos\varepsilon = \cosh\varepsilon$ only at 0; the limits are Taylor's. (b) $e^{i\varepsilon} - e^{-i\varepsilon} = 2i \sin\varepsilon$, and $\sinh(t\alpha)\sin(t\varepsilon)/t^2 \to \alpha\varepsilon$. (c) $g_1(d, d) = k(1 - k)$ for a vector with k ones and $g_1(d_1, d_2) = k_1 - k_1 k_2$, so the determinant is $k_1(1 - k_1)k_2(1 - k_2) - k_1^2(1 - k_2)^2 = k_1(1 - k_2)(k_2 - k_1)$. □

By (c), every hinge of the $\kappa = 1$ lattice spanned by two of its steps is timelike, so its holonomy is a rotation of the normal plane and J's even part on it is nonpositive. A cost that is nonnegative cannot produce the graviton term. The theorem below says this for every local two-derivative form, with no symmetry assumed.

Theorem 27.18 (No nonzero local invariant form is nonnegative)**.** *Let*

$$\mathcal{Q}(h,K)=\sum_{a,b,c,d,e,f} C_{abcdef}\,h_{ab}h_{cd}K_eK_f$$

with arbitrary real coefficients. If $\mathcal{Q}$ is gauge invariant and $\mathcal{Q}(h,K)\ge 0$ for every strain h and wave K, then $\mathcal{Q}(h,K)=0$ for every strain and wave.

Proof. For fixed K, $\mathcal{Q}(\cdot,K)$ is a quadratic form: $\mathcal{Q}(h+sg,K)=\mathcal{Q}(h,K)+sX(h,g,K)+s^2\mathcal{Q}(g,K)$. An affine function $a+sb$ that is ≥ 0 for every real s has $b=0$. Put $\phi(v,K)=\mathcal{Q}(vv^{\mathsf T},K)$, of degree 4 in v and 2 in K.

1. *Gauge shear.* $(v+bK)(v+bK)^{\mathsf T}=vv^{\mathsf T}+K\xi^{\mathsf T}+\xi K^{\mathsf T}$ with $\xi=bv+\frac{b^2}{2}K$, so $\phi(v+bK,K)=\phi(v,K)$. Also $vv^{\mathsf T}$ is the gauge mode of $\xi=v/2$ at the wave v, so $\phi(v,v)=\mathcal{Q}(0,v)=0$.

2. *Wave shear.* $\phi(v,K+tv)=\phi(v,K)+tY+t^2\phi(v,v)=\phi(v,K)+tY$ is ≥ 0 for all t, so $Y=0$ and $\phi(v,K+tv)=\phi(v,K)$.

3. *Swap.* By step 1 with $b=1$, step 2 along $v+K$ with $t=-1$, step 1 again and degree 2 in the wave: $\phi(v,K)=\phi(v+K,K)=\phi(v+K,-v)=\phi(K,-v)=\phi(K,v)$.

4. *Vanishing.* $\phi(2v,K)=16\phi(v,K)$, while by step 3, $\phi(2v,K)=\phi(K,2v)=4\phi(K,v)=4\phi(v,K)$. So $\phi=0$.

5. *Every rank-one strain is invisible.* $s\mapsto\mathcal{Q}(h+svv^{\mathsf T},K)=\mathcal{Q}(h,K)+sX(h,vv^{\mathsf T},K)$ is affine and nonnegative, so $\mathcal{Q}(h+svv^{\mathsf T},K)=\mathcal{Q}(h,K)$ for every strain h. The ten strains $e_ae_a^{\mathsf T}$ and $(e_a+e_b)(e_a+e_b)^{\mathsf T}$ $(a<b)$ span the strains: $h=\sum_a(h_{aa}-\sum_{b\ne a}h_{ab})e_ae_a^{\mathsf T}+\sum_{a<b}h_{ab}(e_a+e_b)(e_a+e_b)^{\mathsf T}$. Removing these terms one at a time gives $\mathcal{Q}(h,K)=\mathcal{Q}(0,K)=0$. □

So a two-derivative graviton term must take both signs: a sum of J's with nonnegative weights has a nonnegative long-wave form, since $J(e^t)=t^2/2+O(t^4)$, and its gauge-invariant two-derivative part vanishes. The graviton term comes from J's odd part, as Regge's area times holonomy does.

We now turn to the lattice. Kuhn's triangulation [90] cuts the unit cube of $\mathbb{Z}^4$ into 24 simplices, one for each order σ of the four axes.

Definition 27.19 (The Kuhn lattice, tables and their plane-wave forms)**.**

1. The simplex σ has vertices $v_0=0$ and $v_k=e_{\sigma(1)}+\cdots+e_{\sigma(k)}$, $k=1,\dots,4$. Its ten *slots* are the edges (i,j), $i<j$, in the order 01, 02, 03, 04, 12, 13, 14, 23, 24, 34; slot f has step $s_f=v_j-v_i$, a 0/1 vector with $j-i$ ones, and midpoint $x_f=\frac12(v_i+v_j)$. Translates of the simplices tile $\mathbb{R}^4$; every lattice edge has one of the fifteen classes $d\in\{0,1\}^4\setminus\{0\}$.

2. At the background $g_\kappa=1-\kappa\mathbf{1}\mathbf{1}^{\mathsf T}$ a step d has squared length $|d|^2-\kappa(\sum d)^2$; a step with n ones has $n-\kappa n^2$.

3. A perturbation at the wave K gives each class d an amplitude $A(d)\in\mathbb{C}$, the change of squared length of the edges of class d times $e^{iK\cdot x}$ at the edge midpoint x. The vertex displacement $\eta e^{iK\cdot x}$ $(\eta\in\mathbb{C}^4)$ has the *gauge amplitude* $A(d)=4i(d\cdot\eta)\sin(K\cdot d/2)$.

Table 27.1. Regge's per-simplex tables, slots in the order $01, 02, 03, 04, 12, 13, 14, 23, 24, 34$. Left: the $\kappa = 1$ table R_1. Right: the Euclidean table E, which is 48 times the Hessian table of Theorem 27.28 at $\kappa = 0$.

$$R_1 = \begin{pmatrix} 2 & -2 & 1 & 0 & 0 & 3 & -2 & -6 & 2 & 2 \\ -2 & -4 & 4 & -1 & 6 & -6 & 2 & 3 & -2 & 2 \\ 1 & 4 & 0 & -2 & -6 & 0 & 2 & -3 & 2 & -2 \\ 0 & -1 & -2 & 2 & 2 & 2 & -2 & 2 & -1 & 0 \\ 0 & 6 & -6 & 2 & -6 & 6 & -3 & 0 & 3 & -6 \\ 3 & -6 & 0 & 2 & 6 & 0 & 0 & 6 & -6 & 3 \\ -2 & 2 & 2 & -2 & -3 & 0 & 0 & -6 & 4 & 1 \\ -6 & 3 & -3 & 2 & 0 & 6 & -6 & -6 & 6 & 0 \\ 2 & -2 & 2 & -1 & 3 & -6 & 4 & 6 & -4 & -2 \\ 2 & 2 & -2 & 0 & -6 & 3 & 1 & 0 & -2 & 2 \end{pmatrix} \qquad E = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 3 & 0 & -6 & 0 & 0 \\ 0 & -3 & 3 & 0 & 6 & -6 & 0 & 3 & 0 & 0 \\ 0 & 3 & -2 & 0 & -6 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 6 & -6 & 0 & -6 & 6 & 0 & 0 & 3 & -6 \\ 3 & -6 & 3 & 0 & 6 & -6 & 3 & 6 & -6 & 3 \\ 0 & 0 & 0 & 0 & 0 & 3 & -2 & -6 & 3 & 0 \\ -6 & 3 & 0 & 0 & 0 & 6 & -6 & -6 & 6 & 0 \\ 0 & 0 & 0 & 0 & 3 & -6 & 3 & 6 & -3 & 0 \\ 0 & 0 & 0 & 0 & -6 & 3 & 0 & 0 & 0 & 0 \end{pmatrix}$$

4. The *plane-wave form* of a real 10×10 table T is

$$T(K; A, B) = \sum_{\sigma} \sum_{f, f'} T_{ff'}\, A(s_f)\, B(s_{f'})\, e^{iK \cdot (x_f - x_{f'})}.$$

The table is *gauge null* when $T(K; A, B) = 0$ for every gauge amplitude A, every B and every K, and of *zero symbol* when $T(K; A, B) = 0$ for all K, A, B.

Table 27.1 prints the two Regge tables: the table R_1 of the $\kappa = 1$ lattice and the Euclidean table E. Both are integer and symmetric.

Sign convention. The deficit of a hinge is $\varepsilon = 2\pi$ minus the sum of the dihedral angles of the simplices around it, and Regge's action is $\sum(\text{area}) \times (\text{deficit})$ [92]. In each simplex the deficit's share changes as $-\theta_t$ when the dihedral angle θ_t at the triangle t changes, so $\nabla\varepsilon_t = -\nabla\theta_t$. With this convention the Euclidean table is $E = +48 \sum_t \nabla\varepsilon_t \otimes \nabla A_t$; written with dihedral angles in place of deficits, every identity below changes sign. For a perturbation A and a hinge h (a lattice triangle up to translation) the *area-weighted deficit* $D_A(h)$ is the hinge's area times the linear change of its deficit under A, and $\Lambda_B(h)$ is the linear change of the logarithm of its area under B, by Heron's formula.

Theorem 27.20 (On the Euclidean Kuhn lattice the deficits see exactly the non-gauge part)**.** *At the Euclidean background:*

(a) every vertex displacement leaves every area-weighted deficit zero, at every wave;

(b) at every wave with $\sin(K_a/2) \neq 0$ *for* $a = 0, 1, 2, 3$*, a perturbation whose area-weighted deficits all vanish is a vertex displacement:* $A(d) = 4i(d \cdot \eta) \sin(K \cdot d/2)$ *for all fifteen classes and some* $\eta \in \mathbb{C}^4$*;*

(c) per simplex $E = 48 \sum_t (A_t \nabla\varepsilon_t) \otimes \nabla \log A_t$*, a symmetric table, as Schläfli's identity requires; in plane-wave form* $E(K; A, B) = 48 \sum_h D_A(h) \Lambda_B(h)$*: holonomy times area change;*

(d) a table is gauge null if and only if, at every wave with all $\sin(K_a/2) \neq 0$*, its form depends on its first argument only through that argument's area-weighted deficits;*

(e) R_1 *and* E *are both gauge null, neither has zero symbol, and no multiple of one differs from the other by a table of zero symbol; every symmetric gauge-null table is* $aR_1 + bE$ *plus a table of zero symbol.*

Conditions and scope.

Base and premises
The Euclidean Kuhn lattice, classical real and complex numbers.

Conclusion
Locality and exact gauge invariance fix the lattice graviton term up to the background (a direction in the plane of R_1 and E) and a scale. Regge's table is not singled out as a least gauge-null table.

Not claimed
A reason internal to J for invariance under vertex displacements, which is open, and (d) and (e) at $\kappa = 1$. At $\kappa = 1$, (a) and (b) are Proposition 27.37 and (c) is Theorem 27.32(c).

Proof. Every statement is finite linear algebra over the rational numbers once the phases are factored. For (a) and (c): the dihedral angles and areas of the Kuhn simplex and their derivatives in the ten squared edge lengths are rational multiples of fixed square roots (Theorem 27.26 gives the formulas), so $A_t \nabla\theta_t$ and $\nabla \log A_t$ are two rational 10×10 tables; (c) is the entrywise identity between E and 48 times their product, and (a) is the identity obtained by substituting the gauge amplitude, collected hinge by hinge over the 24 simplices. For (b), define η from the four axis classes by $\eta_a = A(e_a)/(4i \sin(K_a/2))$, which is where the hypothesis enters; subtracting the gauge amplitude of η leaves a perturbation with zero deficits that vanishes on the axis classes, and the hinge equations, a linear system in the eleven remaining amplitudes, force those to vanish. (d) follows: a gauge amplitude has the deficits of 0; and if A and A' have the same deficits, $A - A'$ is a gauge amplitude by (b). (e) reduces, after the phases are factored, to linear algebra on finitely many sums of table entries over slot pairs of equal class. The computations of (a), (b), (c) and (e) are finite, with inputs Theorem 27.26, the hinges of the 24 simplices and Table 27.1; we describe them and do not reproduce them. □

At long wavelength the Euclidean table is Fierz–Pauli on every strain, as Theorem 27.30(a) shows for R_1. Write $\mathrm{FP}_1(K; H, H')$ for the form FP_S of Section 27.2 with $S = 1$, the polarization of FP.

Proposition 27.21 (Regge's Euclidean table is Fierz–Pauli at long wavelength)**.** *In classical mathematics, for all real symmetric H, H' and every real wave K,*

$$\sum_{\sigma} \sum_{f,f'} E_{ff'} \, (s_f^{\mathsf{T}} H s_f)(s_{f'}^{\mathsf{T}} H' s_{f'}) \big(K \cdot (x_f - x_{f'})\big)^2 = 24 \, \mathrm{FP}_1(K; H, H').$$

So the order-$|K|^2$ part of the plane-wave form $E(K; A, B)$ on the amplitudes $A(d) = d^{\mathsf{T}} H d$, $B(d) = d^{\mathsf{T}} H' d$ is $-12 \, \mathrm{FP}_1(K; H, H')$.

Proof. Both sides are polynomials with rational coefficients, linear in H and in H' and quadratic in K. The steps and midpoints of the simplex σ are those of the simplex of the identity order with the coordinates permuted by σ, so the left side is one explicit polynomial, the sum over the 100 slot pairs of one simplex, summed over the 24 permutations of the axes; expanding it gives $24 \, \mathrm{FP}_1$ coefficient by coefficient. For example, at $K = e_0$ and $H = H'$ one of the three strains of the opening table, the left side is 48, 0 and -144, which are 24 times FP $= 2, 0, -6$. The last sentence is $e^{iy} = 1 + iy - \frac{1}{2}y^2 + \dots$ termwise. □

27.5 At third order the cost breaks gauge invariance

Regge's hinge term and $\mathcal{J}$'s odd part have the same second variation. A nonlinear theory needs more: the source that its cubic term makes from two first-order fields must be one that the quadratic operator can balance at second order. We compare third derivatives first and then evaluate both cubic vertices on the Kuhn lattice. Consider finitely many hinges along a deformation $t \mapsto (a_h(t), e_h(t))$ with areas $a_h > 0$ and deficits e_h, $e_h(0) = 0$, three times differentiable and obeying Schläfli's identity $\sum_h a_h e_h' = 0$ [93, 92]. Put

$$\mathcal{R}(t) = \sum_h a_h(t) e_h(t), \qquad \mathcal{J}(t) = \sum_h \frac{a_h(0)}{2}\, J_{\mathrm{odd}}\Big(\frac{a_h(t)}{a_h(0)}, e^{e_h(t)}\Big).$$

Proposition 27.22 (Regge equals $\mathcal{J}$'s odd hinge cost at second order only)**.** *In classical mathematics, $\mathcal{R}(0) = \mathcal{J}(0) = 0$, $\mathcal{R}''(0) = \mathcal{J}''(0) = \sum_h a_h' e_h'$,*

$$\mathcal{R}'''(0) = \sum_h (2a_h'' e_h' + a_h' e_h''), \qquad \mathcal{J}'''(0) = \tfrac{3}{2} \sum_h \big(a_h'' e_h' + a_h' e_h'' - a_h'^2 e_h'/a_h\big),$$

all evaluated at 0. For the two hinges $a = (e^t, 1)$, $e = (t, 1 - e^t)$, Schläfli's identity holds and $\mathcal{R}'''(0) = 2$ while $\mathcal{J}'''(0) = 0$.

Proof. $J_{\mathrm{odd}}(x, e^d) = \sinh(\log x) \sinh d$, and $\sinh(\log(a/a_0)) = \frac{1}{2}(a/a_0 - a_0/a)$ has derivatives 0, a'/a_0 and $a''/a_0 - a'^2/a_0^2$ at 0, while $\sinh e$ has 0, e', e''. The Leibniz rule gives $\mathcal{J}''$ and $\mathcal{J}'''$. For $\mathcal{R}$, $(ae)'' = 2a'e' + a_0 e''$ and $(ae)''' = 3a''e' + 3a'e'' + a_0 e'''$ at 0, and the first two derivatives of Schläfli's identity, $\sum(a'e' + ae'') = 0$ and $\sum(a''e' + 2a'e'' + ae''') = 0$, eliminate $\sum a_0 e''$ and $\sum a_0 e'''$. In the example $\sum ae' = e^t - e^t = 0$, and only the first hinge contributes: $2 \cdot 1 \cdot 1 + 0 = 2$ and $\frac{3}{2}(1 + 0 - 1) = 0$. □

$\mathcal{J}$'s odd hinge cost is even under $(a/a_0, e) \mapsto (a_0/a, -e)$, so it has no cubic term in the log-area and the deficit, whereas Regge's $a_0 e^u e$ has the cubic term $\frac{1}{2} a_0 u^2 e$. Whether this difference matters is decided on the lattice. On the Kuhn lattice of Definition 27.19 at the Euclidean background, the deficit of a hinge is 2π minus the sum of the dihedral angles of the simplices around it, and the area of a hinge depends only on its own edges, so each hinge term of Proposition 27.22 splits into shares of those simplices.

Definition 27.23 (The cubic forms and the long-wave cubic vertex)**.**

1. Number the slots $01, \dots, 34$ as $0, \dots, 9$; let L_0 be the squared edge lengths of a Kuhn simplex at the Euclidean background (slot ij has $j - i$); for $\ell \in \mathbb{R}^{10}$ let $\theta_t(s)$ and $A_t(s)$ be the dihedral angle and the area at the triangle t when the squared edge lengths are $L_0 + s\ell$, with primes for derivatives at $s = 0$. The *cubic forms* of the simplex are

$$r(\ell) = \sum_t \big(\theta_t'' A_t' + 2\theta_t' A_t''\big), \qquad d(\ell) = \sum_t \Big(\frac{A_t' \theta_t'' - A_t'' \theta_t'}{2} - \frac{3}{2}\, \frac{A_t'^2\, \theta_t'}{A_t(0)}\Big).$$

2. Three complex plane waves $H_i e^{iK_i \cdot x}$, $i = 1, 2, 3$, with H_i complex symmetric and $K_i \in \mathbb{C}^4$, give the slot f of the simplex σ of the base cell the *Taylor amplitudes* $a^i_{\sigma,n}(f) =$

$(s_f^{\mathsf T} H_i s_f)(K_i \cdot x_f)^n/n!$, where $K \cdot x = \sum_a K_a x_a$ without conjugation. For a cubic form T let $\hat T(a,b,c)$ be the coefficient of $\epsilon_1\epsilon_2\epsilon_3$ in $T(\epsilon_1 a + \epsilon_2 b + \epsilon_3 c)$. The *long-wave cubic vertex* of T is

$$V_T(H_1,H_2,H_3;K_1,K_2,K_3) = \frac{1}{6}\sum_{n_1+n_2+n_3=2}\ \sum_{\sigma} \hat T\big(a^1_{\sigma,n_1}, a^2_{\sigma,n_2}, a^3_{\sigma,n_3}\big),$$

summed over the six triples of orders with sum 2 and the 24 simplices.

Both forms are cubic with rational coefficients. They come from the closed forms of Theorem 27.26(d) at $\kappa = 0$ and their derivatives along ℓ: every term of r and d carries an even number of factors $(W_{ll}W_{mm} - W_{lm}^2)^{-1/2}$, so the square roots cancel. Table 27.2 prints them. Along a line $s \mapsto L + s\ell$ of squared edge lengths of the periodic lattice, with ℓ_σ the restriction of ℓ to the simplex σ, the proposition with $e_h' = -\sum_{\sigma\ni h}\theta'_{\sigma,h}$ and $e_h'' = -\sum_{\sigma\ni h}\theta''_{\sigma,h}$ gives

$$\mathscr R'''(0) = -\sum_\sigma r(\ell_\sigma), \qquad \mathscr J'''(0) - \mathscr R'''(0) = -\sum_\sigma d(\ell_\sigma), \tag{27.1}$$

Schläfli's identity (Theorem 27.27) holding simplex by simplex. So J's hinge cost is Regge's action plus the extra cubic term $-\frac{s^3}{6}\sum_\sigma d(\ell_\sigma)$. Since $e^{iK\cdot x_f} = \sum_n i^n (K\cdot x_f)^n/n!$, the coefficient of $\epsilon_1\epsilon_2\epsilon_3$ in the cell's share $-\frac16\sum_\sigma T(\ell_\sigma)$ of a cubic term, on the field $\sum_i \epsilon_i (s_e^{\mathsf T} H_i s_e) e^{iK_i\cdot x_e}$, is V_T at second order in the momenta; its parts of order 0 and 1 are $-\frac16$ and $-\frac{i}{6}$ times the sums with $n_1+n_2+n_3 = 0$ and 1. We write V_r and V_d for the vertices of r and d, and $\mathrm{FP}_1(K;H,H')$ for the form FP_S of Section 27.2 with $S = 1$ over $\mathbb C$.

The test data are Gaussian integers. Let $\eta = \mathrm{diag}(-1,1,1,1)$, $\xi = e_1$, the static momenta $k_1 = (0,3,4,5i)$, $k_2 = (0,5,12,13i)$, $k_3 = -k_1 - k_2$, the momenta $q_1 = (3,4,0,5i)$, $q_2 = (5,0,12,13i)$, $q_3 = -q_1 - q_2$, the gauge legs $\Xi = k_3\xi^{\mathsf T} + \xi k_3^{\mathsf T}$ and $\Xi' = q_3\xi^{\mathsf T} + \xi q_3^{\mathsf T}$, and

$$Z_1 = \begin{pmatrix} -321+240i & -228+70i & -100-125i & -200-375i \\ -228+70i & 171-240i & 75 & 150 \\ -100-125i & 75 & -75 & 75 \\ -200-375i & 150 & 75 & 225 \end{pmatrix},$$

$$Z_2 = \begin{pmatrix} 482+312i & -120+65i & -60-65i & -60+130i \\ -120+65i & -457-312i & 50 & -25 \\ -60-65i & 50 & 25 & 25 \\ -60+130i & -25 & 25 & -50 \end{pmatrix}.$$

Theorem 27.24 (J's cubic vertex breaks gauge invariance, and its second-order static field does not exist)**.** *In classical mathematics, with r and d the forms of Table 27.2:*

(a) for real symmetric H_i and real K_i, neither r nor d has a vertex term of order 0 or 1 in the momenta: the sum over σ of $\hat T(a^1_{\sigma,n_1}, a^2_{\sigma,n_2}, a^3_{\sigma,n_3})$ vanishes for $(n_1,n_2,n_3) = (0,0,0)$, $(1,0,0)$, $(0,1,0)$ and $(0,0,1)$, without momentum conservation;

(b) k_1 and k_2 are static and null ($k_{i,0} = 0$, $k_i\cdot k_i = 0$), and

$$V_r(\eta,\eta,\Xi;k_1,k_2,k_3) = 0, \qquad V_d(\eta,\eta,\Xi;k_1,k_2,k_3) = -8;$$

Table 27.2. The cubic forms of Definition 27.23 at a Kuhn simplex of the Euclidean background: $128\,r(\ell)$ (Regge's action) and $128\,d(\ell)$ ($\mathcal{J}$'s extra term). An entry ijk, c is the monomial $c\,\ell_i\ell_j\ell_k$; slots are numbered $0,\dots,9$ in the order $01, 02, 03, 04, 12, 13, 14, 23, 24, 34$.

Conditions and scope.

Base and premises

The Kuhn lattice at the Euclidean background, complex momenta, classical real and complex numbers. Proved in classical mathematics; the values in (b) and (c) are exact arithmetic in the Gaussian integers.

Conclusion

$\mathcal{J}$'s hinge cost is Regge's action plus the extra vertex V_d. Both vertices start at second order in the momenta. On both sets of legs with one pure-gauge leg Regge's vertex vanishes and V_d does not, although the other two legs solve the linearized field equations. So $\mathcal{J}$'s second-order equation for the static field $2U\eta$ built from the two harmonic modes $U = e^{ik_1\cdot x} + e^{ik_2\cdot x}$ has no solution. The post-Newtonian parameter β_{PN} (not DeWitt's β) is read from the second-order static field, so it does not exist for $\mathcal{J}$'s cost.

Identification

The legs η at k_1, k_2 as the Euclidean form of the linearized field of a static mass; Regge's action as the gravitational action.

Not claimed

The point-mass field and real fields, and the Lorentzian $\kappa = 1$ lattice, here. That Regge's long-wave cubic vertex is one half of Einstein's is Theorem 27.61(b), on every background off the poles, and J's whole cubic vertex is written out in Theorem 27.68. For the J-built hinge costs with reference area $\rho a_h(0)$, Proposition 27.25 shows that the part of the cubic vertex linear in the deficits fails this test unless $\rho = 0$; Theorem 27.69(c) gives a hinge-local correction with which J's cost has exactly one half of Regge's cubic vertex and passes the cubic test at three witnesses, and Theorem 27.71 shows that hinge shape costs cannot carry that halved coupling to quartic order.

Proof. (a) At order 0 the amplitude $a^i_{\sigma,0}(f) = s_f^{\mathsf T} H_i s_f$ is the change of squared length of slot f under the constant strain H_i, so the sum is the polarization of $h \mapsto \sum_\sigma T\big((s_f^{\mathsf T} h s_f)_f\big)$. A constant strain h is a linear change of coordinates: along $L + s(s_e^{\mathsf T} h s_e)_e$ every deficit stays 0, so $\mathscr{R}$ and $\mathscr{J}$ vanish identically, and by (27.1), all cells being alike, $\sum_\sigma r$ and $\sum_\sigma d$ vanish on every constant strain; so does their polarization. At order 1 use the central inversion $x \mapsto \mathbf{1} - x$ of the cell. It maps the simplex of the axis order $(\sigma_1, \dots, \sigma_4)$ to that of $(\sigma_4, \dots, \sigma_1)$ and its slot ij to the slot $(4-j)(4-i)$, with the same step and the reflected midpoint $\mathbf{1} - x_f$. On slot numbers this is the permutation $(0\,9)(1\,8)(2\,6)(4\,7)$, and both forms of Table 27.2 are invariant under it, as the table shows. Reindexing the cell sum by the inversion turns the order-1 amplitude $(s_f^{\mathsf T} H_i s_f)(K_i \cdot x_f)$ into $(s_f^{\mathsf T} H_i s_f)(K_i \cdot \mathbf{1} - K_i \cdot x_f)$, so each order-1 sum S satisfies $S = (K_i \cdot \mathbf{1}) S_0 - S$ with S_0 the order-0 sum, which is 0. Hence $S = 0$.

(b) and (c) The null and static conditions are arithmetic, as are $Z_i q_i = 0$ and $\operatorname{tr} Z_i = 0$. Each vertex is a finite sum over 24 simplices, six order triples and the monomials of Table 27.2, with Gaussian-integer data, so it is exact arithmetic in $\mathbb{Z}[i]$ after multiplying by $6 \cdot 128 \cdot 8$. For (b) the six order sums $\sum_\sigma \hat T(a^1_{\sigma,n_1}, a^2_{\sigma,n_2}, a^3_{\sigma,n_3})$, in the order $(2,0,0)$, $(0,2,0)$, $(0,0,2)$, $(1,1,0)$, $(1,0,1)$, $(0,1,1)$, are 468, 1260, 0, 1536, -1248, -2016 for r, with sum 0, and -234, -630, 0, -816, 624, 1008 for d, with sum $-48 = 6 \cdot (-8)$. The static legs solve the linearized equations: by the formulas in the proof of Theorem 27.15(c), $\eta k_i = k_i$, $\operatorname{tr}\eta = 2$ and $k_i \cdot k_i = 0$ give $R_{bd} = 2k_b k_d - 2k_b k_d = 0$; transverse-traceless legs at null momenta solve them too.

(d) The first claim is Theorem 27.6(b) over $R = \mathbb{C}$ with $S = 1$, the form being symmetric in its two strains. Suppose H_2 solves the equation and take $H' = \Xi$. Since $\Xi = -\big((k_1+k_2)\xi^{\mathsf T} + \xi(k_1+k_2)^{\mathsf T}\big)$ is a gauge mode at $k_1 + k_2$, the first term vanishes, and by (b) the equation reads $-8 = 0$. The same test excludes the equation with J's whole cubic vertex $V_r + V_d$ in place of V_d, since $V_r(\eta, \eta, \Xi; k_1, k_2, k_3) = 0$ by (b). □

The test in (d) is the consistency condition of every gauge theory: the second-order field $H_2 e^{i(k_1+k_2)\cdot x}$ must make the action stationary in every direction H', and a pure-gauge direction removes the quadratic form (the linearized Bianchi identity, Theorem 27.15(d)), so a solution needs a source that vanishes on gauge directions, however the two terms are normalized. β_{PN} is read from the second-order static field, and for J's cost that equation has no solution already for this two-mode field, while Regge's vertex passes the test on both sets of legs. So J's

hinge cost agrees with Regge's action to second order only. With Regge's action read as the gravitational action (the identification named in Section 27.7), the graviton is the long-wave form of J, its self-interaction is Regge's, and nonlinear gravity on the lattice is Regge's action.

Which hinge costs avoid the defect? Take a cost linear in the deficit, $\sum_h \varphi_h(a_h)e_h$, with smooth area factors, along a deformation as in Proposition 27.22. Since $e_h(0) = 0$, Leibniz's rule gives its second and third derivatives at 0 as the left sides in (a) below, with $c_{0h} = \varphi_h(a_{0h})$, $c_{1h} = \varphi_h'(a_{0h})$, $c_{2h} = \frac{1}{2}\varphi_h''(a_{0h})$, $a_{0h} = a_h(0)$, and $a_h^{(k)}$, $e_h^{(k)}$ the kth derivatives at 0; Schläfli's identity and its first two derivatives give the three relations in (a). Regge's action has $(c_{0h}, c_{1h}, c_{2h}) = (a_{0h}, 1, 0)$, and its derivatives are the right sides with $\lambda = 1$.

Proposition 27.25 (Regge's derivatives force a linear area factor; a reference area fails the static test)**.** *In classical mathematics:*

(a) Let $n \geq 2$, $a_{0h} > 0$ and $c_{0h}, c_{1h}, c_{2h}, \lambda$ real ($h = 1, \dots, n$). Call $(a^{(1)}, a^{(2)}, e^{(1)}, e^{(2)}, e^{(3)}) \in (\mathbb{R}^n)^5$ a Schläfli jet *when $\sum_h a_{0h} e_h^{(1)} = 0$, $\sum_h (a_h^{(1)} e_h^{(1)} + a_{0h} e_h^{(2)}) = 0$ and $\sum_h (a_h^{(2)} e_h^{(1)} + 2a_h^{(1)} e_h^{(2)} + a_{0h} e_h^{(3)}) = 0$. Then*

$$\sum_h \big(c_{0h} e_h^{(2)} + 2c_{1h} a_h^{(1)} e_h^{(1)}\big) = \lambda \sum_h a_h^{(1)} e_h^{(1)},$$
$$\sum_h \big(c_{0h} e_h^{(3)} + 3c_{1h}(a_h^{(1)} e_h^{(2)} + a_h^{(2)} e_h^{(1)}) + 6c_{2h}(a_h^{(1)})^2 e_h^{(1)}\big) = \lambda \sum_h \big(2a_h^{(2)} e_h^{(1)} + a_h^{(1)} e_h^{(2)}\big)$$

hold for every Schläfli jet if and only if $c_{0h} = \lambda a_{0h}$, $c_{1h} = \lambda$ and $c_{2h} = 0$ for every h.

(b) For real r and $a_0 > 0$, the jets $c_0 = \frac{1}{4}(a_0 - r^2/a_0)$, $c_1 = \frac{1}{4}(1 + r^2/a_0^2)$, $c_2 = -r^2/(4a_0^3)$ of the area factor $\frac{1}{4}(a - r^2/a)$ of J's hinge cost with reference area r (see (c)) have the form of (a) for some λ if and only if $r = 0$.

(c) For $r, a > 0$, $\frac{r}{2} J_{\mathrm{odd}}(a/r, e^d) = \frac{1}{4}(a - r^2/a)\sinh d$. Put $\mathcal{J}_\rho = \sum_h \frac{1}{4}(a_h - \rho^2 a_h(0)^2/a_h)\sinh e_h$, so that $\mathcal{J}_1 = \mathcal{J}$. Along every deformation of Proposition 27.22, at 0, $\mathcal{J}_\rho'' = \frac{1+3\rho^2}{4}\sum_h a_h' e_h'$ and

$$\mathcal{J}_\rho''' = \sum_h \Big(\tfrac{1+5\rho^2}{4} a_h' e_h'' + \tfrac{1+2\rho^2}{2} a_h'' e_h' - \tfrac{3\rho^2}{2}\frac{a_h'^2 e_h'}{a_h} + \tfrac{1-\rho^2}{4} a_h e_h'^3\Big).$$

(d) With the static legs of Theorem 27.24(b), for every real ρ, $\frac{1+3\rho^2}{4} V_r(\eta, \eta, \Xi; k_1, k_2, k_3) + \rho^2 V_d(\eta, \eta, \Xi; k_1, k_2, k_3) = -8\rho^2$, which is 0 exactly when $\rho = 0$.

Proof. (a) If $c_{0h} = \lambda a_{0h}$, $c_{1h} = \lambda$, $c_{2h} = 0$, each left side minus its right side is λ times the second or third relation. Conversely fix h and another hinge k, and take two Schläfli jets supported on $\{h, k\}$, both with $e^{(1)} = a_{0k}$ at h and $-a_{0h}$ at k: the first with $a^{(1)} = a_{0h}$, $e^{(2)} = -a_{0k}$, $e^{(3)} = 2a_{0k}$ at h, the second with $a^{(2)} = a_{0h}$, $e^{(3)} = -a_{0k}$ at h, all other entries 0. After division by a_{0k}, the two equations for the first jet and the second for the second read $-c_0 + 2a_0 c_1 = \lambda a_0$, $2c_0 - 3a_0 c_1 + 6a_0^2 c_2 = -\lambda a_0$ and $-c_0 + 3a_0 c_1 = 2\lambda a_0$ at h, so $c_1 = \lambda$, $c_0 = \lambda a_0$ and $c_2 = 0$. (b) $c_2 = 0$ forces $r = 0$, and $r = 0$ gives $\lambda = \frac{1}{4}$. (c) $J_{\mathrm{odd}}(a/r, e^d) = \frac{1}{2}(\frac{a}{r} - \frac{r}{a})\sinh d$ by Proposition 27.16(b). Per hinge write $\mathcal{J}_\rho$ as FG with $F = \frac{1}{4}(a - \rho^2 a_0^2/a)$, $G = \sinh e$: at 0, G, G', G'', G''' are $0, e', e'', e''' + e'^3$, and F, F', F'' are $\frac{1}{4}(1 - \rho^2)a_0$, $\frac{1}{4}(1 + \rho^2)a'$,

$\frac{1}{4}((1+\rho^2)a'' - 2\rho^2 a'^2/a_0)$. Leibniz's rule and the two differentiated Schläfli identities, which remove $\sum a_0 e''$ and $\sum a_0 e'''$ as in Proposition 27.22, give the formulas. (d) $V_r = 0$ and $V_d = -8$ on these legs. □

By Proposition 27.22, (c) reads $\mathcal{J}_\rho''' = \frac{1+3\rho^2}{4}\mathcal{R}''' + \rho^2(\mathcal{J}''' - \mathcal{R}''') + \frac{1-\rho^2}{4}\sum_h a_h e_h'^3$, and by (27.1) its first two terms carry the vertex of (d): the static test fails for it at every $\rho \neq 0$, J's own cost $\rho = 1$ included. At $\rho = 0$ the cost is $\frac{1}{4}a\sinh e$; the area enters linearly and J only through the deficit. For charges built from one function of the area, the quadratic test and the cubic test at three witnesses do force Regge's derivatives (Theorem 27.66), and with one function per class of hinge they force them up to three inversion-odd terms that neither test sees (Proposition 27.67); we do not prove the long-wave order of the last term.

27.6 The Regge table for every background

The two tables of Table 27.1 are two points of one rational family. We now compute Regge's table for every background $g_\kappa = 1 - \kappa \mathbf{1}\mathbf{1}^{\mathsf{T}}$ with $\kappa \neq \frac{1}{4}$, from the Gram matrix of one Kuhn simplex. Take the simplex with vertices $v_k = e_1 + \cdots + e_k$, $k = 0, \dots, 4$ (axes numbered 1 to 4 here). Let $n^1, \dots, n^4$ be the dual basis of its edges $v_a - v_0$, and let the facet normals be $n_0 = -(n^1 + \cdots + n^4)$ and $n_i = n^i$, so that $W_{ij} = n_i \cdot n_j$ $(0 \le i, j \le 4)$ is $E^{\mathsf{T}} G^{-1} E$ for the 4×5 matrix E with columns $-\mathbf{1}, e_1, \dots, e_4$. For a triangle t, write lm for the opposite edge (the two vertices not in t) and $Q_t = 16A_t^2 = 2ab + 2bc + 2ca - a^2 - b^2 - c^2$ for Heron's expression in its squared edge lengths.

Theorem 27.26 (The Gram algebra of the Kuhn simplex)**.** *In classical mathematics, for every real κ:*

(a) the Gram matrix of the edges from v_0 is $G_{ab} = \min(a,b) - \kappa ab$ $(a, b = 1, \dots, 4)$, and $\det G = 1 - 4\kappa = \det g_\kappa$; for $\kappa \neq \frac{1}{4}$, G^{-1} is tridiagonal with off-diagonal entries -1 and diagonal $(2, 2, 2, (3\kappa - 1)/(4\kappa - 1))$;

(b) Q_t equals $4(1-2\kappa)$ on the triangles 012, 123, 234; $8(1-3\kappa)$ on 013, 023, 124, 134; $12(1-4\kappa)$ on 014, 034; and $16(1-4\kappa)$ on 024;

(c) for $\kappa \neq \frac{1}{4}$ and every triangle t, $W_{ll}W_{mm} - W_{lm}^2 = Q_t/(4(1-4\kappa))$;

(d) for $\kappa < \frac{1}{4}$, every Q_t, W_{ll} and W_{mm} is positive, the dihedral angle at t is

$$\theta_t = \arccos\!\big(-W_{lm}/\sqrt{W_{ll}W_{mm}}\big),$$

and along a direction of the squared edge lengths

$$\partial\theta_t = \frac{\mathrm{num}_t}{W_{ll}W_{mm}\sqrt{W_{ll}W_{mm} - W_{lm}^2}}, \qquad \partial A_t = \frac{\partial Q_t}{8\sqrt{Q_t}},$$

with $\mathrm{num}_t = \partial W_{lm}\, W_{ll}W_{mm} - \frac{1}{2}W_{lm}(\partial W_{ll}\, W_{mm} + W_{ll}\, \partial W_{mm})$ and $\partial W = -W(\partial G)W$ in the sense $\partial(G^{-1}) = -G^{-1}(\partial G)G^{-1}$.

Proof. (a) The edge $v_b - v_a$ has $b-a$ axis steps, so its squared length is $(b-a)-\kappa(b-a)^2$, and $G_{ab} = \frac{1}{2}(L_{0a}+L_{0b}-L_{ab}) = \min(a,b)-\kappa ab$. So $G = M - \kappa s s^{\mathsf T}$ with $M_{ab} = \min(a,b)$ and $s = (1,2,3,4) = Me_4$. $M = LL^{\mathsf T}$ with L the lower triangular matrix of ones, so $\det M = 1$, and M^{-1} is the tridiagonal matrix of the statement with last diagonal entry 1. By the matrix determinant lemma $\det G = 1 - \kappa s^{\mathsf T} M^{-1} s = 1 - 4\kappa$, and by the formula of Sherman and Morrison [94] $G^{-1} = M^{-1} + \kappa e_4 e_4^{\mathsf T}/(1-4\kappa)$, whose last entry is $(1-3\kappa)/(1-4\kappa)$. (b) A triangle ijk has edges with $j-i$, $k-j$ and $k-i$ steps; substitute the squared lengths $n-\kappa n^2$ into Heron's expression. (c) By Jacobi's theorem on complementary minors [89], a 2×2 principal minor of G^{-1} equals the complementary principal minor of G divided by $\det G$. For $l,m \geq 1$ the left side is the minor of G^{-1} on $\{l,m\}$, and the complementary minor of G is the Gram determinant of the two edges from v_0 that span t, which is $4A_t^2 = Q_t/4$. When l or m is 0, base the edges at another vertex of t; the determinant $1-4\kappa$ does not change. (d) For $\kappa < \frac{1}{4}$ the values in (b) are positive and G is positive definite, so $W_{ll} = |n_l|^2 > 0$. The angle between the outward normals of the facets l and m is $\pi - \theta_t$. Differentiating G^{-1} gives ∂W; the chain rule for $\arccos u$, $u = -W_{lm}/\sqrt{W_{ll}W_{mm}}$, uses $1-u^2 = (W_{ll}W_{mm}-W_{lm}^2)/(W_{ll}W_{mm})$; and $A_t = \sqrt{Q_t}/4$. □

Parts (c) and (d) do not need the Kuhn simplex. Let $L \in \mathbb{R}^{10}$ be any ten numbers, read as the squared lengths of the edges ij of a 4-simplex, and form from L, as above, $G_{ab} = \frac{1}{2}(L_{0a}+L_{0b}-L_{ab})$, $W = E^{\mathsf T} G^{-1} E$ when $\det G \neq 0$, Q_t, $A_t = \sqrt{Q_t}/4$, $\theta_t = \arccos(-W_{lm}/\sqrt{W_{ll}W_{mm}})$ and $D_t = W_{ll}W_{mm} - W_{lm}^2$. Write ∂_e for the derivative in the squared length L_e of the slot e.

Theorem 27.27 (Schläfli's identity for every nondegenerate 4-simplex)**.** *In classical mathematics, for every $L \in \mathbb{R}^{10}$:*

(a) if $\det G \neq 0$, then $4 \det G \cdot D_t = Q_t$ for each of the ten triangles t;

(b) if $\det G \neq 0$ and every triangle has $W_{ll} > 0$, $W_{mm} > 0$, $D_t > 0$ and $Q_t > 0$, then every θ_t has a derivative $\partial_e \theta_t$ for every slot e, and $\sum_t A_t \, \partial_e \theta_t = 0$.

A nondegenerate Euclidean simplex meets the hypotheses of (b) ($W_{ij} = n_i \cdot n_j$ for its facet normals), so (b) is Schläfli's identity [93] for a 4-simplex.

Proof. (a) For $l,m \geq 1$, D_t is the minor of G^{-1} on $\{l,m\}$, and Jacobi's theorem gives it as in Theorem 27.26(c): the complementary minor of G is $xy - \frac{1}{4}(x+y-z)^2 = \frac{1}{4}Q_t$ for the squared sides x, y, z of t. If l or m is 0, renumber the vertices so that 0 lies on t; this changes the edge basis by an integer matrix of determinant ± 1 and changes neither W nor $\det G$. (b) By (a), $\det G > 0$ and $A_t = \frac{1}{4}\sqrt{4 \det G}\sqrt{D_t}$. Near L, W is differentiable and the chain rule of Theorem 27.26(d) gives

$$A_t \, \partial_e \theta_t = \tfrac{1}{4}\sqrt{4 \det G}\Big(\partial_e W_{lm} - \tfrac{1}{2} W_{lm}(x_l + x_m)\Big), \qquad x_i = \partial_e W_{ii}/W_{ii},$$

every W_{ii} being positive since each vertex lies on an edge opposite some triangle. The ten triangles are the ten pairs $l < m$. W is symmetric with zero row sums ($E\mathbf{1} = 0$), near L, so $\partial_e W$ is too. Hence $\sum_{l<m} \partial_e W_{lm} = -\frac{1}{2}\sum_l \partial_e W_{ll}$ and $\sum_{l<m} W_{lm}(x_l + x_m) = \sum_l x_l \sum_{m \neq l} W_{lm} = -\sum_l \partial_e W_{ll}$, and the sum is $\frac{1}{4}\sqrt{4 \det G}(-\frac{1}{2}+\frac{1}{2})\sum_l \partial_e W_{ll} = 0$. □

Table 27.3. The partial-fraction tables of $R(\kappa)$, scaled to integers; slots in the order of Table 27.1. $72B_2$ has the entries 1 at $(01,03)$ and $(02,03)$, -1 at $(03,13)$, $(03,23)$, $(12,14)$ and $(13,14)$, 1 at $(14,24)$ and $(14,34)$, and their mirror images, and 0 elsewhere; $64B_3$ is diagonal with entries -1 at 02, 2 at 13, -1 at 24, and 0 elsewhere.

$$192B_0 = \begin{pmatrix} 6 & -6 & 2 & 0 & 0 & 12 & -6 & -24 & 6 & 6 \\ -6 & -12 & 14 & -3 & 24 & -24 & 6 & 12 & -6 & 6 \\ 2 & 14 & -2 & -6 & -24 & 4 & 6 & -8 & 6 & -6 \\ 0 & -3 & -6 & 6 & 6 & 6 & -6 & 6 & -3 & 0 \\ 0 & 24 & -24 & 6 & -24 & 24 & -8 & 0 & 12 & -24 \\ 12 & -24 & 4 & 6 & 24 & -12 & 4 & 24 & -24 & 12 \\ -6 & 6 & 6 & -6 & -8 & 4 & -2 & -24 & 14 & 2 \\ -24 & 12 & -8 & 6 & 0 & 24 & -24 & -24 & 24 & 0 \\ 6 & -6 & 6 & -3 & 12 & -24 & 14 & 24 & -12 & -6 \\ 6 & 6 & -6 & 0 & -24 & 12 & 2 & 0 & -6 & 6 \end{pmatrix} \qquad 256B_1 = \begin{pmatrix} 2 & -2 & -2 & 0 & 0 & 0 & -2 & 0 & 2 & 2 \\ -2 & 2 & -2 & -1 & 0 & 0 & 2 & 0 & -2 & 2 \\ -2 & -2 & 2 & -2 & 0 & 0 & 2 & 0 & 2 & -2 \\ 0 & -1 & -2 & 2 & 2 & 2 & -2 & 2 & -1 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \\ -2 & 2 & 2 & -2 & 0 & 0 & 2 & 0 & -2 & -2 \\ 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 2 & -2 & 2 & -1 & 0 & 0 & -2 & 0 & 2 & -2 \\ 2 & 2 & -2 & 0 & 0 & 0 & -2 & 0 & -2 & 2 \end{pmatrix}$$

For $\kappa \notin \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$ put

$$R(\kappa) = B_0 + \frac{B_1}{\kappa - \frac{1}{4}} + \frac{B_2}{\kappa - \frac{1}{3}} + \frac{B_3}{\kappa - \frac{1}{2}},$$

with the tables of Table 27.3. For a hinge h spanned by the steps p and q, with edges p, q, $q-p$, let $G_0(h) = |p|^2|q|^2 - (p \cdot q)^2$ be its Euclidean Gram determinant, L_κ the squared length at g_κ, and, for an edge e of h with other edges a, b, $N_\kappa(h,e) = L_\kappa(a) + L_\kappa(b) - L_\kappa(e)$, which is half the derivative of Q_h in $L_\kappa(e)$. Then $N_\kappa = N_0 - \kappa S$ with $S(h,e) = \sigma_a^2 + \sigma_b^2 - \sigma_e^2$, σ the coordinate sum of a step.

Theorem 27.28 (The Regge table for every background)**.** *In classical mathematics, for every real $\kappa \notin \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$:*

(a) $48R(0) = E$ *and* $48R(1) = R_1$*;*

(b) B_2 *and* B_3 *are nonzero tables of zero symbol, and* B_1 *is not of zero symbol: the plane-wave form of* $R(\kappa)$ *has its only pole at the degenerate background* $\kappa = \frac{1}{4}$*, and* $\kappa = 1$ *is a regular point;*

(c) for every wave K and all perturbations A, B,

$$R(\kappa)(K; A, B) = \sum_h D_A(h)\, \frac{1}{4(1-4\kappa)} \sum_{e \in h} \frac{N_\kappa(h,e)}{G_0(h)}\, B(e)\, e^{-iK \cdot x_e},$$

where D_A is the Euclidean area-weighted deficit of Theorem 27.20, and x_e is the midpoint of the edge e measured from the hinge's first vertex; at $\kappa = 0$ the inner factor is the log-area change Λ_B; by (b), the identity holds for every $\kappa \neq \frac{1}{4}$ with $B_0(K; A, B) + B_1(K; A, B)/(\kappa - \frac{1}{4})$ on the left;

(d) for $\kappa < \frac{1}{4}$, with the true derivatives of Theorem 27.26(d), $-\sum_t \partial_e \theta_t\, \partial_f A_t = \sqrt{1-4\kappa}\, R(\kappa)_{ef}$ for all slots e, f;

(e) for $\kappa \notin \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$ the algebraic expression $-\sum_t \mathrm{num}_t(e)\, \partial_f Q_t / (4 W_{ll} W_{mm} Q_t)$ equals $R(\kappa)_{ef}$.

Conditions and scope.

Base and premises

The Kuhn simplex at g_κ; classical real numbers.

Conclusion

With Schläfli's identity (Theorem 27.27), $-\sum_t \nabla\theta_t \otimes \nabla A_t$ is the Hessian of Regge's action at the flat background, with true second derivatives, so for $\kappa < \frac{1}{4}$ the Hessian is $\sqrt{\det g_\kappa}\, R(\kappa)$ (Theorem 27.29): one rational family, with the Euclidean and the lattice tables as its values at 0 and 1. The linearized deficits do not change with κ; the background enters only on the area side, through $N_\kappa/(4 \det g_\kappa)$.

Not claimed

True derivatives for $\kappa > \frac{1}{4}$, where angles are Lorentzian; there $R(\kappa)$ is the algebraic continuation. The $\kappa = 1$ derivation on $\mathbb{R}_\delta$ is Theorem 27.32.

Proof. (a) At $\kappa = 0$ the coefficients $1/(\kappa - \frac{1}{4})$, $1/(\kappa - \frac{1}{3})$, $1/(\kappa - \frac{1}{2})$ are -4, -3, -2, and at $\kappa = 1$ they are $\frac{4}{3}$, $\frac{3}{2}$, 2; the identities are entrywise arithmetic with Tables 27.1 and 27.3. (b) Group the terms of a plane-wave form by the classes of the two slots and the difference of their midpoints; a table has zero symbol exactly when every group sums to zero, which is a finite check, and it holds for B_2 and B_3 and fails for B_1. (c) The ratios N_0/G_0 and S/G_0 do not depend on the simplex in which a hinge edge is met, so the right side is $(W_0 - \kappa W_S)/(4(1 - 4\kappa))$ for two fixed rational tables W_0, W_S; and $R(\kappa)$ minus this is a combination of four fixed rational tables of zero symbol, checked by (b)'s criterion; forming them from the deficit rates, N_0, S, G_0 and Table 27.3 is a finite computation, which we describe and do not reproduce. At $\kappa = 0$, $Q_h = 4G_0$ and $\partial \log A_h/\partial L_e = N_0/(4G_0)$. (d) and (e) Assemble Theorem 27.26(d): $-\sum_t \partial\theta_t\, \partial A_t = -\sum_t \mathrm{num}_t\, \partial Q_t/(8\sqrt{Q_t}\, W_{ll} W_{mm} \sqrt{\mathrm{jac}_t})$ with $\mathrm{jac}_t = W_{ll}W_{mm} - W_{lm}^2$, and by (c) of that theorem $\sqrt{\mathrm{jac}_t} = \sqrt{Q_t}/(2\sqrt{1 - 4\kappa})$. So the left side of (d) is $\sqrt{1 - 4\kappa}$ times the expression in (e), which is a rational function of κ entry by entry and equals $R(\kappa)$ off the three poles. □

Fix $\kappa < \frac{1}{4}$, let L_κ be the squared edge lengths of the Kuhn simplex at g_κ, and put $S(L) = \sum_t A_t(L)\big(\theta_t(L_\kappa) - \theta_t(L)\big)$. The flat angles at each hinge of the lattice add to 2π, so a hinge's deficit is the sum over its simplices of $\theta_t(L_\kappa) - \theta_t(L)$, and S is one simplex's share of Regge's action.

Theorem 27.29 (Regge's Hessian at every Euclidean background, with true second derivatives)**.** *In classical mathematics, for every $\kappa < \frac{1}{4}$ and all slots e, f: for every s near 0, S has a derivative $g(s)$ in L_e at $L_\kappa + s\mathbf{1}_f$ ($\mathbf{1}_f$ the unit vector of the slot f), and $g'(0) = \sqrt{1 - 4\kappa}\, R(\kappa)_{ef}$.*

Proof. At L_κ, $\det G = 1 - 4\kappa > 0$ and Q_t, W_{ll}, W_{mm}, $D_t = Q_t/(4(1 - 4\kappa))$ are positive (Theorem 27.26), and they stay so nearby. There the product rule and Theorem 27.27(b) give $\partial_e S(L) = \sum_t \big(\theta_t(L_\kappa) - \theta_t(L)\big)\partial_e A_t(L)$. Along $L_\kappa + s\mathbf{1}_f$ the first factor vanishes at $s = 0$ with derivative $-\partial_f\theta_t$, so $g'(0) = -\sum_t \partial_f\theta_t\, \partial_e A_t = \sqrt{1 - 4\kappa}\, R(\kappa)_{fe}$ by Theorem 27.28(d), and $R(\kappa)$ is symmetric. □

27.7 The near-flat chain on $\mathbb{R}_\delta$

Everything in this section is proved on $\mathbb{R}_\delta$ with no omniscience principle and no choice principle, except the decisions whose prices are named. The cosine, π and the square root are δ's own (Definition 21.6, Theorem 21.8, Proposition 12.19). The lattice is the periodic Kuhn lattice of side N: vertices $(\mathbb{Z}/N)^4$, each unit cube cut into the 24 simplices of Definition 27.19. At the background g_1 an edge with n axis steps has squared length $n(1-n)$: the axis edges are light-like and every longer edge is timelike. For edge fields u, v the *flat Hessian* is

$$\mathscr{H}(u,v) = \frac{1}{16\sqrt{3}} \sum_{x} \sum_{\sigma} \sum_{f,f'} (R_1)_{ff'}\, u(e_{x\sigma f})\, v(e_{x\sigma f'}),$$

with $e_{x\sigma f}$ the edge of slot f of simplex σ at the vertex x. The *plane wave* of an integer wave m and a symmetric amplitude H is $u_{m,H}(e) = (s_e^{\mathsf{T}} H s_e)\cos(2\pi m\cdot x_e/N)$, with s_e the step and x_e the midpoint of the edge e. The *cell symbol* at $k \in \mathbb{R}_\delta^4$ is

$$\operatorname{sym}(k;X,Y) = \sum_{\sigma} \sum_{f,f'} (R_1)_{ff'}\,(s_f^{\mathsf{T}} X s_f)(s_{f'}^{\mathsf{T}} Y s_{f'})\cos y_{ff'}, \qquad y_{ff'} = k\cdot(x_f - x_{f'}),$$

and $\operatorname{rem}(k;X,Y)$ is the same sum with $\cos y$ replaced by $y^2 - 2 + 2\cos y$.

Theorem 27.30 (Regge's Hessian is Fierz–Pauli at long wavelength, with rate)**.** *For symmetric X, Y over $\mathbb{R}_\delta$ and $k \in \mathbb{R}_\delta^4$:*

(a) $\sum_\sigma \sum_{f,f'} (R_1)_{ff'} (s_f^{\mathsf{T}} X s_f)(s_{f'}^{\mathsf{T}} Y s_{f'}) = 0$, *and*

$$\sum_{\sigma} \sum_{f,f'} (R_1)_{ff'} (s_f^{\mathsf{T}} X s_f)(s_{f'}^{\mathsf{T}} Y s_{f'})\, y_{ff'}^2 = 24\,\mathrm{FP}_{g_1}(k;X,Y);$$

on strains TT at k the right side is $24\,(k\cdot k)\operatorname{tr}(XY)$, and when $\operatorname{tr}(XY)$ is apart from 0 it vanishes exactly when k is on the cone;

(b) $2\operatorname{sym}(k;X,Y) = -24\,\mathrm{FP}_{g_1}(k;X,Y) + \operatorname{rem}(k;X,Y)$, *and* $0 \le y^2 - 2 + 2\cos y \le y^4/12$; *so the symbol of $\mathscr{H}$ is $-\frac{\sqrt{3}}{4}\mathrm{FP}_{g_1} + O(k^4)$ with an explicit remainder;*

(c) if N does not divide $2m_c$ for some c, then $16\sqrt{3}\,\mathscr{H}(u_{m,X}, u_{m,Y}) = \frac{1}{2}N^4 \operatorname{sym}(2\pi m/N; X, Y)$;

(d) under the same condition,

$$192\,\mathscr{H}(u_{m,X},u_{m,Y}) = -96\sqrt{3}\,\pi^2 N^2\,\mathrm{FP}_{g_1}(m;X,Y) + \sqrt{3}N^4\operatorname{rem}(2\pi m/N;X,Y);$$

(e) if $m_c \neq 0$ and $2|m_c| < N$ for some c, then

$$\left|\frac{192}{N^2}\mathscr{H}(u_{m,X},u_{m,Y}) + 96\sqrt{3}\pi^2\,\mathrm{FP}_{g_1}(m;X,Y)\right| \le \frac{\sqrt{3}\pi^4}{N^2}\,B(m,X,Y),$$

with $B = \frac{1}{12}\sum_\sigma\sum_{f,f'} |(R_1)_{ff'}(s_f^{\mathsf{T}} X s_f)(s_{f'}^{\mathsf{T}} Y s_{f'})|\,(2m\cdot(x_f - x_{f'}))^4$. So

$$N^{-2}\mathscr{H}(u_{m,X},u_{m,Y}) \to -\frac{\sqrt{3}\pi^2}{2}\mathrm{FP}_{g_1}(m;X,Y)$$

at the rate $O(N^{-2})$.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ with δ's π, cosine and $\sqrt{3}$; integer tables. Free.

Conclusion

The flat Hessian of the $\kappa = 1$ Regge lattice is, at long wavelength and with an explicit error, $-\sqrt{3}\pi^2/2$ times the Fierz–Pauli form of the lattice metric; on transverse-traceless waves it is the dispersion times $\mathrm{tr}(XY)$.

Identification

The Kuhn lattice as discretized spacetime, $\kappa = 1$, the flat field $n(1-n)$ and Regge's action as the gravitational action.

Proof. (a) Both sums are polynomial identities with integer coefficients in the entries of X, Y and k, obtained by expanding over the 24 simplices and 100 slot pairs; the reader can expand them, or compare the coefficients of the 6-index integer tensor they define with those of $24\,\mathrm{FP}_{g_1}$. On TT strains $\mathrm{FP}_{g_1} = (k\cdot k)\,\mathrm{tr}(XY)$ by Theorem 27.6(c), and a product with a factor apart from 0 is 0 exactly when the other factor is. (b) Termwise $2\cos y = 2 - y^2 + (y^2 - 2 + 2\cos y)$; the constant terms cancel by the first identity of (a), and the y^2 terms give $-24\mathrm{FP}_{g_1}$ by the second. The bounds on $y^2 - 2 + 2\cos y$ are the alternating-series bounds for δ's cosine. (c) Sum over the torus: $\sum_x \cos(\theta + 2\pi m\cdot x/N)\cos(\theta' + 2\pi m\cdot x/N) = \frac{1}{2}N^4\cos(\theta-\theta')$, because the doubled-frequency terms sum to 0 over a full period when $N \nmid 2m_c$. (d) is (c) with (b) at $k = 2\pi m/N$, using $\mathrm{FP}_{g_1}(2\pi m/N) = (4\pi^2/N^2)\mathrm{FP}_{g_1}(m)$. (e) Divide (d) by N^2 and bound the remainder by (b), with $y = (\pi/N)\,2m\cdot(x_f - x_{f'})$. □

J reads the same comparison. Compare the record metric $g_1 + \varepsilon H$ with g_1: the ratio is $g_1^{-1}(g_1 + \varepsilon H) = 1 + \varepsilon X$ with the metric strain $X = g_1^{-1}H$.

Proposition 27.31 (*J's transverse form is Fierz–Pauli with coefficient one in lattice units*)**.** *On $\mathbb{R}_\delta$, free:*

(a) if $(1+\varepsilon X)B = 1$, then $J(1+\varepsilon X) = \frac{1}{2}(\mathrm{tr}(1+\varepsilon X) + \mathrm{tr}\,B) - 4 = \frac{\varepsilon^2}{2}\,\mathrm{tr}(X^2B)$;

(b) for H TT at m, $Q_J(m,H) = (m\cdot m)\cdot 2J_2(g_1^{-1}H)$ equals $\mathrm{FP}_{g_1}(m;H,H)$;

(c) for H TT at the integer wave m and $N \nmid 2m_c$ for some c, $192\,\mathscr{H}(u_{m,H},u_{m,H}) = -24\sqrt{3}N^4\,Q_J(2\pi m/N,H) + \sqrt{3}N^4\,\mathrm{rem}(2\pi m/N;H,H)$.

Proof. (a) is the identity of Theorem 27.2 with the inverse given as data. (b) $H\mathbf{1} = 0$ gives $g_1^{-1}H = H$; then Theorem 27.6. (c) is Theorem 27.30(d) with (b). □

So J's calibrated transverse form is Fierz–Pauli with coefficient one in the lattice's units; $J''(1) = 1$ fixes the shape of the action, and its strength comes from outside J (Proposition 27.14).

The flat Hessian is the second variation of Regge's action itself, computed on $\mathbb{R}_\delta$. A cell is *nondegenerate* when the denominators of its angle formulas are apart from 0.

Theorem 27.32 (Regge's action on $\mathbb{R}_\delta$ and its second variation)**.** *On $\mathbb{R}_\delta$, free:*

(a) δ's cosine has an inverse arccos *on $[-1,1]$:* $\cos(\arccos c) = c$, $0 \le \arccos c \le \pi_\delta$ *and* $\sin(\arccos c) = \sqrt{1-c^2}$*; on $[-1+\frac{1}{m+1}, 1-\frac{1}{m+1}]$ it is Lipschitz with constant $L = 64(m+1)^2$ and has a first-order rate with error at most $4L^2(c'-c)^2$;*

(b) every nondegenerate Kuhn cell has native dihedral angles with first-order rates, and Schläfli's identity $\sum_t A_t \, \mathrm{d}\theta_t = 0$ holds for it;

(c) at the flat $\kappa = 1$ cell, with ε_t the simplex's share of the deficit ($\partial\varepsilon_t = -\partial\theta_t$), $\sum_t \partial_e A_t \, \partial_f \varepsilon_t = -\sum_t \partial_e A_t \, \partial_f \theta_t = (R_1)_{fe}/(16\sqrt{3})$; the first-order rates are the derivatives of δ's own areas and angles, with second-order remainders bounded by one constant near the flat cell;

(d) there is a constant $K > 0$ such that for every side N, every edge field w with $|w_e| \le 1$ and every $|x| \le 1/40000000$ for which every cell of ℓ and of $\ell + xw$ is nondegenerate (so that S is defined at both), the Regge action S (the sum over hinges of area times deficit, with the angles of (b)) satisfies

$$\left| S(\ell + xw) - S(\ell) - \tfrac{1}{2} x^2 \, \mathscr{H}(w,w) \right| \le 24 N^4 K |x|^3,$$

where ℓ is the flat field.

Proof. The proof assembles finite identities and estimates; we give its route and the source of each estimate, and do not carry the bounds out. (a) $\arccos c = \pi_\delta/2 - \arcsin c$, with δ's arcsine, the inverse of the sine on $[-\pi_\delta/2, \pi_\delta/2]$, given on a grid of points with explicit moduli; the bounds follow from $\sin^2 + \cos^2 = 1$ and the bounds of the cosine on the closed subinterval. (b) The dihedral angle at a triangle is π_δ minus the arccos of the normalized product of the two facet normals (the angle between the normals), as in Theorem 27.26(d); its rate is the chain rule of (a). Schläfli's identity is then an identity between rational expressions in the squared edge lengths and the square roots of the cell's Gram determinants, which holds after clearing denominators. (c) At the flat cell the area rates A_t'/A_t are $1/12$ times an integer table and the weighted deficit rates $A_t\varepsilon_t'$ are $1/(8\sqrt{3})$ times another; their product over the ten triangles is $6R_1$, and $6/(12 \cdot 8\sqrt{3}) = 1/(16\sqrt{3})$. Second-order remainders come from (a) applied along a line of cells. (d) Census: the 240 slot types of the lattice fall into 50 hinge fibers, and the flat angles of each fiber add to 2π, so the flat field has zero deficit. Along $x \mapsto \ell + xw$, Schläfli's identity removes the angle-change term at each step of a telescoping sum, summation by parts handles the area term, and (c) identifies the quadratic term; the cubic bound collects the remainders of (a) and (c), cell by cell, which gives the factor $24N^4$. The constant is $K = 100K_0^2$, where K_0 bounds, on every cell whose ten squared lengths lie within $1/40000000$ of the flat cell's and along every direction with entries in $[-1,1]$, the areas, their rates, the angle rates, and the first-order remainders of areas and angles divided by x^2; K_0 exists by (a) at $m = 4999$ and by bounds on the Gram polynomials of these cells, and we do not compute it. □

So the chain from Regge's action through its Hessian, 24 times Fierz–Pauli and the long-wave limit $-(\sqrt{3}\pi^2/2)\,\mathrm{FP}_{g_1}$ runs on $\mathbb{R}_\delta$ with no choice and no omniscience.

The same assembly reaches one order higher. At the flat $\kappa = 1$ cell let A_t', A_t'' and ε_t', ε_t'' be the first and second derivatives, along a direction d of the ten squared edge lengths, of

the area of the triangle t and of the simplex's share ε_t of its deficit. The *cubic cell form* is $C(d) = \sum_t \big(2A_t''\varepsilon_t' + A_t'\varepsilon_t''\big)$, the analogue at $\kappa = 1$ of $-r$ in Definition 27.23; it is $(1152\sqrt{3})^{-1}$ times a cubic form with integer coefficients.

Theorem 27.33 (Regge's cubic vertex on $\mathbb{R}_\delta$)**.** *On $\mathbb{R}_\delta$, free: there is $C_0 > 0$ such that for every side N, every edge field w with $|w_e| \le 1$ and every $|x| \le 1/40000000$ for which every cell of ℓ and of $\ell + xw$ is nondegenerate,*

$$\Big|S(\ell + xw) - S(\ell) - \tfrac{1}{2}x^2\,\mathscr{H}(w,w) - \tfrac{1}{6}x^3 \sum_y \sum_\sigma C(w_{y\sigma})\Big| \le 24N^4 C_0\, x^4,$$

where $w_{y\sigma}$ lists the values of w on the slots of the simplex σ at the vertex y. At the flat cell the mixed differences of δ's own area and angle differ from xy times their second derivatives by at most a constant times $|xy|(|x| + |y|)$, for $|x|, |y| \le 1/80000000$ (for the angle, at nondegenerate cells).

Proof. As for Theorem 27.32(d), one order further, and again we give the route and the source of each estimate. Per simplex put $a_t(\tau) = A_t(\ell + \tau xw)$ and $b_t(\tau) = \varepsilon_t(\ell + \tau xw) - \varepsilon_t(\ell)$, so that $S(\ell + xw) - S(\ell)$ sums $\sum_t a_t(1)b_t(1)$. Summation by parts on the grid $\tau = k/m$, with Schläfli's identity at each grid point, reduces $\sum_t a_t(1)b_t(1)$ to $\sum_t \int_0^1 a_t' b_t\, d\tau$ up to $O(1/m)$. With the quadratic Taylor coefficients $a_1 = xA_t'$, $a_2 = x^2A_t''$ and b_1, b_2 likewise, this integral is $\frac{1}{2}a_1b_1 + \frac{1}{6}(2a_2b_1 + a_1b_2) + \frac{1}{8}a_2b_2$ up to the Taylor remainders; the last term and the remainders are $O(x^4)$, since δ's area and angle have cubic remainders bounded by fixed constants k_A, k_θ and a_1, b_1 are $O(|x|)$. By Theorem 27.32(c) the first term is the simplex's share of $\frac{1}{2}x^2\mathscr{H}(w,w)$, and $\sum_t(2a_2b_1 + a_1b_2) = x^3C(w_{y\sigma})$; sum over the $24N^4$ simplices. The mixed differences are bounded by Taylor's theorem in the regimes $|y| \le |x|$ and $|x| \le |y|$; the bound is a non-strict inequality, the negation of a strict one, so the case split, which holds up to double negation, needs no omniscience. The constant is $C_0 = 1 + \sum_t\big(k_A(2K_0 + \beta_t + k_\theta) + (K_0 + \alpha_t)k_\theta + \alpha_t\beta_t\big)$, with K_0 from the proof of Theorem 27.32 and α_t, β_t the sums of the absolute values of the entries of the second-order tables of A_t and ε_t at the flat cell. □

Why area times deficit? A *hinge charge* $\sigma(A)$ is the action a hinge of area A carries per unit of deficit. At background $\kappa \ge \frac{1}{2}$ the flat cell has four hinge classes with squared areas $(4\kappa - 2)/8$, $(12\kappa - 4)/8$, $3(4\kappa - 1)/4$ and $4\kappa - 1$ (Theorem 27.26(b), up to sign), all nonnegative; call their nonnegative roots $a_0, \dots, a_3$. The flat field is *stationary* at $\kappa \ge \frac{1}{2}$ for the charge σ when $\sigma(a_2)a_3 = \sigma(a_3)a_2$ and $a_0\sigma(a_0) - a_1\sigma(a_1) + \frac{1}{4}a_3\sigma(a_3) = 0$. For $\kappa > \frac{1}{2}$ these are the two conditions of the stationarity criterion [96, Prop. 4.1]: for an action that sums a continuously differentiable hinge charge $C(A, \delta)$ with $C(A, 0) = 0$ and slope $\sigma(A) = \partial_\delta C(A, 0)$ over the hinges, they hold exactly when the flat lattice is a stationary point of the action. We take them as the definition. The function σ is *pointwise continuous on* $[\frac{1}{2}, \infty)$ when for every $x \ge \frac{1}{2}$ and k there is a j with $|\sigma(y) - \sigma(x)| \le \frac{1}{k+1}$ whenever $y \ge \frac{1}{2}$ and $|y - x| \le \frac{1}{j+1}$.

Theorem 27.34 (The slope theorem is free). *On $\mathbb{R}_\delta$:*

(a) Regge's charge $\sigma(A) = \lambda A$ is stationary at every $\kappa \geq \frac{1}{2}$;

(b) if σ is pointwise continuous on $[\frac{1}{2}, \infty)$ and the flat field is stationary for σ at every $\kappa > 1$, then $\sigma(A) = \sigma(1)A$ for every $A \geq \frac{1}{2}$; free;

(c) without continuity the conclusion fails under the WLPO function: given it, the slope $\omega(A) = A$ when A^2 is rational and $\omega(A) = 0$ otherwise is a map, stationary at every $\kappa \geq \frac{1}{2}$, and not linear.

Proof. (a) Both conditions are linear identities in λ once $\sigma(a) = \lambda a$; the second is $\lambda\big(\frac{4\kappa-2}{8} - \frac{12\kappa-4}{8} + \frac{4\kappa-1}{4}\big) = 0$.

(b) Put $h(u) = \sqrt{u}\,\sigma(\sqrt{u})$ for $u \geq \frac{1}{4}$, so that $a_i\sigma(a_i) = h(a_i^2)$; h is pointwise continuous on $[\frac{1}{4}, \infty)$, as σ is on $[\frac{1}{2}, \infty)$. Write $t = 4\kappa - 1$, so that $\kappa > 1$ is $t > 3$ and the squared areas are $(t-1)/8$, $(3t-1)/8$, $3t/4$ and t. Multiplying the first condition by a_2a_3 and dividing by t, stationarity at every $\kappa > 1$ says that for every $t > 3$

$$\text{(E1)} \quad h\big(\tfrac{3}{4}t\big) = \tfrac{3}{4}h(t), \qquad\qquad \text{(E2)} \quad h\big(\tfrac{t-1}{8}\big) - h\big(\tfrac{3t-1}{8}\big) + \tfrac{1}{4}h(t) = 0.$$

The limit. Read upwards, (E1) gives $h((\frac{4}{3})^n z) = (\frac{4}{3})^n h(z)$ for $z \geq 3$. Let $x \geq 25$ and apply (E2) at $t = (\frac{4}{3})^n x$, that is, at $\kappa = ((\frac{4}{3})^n x + 1)/4$. As $(t-1)/8 = (\frac{4}{3})^n(x/8 - \varepsilon_n)$ and $(3t-1)/8 = (\frac{4}{3})^n(3x/8 - \varepsilon_n)$ with $\varepsilon_n = (\frac{3}{4})^n/8$, and $x/8 - \varepsilon_n \geq 3$, dividing by $(\frac{4}{3})^n$ gives $h(x/8 - \varepsilon_n) - h(3x/8 - \varepsilon_n) + \frac{1}{4}h(x) = 0$ for every n. As $\varepsilon_n \to 0$, continuity of h at $x/8$ and at $3x/8$ gives

$$\text{(H)} \quad h(x/8) - h(3x/8) + \tfrac{1}{4}h(x) = 0 \qquad \text{for every } x \geq 25.$$

Ratios near 1. For every $J \geq 4$ there are $n, m \geq 1$ with $\rho = 2^n(\frac{3}{4})^m$ and $|\rho - 1| \leq \frac{1}{J+1}$. Let k_j be the largest k with $2^k \leq 3^j$. Of the $J+2$ ratios $3^j 2^{-k_j} \in [1, 2)$, $j = 0, \dots, J+1$, two lie in one of the $J+1$ intervals $[1 + \frac{i}{J+1}, 1 + \frac{i+1}{J+1})$; the later over the earlier is $\rho = 3^m 2^{-k}$ with $m \geq 1$ and $|\rho - 1| \leq \frac{1}{J+1} \leq \frac{1}{5}$, so $2^k \leq \frac{5}{4}\,3^m < 4^m$ and $\rho = 2^n(\frac{3}{4})^m$ with $n = 2m - k \geq 1$.

Period two. Let $W(u) = h(4u) - 4h(2u) + 4h(u)$. (H) at $x = 8u$ with (E1) at $t = 4u$ gives $h(8u) - 3h(4u) + 4h(u) = 0$, that is, $W(2u) = -W(u)$ for $u \geq 4$; (E1) at $4t$, $2t$ and t gives $W(\frac{3}{4}t) = \frac{3}{4}W(t)$ for $t > 3$. Let $u \geq 6$ and ρ as above. The points $2^n u(\frac{3}{4})^i$, $i < m$, exceed 3, so $W(\rho u) = (\frac{3}{4})^m W(2^n u)$, while $|W(2^n u)| = |W(u)|$; as $m \geq 1$, $|W(\rho u)| \leq \frac{3}{4}|W(u)|$. (With $m = 0$ this fails: $|W(2u)| = |W(u)|$.) Continuity of h at u, $2u$ and $4u$ gives $|W(\rho u) - W(u)| \leq \frac{9}{k+1}$ once J is large, for each k; so $\frac{1}{4}|W(u)| \leq \frac{9}{k+1}$ for every k, and $W(u) = 0$. Then $V(u) = h(2u) - 2h(u)$ has $V(2u) - 2V(u) = W(u) = 0$ for $u \geq 6$, so $2h(2^n u) = 2^n(2h(u) + nV(u))$, and by (E1) $h(\rho u) = (\frac{3}{4})^m h(2^n u)$. Hence $n\rho V(u) = 2(h(\rho u) - h(u)) - 2(\rho - 1)h(u)$ with $n\rho \geq \frac{4}{5}$, and continuity of h at u gives $V(u) = 0$: $h(2u) = 2h(u)$ for every $u \geq 6$.

Linear far out. For $u \geq 6$, (E1) at $t = 4u$ gives $h(3u) = \frac{3}{4}h(4u) = 3h(u)$; so for $t \geq 49$, eight times (E2) is $h(t-1) - 3h(t - \frac{1}{3}) + 2h(t) = 0$. On the points $r_j = 49 + j/3$ the values

$R_j = h(r_j)$ satisfy $2R_{j+3} - 3R_{j+2} + R_j = 0$, whose characteristic polynomial is $(r-1)^2(2r+1)$; so $R_j = a + bj + c(-\frac{1}{2})^j$. As $2r_j = r_{147+2j}$, period two gives $R_{147+2j} = 2R_j$, which at $j = 0$ and $j = 1$ reads $147b - a + c((-\frac{1}{2})^{147} - 2) = 0$ and $147b - a + c(\frac{1}{4}(-\frac{1}{2})^{147} + 1) = 0$. The difference is $c(\frac{3}{4}(-\frac{1}{2})^{147} - 3) = 0$, so $c = 0$, $a = 147b$ and $h(r_j) = Cr_j$ with $C = 3b$. Halving, $h(r) = Cr$ at every point $r_j/2^i \geq 49$; these points lie $1/(3 \cdot 2^i)$ apart, and continuity of h at each $y \geq 49$ gives $h(y) = Cy$.

The descent. For $v > \frac{1}{4}$, (E2) at $t = 8v + 1 > 3$ reads $h(v) = h(3v + \frac{1}{4}) - \frac{1}{4}h(8v + 1)$. If $h(w) = Cw$ for every $w > \frac{1}{4}$ with $w \geq Y$, then for every $v > \frac{1}{4}$ with $v \geq Y/3$ both arguments on the right are at least Y, and $h(v) = C(3v + \frac{1}{4}) - \frac{C}{4}(8v + 1) = Cv$. From $Y = 49$, $h(v) = Cv$ for every $v > \frac{1}{4}$ after finitely many steps; so $C = h(1)$, and continuity at $\frac{1}{4}$ gives $h(\frac{1}{4}) = \frac{C}{4}$. With $u = A^2$, $\sigma(A) = \sigma(1)A$ for every $A \geq \frac{1}{2}$. Continuity is used only at the points $x/8$, $3x/8$, u, $2u$, $4u$, y and $\frac{1}{4}$, one point at a time; no modulus and no omniscience enter, as the ratios ρ come from a search over integers.

(c) The WLPO function decides, by three nested applications and the zero test it yields, whether a point is a ratio, so ω is a map. At every $\kappa \geq \frac{1}{2}$ the four squared areas are all ratios when κ is rational and none is otherwise, so each condition holds term by term, by (a) or trivially. At $A = 2^{1/4}$, $A^2 = \sqrt{2}$ is not a ratio, so $\omega(A) = 0 \neq A\,\omega(1)$. □

The theorem is the slope theorem of [96]; on $\mathbb{R}_\delta$ it costs nothing, and no route through uniform continuity is needed.

Proposition 27.35 (Regge's charge and the doublers)**.** *On $\mathbb{R}_\delta$, free:*

(a) if a hinge charge reads only the content, $C(A, \delta) = F(A\delta)$, and one posting record fixes it at the posting unit, $C(A, 2\pi_\delta/k) = sA \cdot 2\pi_\delta/k$ for every A, then $C(A, \delta) = sA\delta$ for all A and δ, with no continuity;

(b) the four corner modes of the Kuhn lattice (momentum π along one axis) are non-gauge zero modes of the flat Hessian of the background g_κ, among all $\kappa > \frac{1}{2}$ and on every torus of even side, exactly when $\kappa = 1$.

Proof. (a) $A\delta = (A\delta k/2\pi_\delta) \cdot (2\pi_\delta/k)$, so $C(A, \delta) = F(A\delta) = C(A\delta k/2\pi_\delta, 2\pi_\delta/k) = sA\delta$. (b) On a corner mode the flat Hessian reduces to a 15×15 matrix over the edge classes, with entries rational in κ and built from the flat table of the background g_κ, which is itself computed on $\mathbb{R}_\delta$; its kernel, computed as a function of κ, consists of the vertex moves unless $\kappa = 1$. For $\kappa > \frac{1}{2}$ the entries are a positive factor times integer polynomials of degree one in κ; the vertex moves are null, the doubler h_c of Proposition 27.36 is null at $\kappa = 1$ and is no vertex move, and for κ apart from 1 an integer certificate with the factor $12\kappa(\kappa-1)(2\kappa-1)(3\kappa-1)(7\kappa-2)(12\kappa^2-1)$ makes every null vector a vertex move. These polynomial identities are finite; we describe them and do not reproduce them. □

These corner modes, the lattice's doublers, are where a one-loop computation first meets trouble, and we record its exact inputs. On the torus of even side $N \geq 4$ let $\delta'_h(u)$ be the linear change of the deficit of the hinge h under the edge field u, A_h its flat area, n_h the

number of simplices around it, and $D(u,v) = \frac{1}{2}\sum_h (A_h/n_h)\,\delta_h'(u)\,\delta_h'(v)$. The doubler at the corner c is $h_c(e) = (-1)^{x_c} v_c(d)$ on the edge of class d based at x, with $v_c(d) = 2^{|d|-1}$ if $d_c = 0$ and $v_c(d) = 0$ otherwise. Let K_c be the symmetric integer matrix with diagonal entries -2 at c and 52 elsewhere and off-diagonal entries 9 in row and column c and -3 elsewhere, and $u_c(q) = q^{\mathsf{T}} K_c q$. For the residue let $T(u,v,w) = \sum_t \big(\varepsilon_t''(u,v)A_t'(w) + \varepsilon_t'(u)A_t''(v,w) + \varepsilon_t'(v)A_t''(u,w)\big)$, with the first and mixed second derivatives at the flat $\kappa = 1$ cell, so that $T(d,d,d) = C(d)$. The *probes* are the constant strains $a(d) = d^{\mathsf{T}} H_a d$, $a = E, T$: H_E is 0 on the diagonal, 2 at $(0,1)$, $(1,0)$, $(2,3)$, $(3,2)$ and -1 elsewhere; H_T is diag$(-1,-1,1,1)$ with 1 at $(0,1)$, $(1,0)$, -1 at $(2,3)$, $(3,2)$ and 0 elsewhere. For a simplex σ of the unit cell let a_σ and h_σ list the values of a and of h_c on its ten edges. The *corner pairing* is $p_a(c) = \sum_\sigma T(a_\sigma, h_\sigma, h_\sigma)$, the *residue* is $\mathrm{res}_a(c) = p_a(c)^2/\big(\sum_d v_c(d)^2\big)^2$, and the corners' *anisotropic residue* is $\rho = \sum_c \big(\mathrm{res}_E(c)/24 - \mathrm{res}_T(c)/8\big)$.

Proposition 27.36 (The doublers' weight, dispersion form and logarithm)**.** *On $\mathbb{R}_\delta$, free:*

(a) $D(h_c,h_c) = N^4 w_c$ *with* $w_c = \frac{5}{2} + \frac{3}{4}\sqrt{3} > 0$ *at every corner c, that is* $D(h_c,h_c) = \frac{10+3\sqrt{3}}{124}\sum_e h_c(e)^2$*;*

(b) $\det K_c = -1013375 = -55^2 \cdot 335$*, and each u_c has one negative and three positive directions;*

(c) the corners' anisotropic residue is $\rho = -3/7688$*, and with* $d_L = 3\sqrt{1013375}/1240^2$*,* $\rho(-\pi^2)/(2d_L(2\pi)^4) = 5/(44\sqrt{335}\,\pi^2)$*; so if* $|I(\varepsilon) + \pi^2 L(\varepsilon)| \le B$ *for* $0 < \varepsilon \le 1$*, then* $\rho I(\varepsilon)/(2d_L(2\pi)^4) - \frac{5}{44\sqrt{335}\pi^2} L(\varepsilon)$ *is bounded on* $(0,1]$*.*

Proof. (a) On an even torus each $\delta_h'(h_c)$ is $(-1)^{y_c}(m\sqrt{3}/3 + n)$, with y the first vertex of h and integers $m \in \{0, \pm1, \pm3\}$, $n \in \{0, \pm1\}$ fixed by the hinge's class through the flat deficit rates; summing $(A_h/n_h)(m\sqrt{3}/3 + n)^2$ over the fifty hinge classes at a vertex gives $2w_c$, and $\sum_d v_c(d)^2 = 3 + 12 + 16 = 31$. (b) K_c is K_0 with the coordinates 0 and c exchanged, and $6u_0(q) = -3y_0^2 + 165y_1^2 + 55y_2^2 + 335y_3^2$ with $y_0 = 2q_0 - 9(q_1+q_2+q_3)$, $y_1 = q_1 - q_2$, $y_2 = q_1 + q_2 - 2q_3$, $y_3 = q_1 + q_2 + q_3$, a substitution of determinant 12; so $\det K_0 = 12^2(-3 \cdot 165 \cdot 55 \cdot 335)/6^4$. (c) At every corner $p_E(c) = 0$ and $1152\sqrt{3}\,p_T(c) = 1728 s_c$ with $s_c = -1, -1, 1, 1$; these are finite sums over the 24 simplices with the integer coefficients of $1152\sqrt{3}\,T$, which we describe and do not reproduce. So $\mathrm{res}_E(c) = 0$, $\mathrm{res}_T(c) = \frac{3}{4}/31^2 = 3/3844$ and $\rho = -4 \cdot 3/(8 \cdot 3844)$. Then $\sqrt{1013375} = 55\sqrt{335}$ and $3 \cdot 1240^2/(7688 \cdot 2 \cdot 165 \cdot 16) = 5/44$, and the difference in the last claim is $\rho\big(I(\varepsilon) + \pi^2 L(\varepsilon)\big)/(2d_L(2\pi)^4)$. □

Read physically, on four named identifications, D is the Hessian of the weight that the ledger cost of the hinge holonomies gives a lattice history, so (a) says that this weight gaps all four doublers; u_c is the doubler's dispersion: $(\sqrt{3}/640)\,u_c$ is the second-order jet of the Schur complement onto the doubler computed from tabulated Taylor coefficients at the corner, on the named premises that these are the Taylor coefficients of the gauge-fixed $\kappa = 1$ operator (a computation not proved here) and that the doubler's eigenvalue follows the jet; and with I the imaginary part of the model integral and $L = \log(1/\varepsilon)$, (c) gives the bare action's doubler logarithm on these premises and that of the integral's asymptotics, the side going to infinity before the damping ε goes to 0. The one-loop transverse-traceless remainder itself is not computed. The quartic cell form at $\kappa = 1$ is $(576\sqrt{3})^{-1}$ times a symmetric integer table, built from third-order formulas whose identification with third derivatives is open.

Are the doublers flat? We answer this, with the $\kappa = 1$ form of Theorem 27.20(a),(b), one wave at a time over any commutative ring R. Let $z_0, \dots, z_3$ be units of R (for a wave K, $z_a = e^{iK_a}$) and $z^x = \prod_a z_a^{x_a}$. A *strain* of the wave z is a map v from the fifteen classes to R, the edge of class d from x to $x+d$ changing its squared length by $v(d)z^x$ (in Definition 27.19, $A(d) = e^{-iK\cdot d/2}v(d)$). The vertex displacement ηz^x ($\eta \in R^4$) has the strain $G_\eta(d) = 2\,(d^{\mathsf T} g_1\eta)(z^d - 1)$, as an amplitude $4i(d \cdot g_1\eta)\sin(K\cdot d/2)$, the gauge amplitude of $g_1\eta$ in Definition 27.19. The fifty hinges at the origin are the triangles $\{0, p, q\}$ with $0 < p < q$ in $\{0,1\}^4$ (coordinatewise). With $P_{tf} = 8\sqrt{3}\,A_t\,\partial_f\varepsilon_t$, the integer table of the flat $\kappa = 1$ cell (Theorem 27.32(c)), the same for every simplex, the strain vz^x has area-weighted deficit $z^y D_v(h)$ at the hinge $h + y$, where $\mathscr{D}_v(h) = 8\sqrt{3}\,D_v(h) = \sum P_{tf}\,v(s_f)\,z^{x_f}$ over the simplices having h as their triangle t and their slots f, x_f the lower end of the slot's edge.

Proposition 27.37 (Beyond gauge, the $\kappa = 1$ lattice has only the flat moduli)**.** *Over every commutative ring R, free:*

(a) at every wave, $\mathscr{D}_{G_\eta} = 0$ for every $\eta \in R^4$;

(b) if 6 is invertible, each z_a is 1 or has $z_a - 1$ invertible, and not every z_a is 1, then every strain v with $\mathscr{D}_v = 0$ is G_η for some $\eta \in R^4$;

(c) at $z = 1$, if 6 is invertible, $\mathscr{D}_v = 0$ exactly when $v(d) = d^{\mathsf T} H d$ for a symmetric 4×4 matrix H over R, and H is unique: these are the ten constant metric strains;

(d) on $\mathbb{R}_\delta$ and the torus of even side $N \geq 4$, the doubler h_c of Proposition 27.36, the strain v_c of the wave $z_c = -1$, $z_b = 1$ ($b \neq c$), is a zero mode of the flat Hessian, but $\mathscr{D}_{v_c}$ is 12, 12, 12, -8 for $c = 0, 1, 2, 3$ at the hinge $\{0, e_3, q\}$, with $q = e_2 + e_3$ for $c = 0$ and $c = 1$, $q = e_1 + e_3$ for $c = 2$ and $q = e_1 + e_2 + e_3$ for $c = 3$; so h_c is the strain of no vertex displacement.

Proof. Each step is a polynomial identity, checked coefficient by coefficient, or linear algebra over R. Write $\mathscr{D}_v(h) = \sum_d \mathscr{D}_{hd} v(d)$, $G_\eta(d) = \sum_a G_{da}\eta_a$: Laurent polynomials in z with integer coefficients, built from the rows P_t (slots in the order 01, … , 34; each column sums to 0, Schläfli's identity):

012	0	2	−1	0	0	0	0	0	1	−2
013	2	−4	2	0	0	−6	4	12	−8	4
014	0	0	0	0	0	9	−6	−18	9	0
023	−4	2	−6	4	0	12	−8	−6	4	0
024	0	−6	12	−6	12	−24	12	12	−6	0

034	0	9	−6	0	−18	9	0	0	0	0
123	0	0	3	−2	0	−6	3	0	0	0
124	0	4	−8	4	−6	12	−6	0	2	−4
134	4	−8	4	0	12	−6	2	0	−4	2
234	−2	1	0	0	0	0	−1	0	2	0

(a) is $\sum_d \mathscr{D}_{hd}G_{da} = 0$ (fifty hinges, four axes); read with z_a the translation along e_a, it covers every displacement field. (b) If every $z_a - 1$ is invertible, take η with $(g_1\eta)_a = v(e_a)/(2(z_a - 1))$, using $g_1^{-1} = 1 - \frac{1}{3}\mathbf{1}\mathbf{1}^{\mathsf T}$; $r = v - G_\eta$ vanishes on the axis classes and $\mathscr{D}_r = 0$. For each three-step class T the hinge $\{0, T, \mathbf{1}\}$ carries -36 on T and otherwise only classes below T; eliminating the $r(T)$ by these, the hinges $\{0, e_3, e_0 + e_2 + e_3\}$, $\{0, e_1, e_0 + e_1 + e_3\}$, $\{0, e_1 + e_2, e_1 + e_2 + e_3\}$, $\{0, e_1 + e_2, e_0 + e_1 + e_2\}$ and $\{0, e_a + e_3, \mathbf{1}\}$ ($a \leq 2$) give seven equations in the two-step amplitudes and $r(\mathbf{1})$ with determinant $2^{18}3^3(z_0z_2)^{-1}(z_0 - 1)^3(z_1 - 1)^3(z_2 - 1)^4(z_3 - 1)^2$, a unit; so these vanish, and then every $r(T)$. Otherwise read η off e_a ($z_a - 1$ invertible) and $e_a + e_b$ ($z_a = 1$; b least with $z_b - 1$ invertible), where $G_\eta(e_a + e_b) = 2((g_1\eta)_a + (g_1\eta)_b)(z_b - 1)$; in each of the fourteen cases a Laurent combination of hinge equations gives $\Delta r = 0$ on the other eleven

classes, Δ a unit (± 8, ± 48, ± 72 or ± 144 times a monomial and powers of the invertible $z_a - 1$); the determinant and these eliminations are finite computations with the table above, which we describe and do not reproduce. (c) At $z = 1$, $G_\eta = 0$ and $\sum_d \mathscr{D}_{hd}(1)\, d_a d_b = 0$ for all h, a, b. Conversely $H_{aa} = \nu(e_a)$, $2H_{ab} = \nu(e_a + e_b) - \nu(e_a) - \nu(e_b)$ make $r(d) = \nu(d) - d^{\mathsf{T}} H d$ vanish on the axis and two-step classes; the hinges $\{0, T, \mathbf{1}\}$ give $r(T) = 0$, and $\{0, e_3, e_2 + e_3\}$, with entry -4 at $\mathbf{1}$, gives $r(\mathbf{1}) = 0$. The same formulas recover H. (d) At the corner every entry is an integer; $\mathscr{D}_{\nu_c}$ is nonzero at 38 hinges, with the stated values, while by (a) a displacement has none. Grouped by hinges, Theorem 27.32(c) reads $\mathscr{H}(w, \nu) = \sum_h \Lambda_w(h) D_\nu(h)$, $\Lambda_w(h)$ the linear change of $\log A_h$; summed over translations, $\mathscr{H}(w, h_c) = 0$ is the rational identity $\sum_h \Lambda_{hd} \mathscr{D}_{\nu_c}(h) = 0$ for every class d, Λ_{hd} the coefficient of $\nu(d)$ in $\Lambda_\nu(h)$ at the corner. □

So the doublers are massless without being flat; and over $\mathbb{C}$, classically, (b) holds at every $K \notin (2\pi\mathbb{Z})^4$, a wider range than that of Theorem 27.20(b) at the Euclidean background.

27.8 The background $\kappa = 1$ at its exact scope

J is blind to the background (Proposition 27.7), and the native chain assumes $\kappa = 1$. What fixes it? This section proves that $\kappa = 1$ is equivalent to each of several statements about records and postings, and isolates the weakest: some record of a ledger history is definite. It is not derived. All results are proved in classical mathematics.

Records are those of Chapter 24: a 2×2 coherent record $R(p) = \frac{1}{2}(p_0 1 + \vec{p} \cdot \vec{\sigma})$ has coordinates $p = (p_0, \vec{p}) \in \mathbb{R}^4$, the record cone is $\mathscr{K} = \{p_0 \geq |\vec{p}|\}$, and $Q(p) = p_0^2 - |\vec{p}|^2 = 4 \det R(p)$, so a record is pure exactly when $Q(p) = 0$. A record with $p_0 = 1$ has *squared Bloch length* $|\vec{p}|^2$. The pairing $\langle p, q \rangle = \operatorname{tr}(R(p)R(q)) = \frac{1}{2}(p_0 q_0 + \vec{p} \cdot \vec{q})$ is the probability a test assigns to a record.

Definition 27.38 (The Kuhn form, cone identifications and definite records)**.**

1. The *Kuhn form* at κ is $q_\kappa(v) = \kappa(\sum v)^2 - |v|^2$, minus the squared length of v at g_κ; its future cone is $\{\sum v \geq 0,\ q_\kappa(v) \geq 0\}$. A single posting is a unit vector e_p; an edge class d with $|d|$ ones has $q_\kappa(d) = |d|(\kappa|d| - 1)$; the posting plane of $p \neq q$ consists of the vectors $De_p + Ce_q$.

2. A *cone identification* at $\kappa > \frac{1}{4}$ is a linear bijection Λ of $\mathbb{R}^4$ with v in the future cone of q_κ exactly when $\Lambda v \in \mathscr{K}$. It is *tick-normalized* when $(\Lambda e_i)_0 = 1$ for every i.

3. A *test* is e with $e \in \mathscr{K}$ and $(2, \vec{0}) - e \in \mathscr{K}$; it is *sharp* when moreover $e_0 = 1$ and $Q(e) = 0$. A record $p \in \mathscr{K}$ is *definite* in the sense X (extreme) if every splitting $p = \sigma + \tau$ into records has σ a multiple of p; C (certain) if some test other than $(2, \vec{0})$ has $\langle e, p \rangle = p_0$; U (undisturbed) if some sharp test's reading $R(e)R(p)R(e)$ leaves it unchanged; I (indivisible) if no two nonzero records σ, τ with $\langle \sigma, \tau \rangle = 0$ have $p - \sigma - \tau \in \mathscr{K}$; E (excluding) if $\langle p, \sigma \rangle = 0$ for some nonzero record σ.

4. An *exact readout* assigns to each posting word w a record $\rho(w)$, additive over concatenation, with each single post's record of trace 1, such that some test E satisfies $\operatorname{tr}(E\rho(w)) =$ the number of debits of w, for every w.

5. A *world of records* bundles the accepted premises (the foundation's facts, with definite comparison outcomes), the reading of a debit and a credit as two lattice steps, an exact readout, a causal bound at $\kappa = \frac{1}{4} + c_J^2$ with c_J the light speed in lattice lengths per tick, and a cone identification at that κ. It does not identify a post's own record with the image of its posting.

Let $u_1 = (1,1,1)$, $u_2 = (1,-1,-1)$, $u_3 = (-1,1,-1)$, $u_4 = (-1,-1,1)$, the vertices of a regular tetrahedron: $u_i \cdot u_i = 3$, $u_i \cdot u_j = -1$ for $i \neq j$, and $\sum u_i = 0$. For $\kappa > \frac{1}{4}$ put $T_\kappa v = \big(\sum v,\ r \sum_i v_i u_i\big)$ with $r = (4\kappa - 1)^{-1/2}$.

Theorem 27.39 (A posting's record has squared Bloch length $3/(4\kappa-1)$)**.**

(a) $q_\kappa(De_p + Ce_q) = \kappa(D+C)^2 - D^2 - C^2$ *equals* $\lambda \cdot 4DC$ *for all natural* D, C *if and only if* $\kappa = 1$ *and* $\lambda = \frac{1}{2}$*; at* $\kappa = 1$ *the lattice proper time of a word's straight displacement is its ledger proper time* $2\sqrt{DC}$ *divided by* $\sqrt{2}$*.*

(b) $Q(T_\kappa v) = \frac{4}{4\kappa-1}\, q_\kappa(v)$*, and* T_κ *is a cone identification.*

(c) $T_\kappa e_i$ *has time* 1 *and squared Bloch length* $3/(4\kappa-1)$*: a pure record exactly at* $\kappa = 1$*, a mixed record for* $\kappa > 1$*, and no record for* $\kappa < 1$*.*

(d) Every cone identification satisfies $Q(\Lambda v) = c\, q_\kappa(v)$ *for some* $c > 0$*; so under every identification a single posting's record is pure exactly when* $\kappa = 1$*.*

(e) If $\kappa \geq 1$*, a post's own record under an exact readout is* Λd *for an edge class* d *only if* $\kappa = 1$ *and* $|d| = 1$*; and at* $\kappa = 1$ *some exact readout and cone identification carry a post's own record to a single posting.*

Proof. (a) $(D,C) = (1,0)$ gives $\kappa = 1$, then $(1,1)$ gives $\lambda = \frac{1}{2}$; at $\kappa = 1$, $(D+C)^2 - D^2 - C^2 = 2DC$, and $\sqrt{2DC} = 2\sqrt{DC}/\sqrt{2}$. (b) $|\sum v_i u_i|^2 = 4|v|^2 - (\sum v)^2$ by the Gram values, so $Q(T_\kappa v) = (1+r^2)(\sum v)^2 - 4r^2|v|^2 = \frac{4}{4\kappa-1}(\kappa(\sum v)^2 - |v|^2)$; the time coordinate is $\sum v$, so the future sides correspond. (c) $|ru_i|^2 = 3r^2$. (d) ΛT_κ^{-1} keeps $\mathscr{K}$, so by the rigidity theorem of Chapter 24 it multiplies Q by a positive constant; combine with (b). (e) The test of the readout has $\mathrm{tr}(E\rho_d) = 1 = \mathrm{tr}\,\rho_d$ and $\mathrm{tr}(E\rho_c) = 0$ for the single-debit and single-credit records; if ρ_d had full rank, E would be 1 and $\mathrm{tr}(E\rho_c) = 1$. So the post's record is pure, and by (d) $0 = c\,|d|(\kappa|d| - 1)$ forces $\kappa|d| = 1$, hence $\kappa = |d| = 1$. Conversely, at $\kappa = 1$, $T_1 e_p = (1, \vec{n})$ with $|\vec{n}| = 1$ by (c); the readout with debit record $R(1,\vec{n})$, credit record $R(1,-\vec{n})$, extended additively, and the test $R(1,\vec{n})$ is exact, and with $\Lambda = T_1$ the debit's record is Λe_p. □

Theorem 27.40 (Definiteness of a posting record is $\kappa = 1$; the supplied definiteness is not)**.** *Let* $\kappa > \frac{1}{4}$ *and let* Λ *be a cone identification.*

(a) Λe_i *is a record exactly when* $\kappa \geq 1$*, and it is definite in any one of the senses X, C, U, I, E exactly when* $\kappa = 1$*.*

(b) If $\kappa \geq 1$ *and* $v \geq 0$ *is a nonzero history whose record* Λv *is definite, then* $\kappa = 1$ *and* v *lies on one account:* $v_a v_b = 0$ *for* $a \neq b$*.*

(c) If Λ is tick-normalized, every posting record has squared Bloch length $3/(4\kappa-1)$, distinct posting records have pairing $(2\kappa-1)/(4\kappa-1)$, and a sharp test that passes a posting record with probability at least $1-\varepsilon$, $\varepsilon<\frac{1}{2}$, forces $\kappa\le\frac{1}{4}+\frac{3}{4(1-2\varepsilon)^2}$.

(d) For every $\kappa>1$ there is a world of records at κ. In it the comparisons are definite and each post's own record is pure, yet the record of every nonzero posting history is mixed. If the image of each post is its own record seen through a depolarizing channel, $\Lambda(\mathit{post})=(1-r)(1,\vec{0})+r\,\rho(\mathit{post})$, then $r^2(2\kappa-1)=1$; this coupling is met at every $\kappa>1$, and it gives each posting off the posting plane a record of trace $2\kappa/(2\kappa-1)\neq 1$.

Proof. On the record cone each of X, C, U, I, E is equivalent to purity. A record with $Q>0$ is an interior point of the cone over a ball and splits into two non-proportional records; a full-rank ρ with $\operatorname{tr}(E\rho)=\operatorname{tr}\rho$ forces $E=1$; Lüders' reading by a rank-one projector P gives $\operatorname{tr}(P\rho)P$ [91], which is ρ only for pure ρ; a full-rank ρ contains ϵP and $\epsilon(1-P)$; and $\operatorname{tr}(\rho\sigma)=0$ with $\sigma\neq 0$ needs a kernel. Conversely a pure record has all five properties. (a) By Theorem 27.39(d), $Q(\Lambda e_i)=c(\kappa-1)$. (b) $Q(\Lambda v)=c\,q_\kappa(v)=c\big((\kappa-1)(\sum v)^2+2\sum_{a<b}v_av_b\big)$, a sum of nonnegative terms that must vanish. (c) With $(\Lambda v)_0=\sum v$, write $\Lambda v=(\sum v, Mv)$ with M of size 3×4; then $M^{\mathsf T}M=(1-c\kappa)\mathbf{1}\mathbf{1}^{\mathsf T}+c\,1$ has rank at most three, so its determinant $c^3(c+4(1-c\kappa))$ vanishes and $c=4/(4\kappa-1)$. Hence $|Me_i|^2=1+c(1-\kappa)=3/(4\kappa-1)$ and $Me_i\cdot Me_j=1-c\kappa=-1/(4\kappa-1)$, giving the pairing. A sharp test $(1,\vec{m})$ with $|\vec{m}|=1$ passes $(1,\vec{p})$ with probability P, $2P-1=\vec{m}\cdot\vec{p}$, so $(1-2\varepsilon)^2\le 3/(4\kappa-1)$. (d) A world at κ is built from a linear map that multiplies the forms by a positive constant and sends one future vector forward, which is a cone identification; the history records are mixed by the identity in the proof of (b), as $\kappa>1$. For the coupling: the readout makes the two posts' records pure with antipodal Bloch vectors $\pm n$, so $\Lambda e_p=(1,rn)$, $\Lambda e_q=(1,-rn)$ and $\Lambda(e_p+e_q)=(2,\vec{0})$. Rigidity at e_p+e_q gives $4=c(4\kappa-2)$, and at e_p gives $1-r^2=c(\kappa-1)=2(\kappa-1)/(2\kappa-1)$, so $r^2=1/(2\kappa-1)$. For $k\neq p,q$ the bilinear form gives $2(\Lambda e_k)_0=c\cdot 2\kappa$. □

The definiteness the foundation supplies (definite comparison outcomes, pure own records) therefore holds at every $\kappa>1$ and does not fix κ. What does is one sentence about the ledger's history.

Theorem 27.41 ($\kappa=1$ exactly when some history record is definite)**.** *In every world of records:*

(a) $\kappa=1$ if and only if some nonempty ledger history has a definite record, if and only if some positive linear reading (one that maps records to records) recovers every run's own record from its lattice record, and, under the depolarizing coupling, if and only if $r^2=1$;

(b) records are append-only, persist and can be re-examined; the event ledger is double-entry and append-only; the posts' own records keep which post occurred and a run's counts, and the lattice record keeps the counts and recovers them linearly; all of this holds at every $\kappa>1$; keeping the order of posts fails at every κ, since a debit then a credit leave the same own record as a credit then a debit;

(c) for $\kappa\ge 1$, each of the statements in Table 27.4 is equivalent to $\kappa=1$.

$\kappa=1$ is not derived: worlds of records exist at every $\kappa\ge 1$.

Conditions and scope.

Base and premises

Classical real and complex numbers; the cone identification is a named premise.

Conclusion

Every permanence statement of the foundation holds at every $\kappa > 1$; $\kappa = 1$ is exactly the named premise that the ledger's history record loses nothing, equivalently that some history record is definite.

Not claimed

A derivation of $\kappa = 1$. The doublers of Proposition 27.35(b) are massless exactly at $\kappa = 1$, the same premise, and add no further one.

Proof. (a) By Theorem 27.40(b) a definite record of a nonzero history forces $\kappa = 1$; at $\kappa = 1$ a single posting has a pure record. If a positive Φ sends an interior record x to a pure record, then for any record y and small $\epsilon > 0$, $x - \epsilon y$ is a record and $\Phi x = \epsilon \Phi y + \Phi(x - \epsilon y)$ splits a pure record, so Φy is a multiple of Φx. At $\kappa > 1$ the posting image Λe_p is interior and the debit's own record is pure, so a recovering Φ would send Λe_q to a multiple of the debit's record, while the credit's record is antipodal to it. At $\kappa = 1$ a measure-and-prepare reading recovers. The coupling: $r^2(2\kappa - 1) = 1$. (b) Each statement holds in every world of records, and worlds exist at every $\kappa > 1$ (Theorem 27.40(d)); own records add, so the two orders give $\rho_d + \rho_c$. (c) The first row holds because $q_\kappa(e_p) = \kappa - 1$ (Definition 27.38); rows two to four are Theorem 27.39(a), (c) and (e); the remaining rows are (a) and Theorem 27.40(d). □

Table 27.4. Equivalent forms of $\kappa = 1$, for $\kappa \geq 1$.

Statement	Settled by
A single lattice step is light-like: $q_\kappa(e_p) = 0$	Definition 27.38
The lattice interval on a posting plane is a fixed multiple of the ledger interval $4DC$	Theorem 27.39(a)
A posting's record under T_κ is pure: $3/(4\kappa - 1) = 1$	Theorem 27.39(c)
Some exact readout and cone identification carry a post's own record to an edge class	Theorem 27.39(e)
Some ledger history has a definite record	Theorem 27.41(a)
The history record loses nothing (a positive reading recovers every run's record)	Theorem 27.41(a)
Under the depolarizing coupling, $r^2 = 1$	Theorem 27.40(d)

The link between the posts' own records and their lattice records runs in two directions, and they differ. A real linear map Φ of record coordinates extends, through $p \mapsto R(p)$, to complex 2×2 matrices; it is *completely positive* when its Choi matrix $\sum_{i,j} E_{ij} \otimes \Phi(E_{ij})$ is positive semidefinite [23]. In a world of records let $x = \Lambda e_p$, $y = \Lambda e_q$ be the posting images and ρ_d, ρ_c the posts' own records. A *heralded discrimination* is a pair of tests e_1, e_2 with $(2, \vec{0}) - e_1 - e_2$ a record and $\langle e_1, y \rangle = \langle e_2, x \rangle = 0$; a test e *guesses* the post with success $\frac{1}{2}(\langle e, x \rangle / x_0 + \langle (2, \vec{0}) - e, y \rangle / y_0)$.

Theorem 27.42 ($\kappa = 1$ is the purity of one posting's lattice record)**.** *In classical mathematics, in every world of records (where $\kappa \geq 1$):*

(a) writing is positive: Λ sends every nonnegative account vector, so every run's lattice displacement, to a record, and the completely positive map $W(z) = \langle \rho_d, z\rangle x + \langle \rho_c, z\rangle y$ sends each run's own record to its lattice record; for every $\kappa > 1$ some world of records has all this while the reading in (b) fails;

(b) on the plane of x and y the only linear map with $x \mapsto \rho_d$, $y \mapsto \rho_c$ sends records to records exactly when $\kappa = 1$, exactly when x and y are pure, exactly when some positive reading recovers every run's own record; and a completely positive reading that recovers both posts' records, or every run's own record, exists exactly when $\kappa = 1$;

(c) if $\kappa > 1$, every heralded discrimination has $e_1 = e_2 = 0$, and every guess succeeds with probability at most $\frac{1}{2}(1 + 1/\sqrt{2\kappa - 1})$, which the depolarizing coupling of Theorem 27.40(d) attains.

Proof. (a) For $v \geq 0$, $q_\kappa(v) = (\kappa - 1)(\sum v)^2 + 2\sum_{a<b} v_a v_b \geq 0$. The own records are pure and antipodal, as in the proof of Theorem 27.39(e), so $\langle \rho_d, \rho_d\rangle = 1$, $\langle \rho_d, \rho_c\rangle = 0$, and W sends $D\rho_d + C\rho_c$ to $Dx + Cy$; its Choi matrix is a sum of Kronecker products of positive semidefinite matrices. The separating worlds are those of Theorem 27.40(d). (b) At $\kappa = 1$, $Q(sx + ty) = c\,q_1(se_p + te_q) = 2cst$, so records of the plane have $s, t \geq 0$. At $\kappa > 1$, $Q(x) = c(\kappa - 1) > 0$, so $x - \epsilon y$ is a record for small $\epsilon > 0$, while ρ_d, ρ_c are pure and antipodal and $Q(\rho_d - \epsilon\rho_c) = -4\epsilon$. Purity is $\kappa = 1$ by Theorem 27.39(d), and recovery is Theorem 27.41(a). A completely positive map is positive ($w^*\Phi(uu^*)w = \xi^* C\xi$ with $\xi = \bar{u} \otimes w$, C the Choi matrix). At $\kappa = 1$, with e_1, e_2 the sharp tests vanishing on y and on x, $z \mapsto \lambda_1\langle e_1, z\rangle\rho_d + \lambda_2\langle e_2, z\rangle\rho_c$ with $\lambda_1\langle e_1, x\rangle = \lambda_2\langle e_2, y\rangle = 1$ is completely positive and recovers. (c) A nonzero test pairs positively with the interior records x, y. A test has $|\vec{e}| \leq 1$, so a guess succeeds with probability at most $\frac{1}{2} + \frac{1}{4}\sqrt{S}/(XY)$ with $X = x_0$, $Y = y_0$, $S = |\vec{x}Y - \vec{y}X|^2$. Rigidity gives $X^2 - |\vec{x}|^2 = Y^2 - |\vec{y}|^2 = c(\kappa - 1)$ and $XY - \vec{x}\cdot\vec{y} = c\kappa$, so $S = 2c\kappa XY - c(\kappa - 1)(X^2 + Y^2)$ and $4X^2Y^2 - (2\kappa - 1)S = |\vec{x}Y + \vec{y}X|^2 + 2c\kappa(\kappa - 1)(X - Y)^2 \geq 0$. Under the coupling $x = (1, \vec{m})$, $y = (1, -\vec{m})$, $r^2(2\kappa - 1) = 1$, the test $(1, \vec{n})$ succeeds with probability $\frac{1}{2}(1 + r)$. □

So writing the ledger into the lattice picture is positive at every $\kappa \geq 1$, and reading the posts back is positive exactly at $\kappa = 1$: the premise of Theorem 27.41, unchanged by asking for complete positivity.

27.9 The locality clause is a named premise

The lattice of Section 27.7 posts at sites, and its gravity sector assumes a locality clause: each posting is decided by one comparison of the site's record with one partner's. This section proves what that clause is, and that nothing proved so far supplies it. The results are proved in classical mathematics; the definitions and the implication from one comparison are choice-free.

Definition 27.43 (Posting laws and the locality clause)**.** A *posting law* on a set V of sites, with records in R, assigns to each site x and each assignment $r : V \to R$ the post $F(x, r)$. The law *reads only* $A \subseteq V$ at x when $F(x, r) = F(x, r')$ whenever r and r' agree on A, and the site *recognizes* when the law does not read only $\{x\}$ at x. The *locality clause* (pair-reading) holds when every site x has a partner y such that $F(x, r)$ is determined by $r(x)$ and $r(y)$; *least read* holds when every x has a set $A \ni x$ of at most two sites that the law reads only. The law is decided by *one comparison* when $F(x, r) = g(x, \mathrm{cmp}(r(x), r(\pi x)))$ for a partner map π, a Boolean test cmp and some g.

Theorem 27.44 (The locality clause is least read)**.** *For every posting law F:*

(a) one comparison implies the locality clause;

(b) every set that contains a recognizing site and that the law reads only at it has at least two sites; so with records of $L + 1$ bits, a recognizing posting that reads its own record needs a window of at least $2(L + 1)$ bits, which pair-reading laws attain;

(c) the locality clause is equivalent to least read;

(d) the parity law on three sites (post a debit exactly when $r_0 + r_1 + r_2$ is even) is not pair-reading, yet each of its posts costs exactly what any single unit post costs on the ledger.

Proof. (a) Take $y = \pi x$. (b) If the set were $\{x\}$, the site would not recognize; x belongs to the set by hypothesis. (c) Given a partner y, take $A = \{x, y\}$; given A, take its other element, or $y = x$. (d) For any site x and partner y, changing the third record flips the parity. Each post is one unit post on one account, whose cost does not depend on what decided it. □

Proposition 27.45 (Nothing proved so far selects the clause)**.** *In classical mathematics:*

(a) in the foundation's semantics, the three facts (distinguishable occurrences exist; comparing needs information about both; a later examination is an occurrence) are equivalent in every world to the first; the world in which every post, once three records exist, records whether records 0, 1 and 2 all agree meets them; and for any two record positions it has two permitted histories that agree at both positions and whose forced next posts differ, so no pair of records decides a post;

(b) $J(x) = 0$ exactly when $x = 1$, so any number of agreeing comparisons costs 0, and $J(1) + J(1) < J(2) = \frac{1}{4}$; every unit post costs the same whatever decided it; so J does not count comparisons, and a uniform positive price per comparison only renames the clause.

Proof. (a) In the foundation's interpreter comparisons read two present records and re-examination is an event, so the second and third facts hold in every world. For positions i, j choose two seeds that agree at i and j and differ at the third of the positions $0, 1, 2$ so that the all-equal test changes. (b) $J(x) = (x - 1)^2/(2x)$, and $J(2) = \frac{1}{4}$. □

The clause can still be written into a world's rule. We describe such worlds and show that none of the standard worlds of the foundation's interpreter is one.

Definition 27.46 (Worlds, clause worlds and the standard worlds)**.**

1. Records and asking histories (lists of the acts post r, retain and compare (i, j)) are those of Chapter 30. A *world* is a set of histories, its permitted ones, containing the empty history and closed under prefixes; it is *rich* when for every n it permits a history with at least n records and n outcomes.

2. Let V be a set of sites with decidable equality, $\sigma : \mathbb{N} \to V$ a placement (post k is made at $\sigma(k)$) and $\pi : V \to V$ a partner map. With k records, $\ell_k(y)$ is the last position $i < k$ with $\sigma(i) = y$, if any; its record is the *current record* of y. The *clause world* $W_{\sigma,\pi}$ permits a history when each post made with $k \geq 3$ records comes right after compare $(\ell_k(\sigma k), \ell_k(\pi\sigma k))$, both positions existing, and is the one-letter record of its outcome. A world is *inside a clause world* when some clause world permits every history it permits.

3. The eighteen *standard worlds*, for all values of their parameters, are: all histories, and the two worlds of a located probe (a probe read as the post of its one-bit result, a move as a retain), which permit every history; the prefixes of one history, of the empty history, of the canonical query (post the codes of a sentence and of its negation, retain, compare; two constructions), and of the histories of a finite record of events; the clock of a sequence s of records (the prefixes of post $s(0)$, ..., post $s(n-1)$ followed by one comparison), its truncation to $n \leq N$, the tally clock (s constantly 1) and the uncompared tally (posts of 1 only); the capacity world of B (after each nonempty prefix the ledger's standard code has at most B bits) and the patch world of N (posts of 1 only, or the capacity world of N); the retain world (retains only); the free tally (posts of 1 and comparisons); and the window world of capacity N of Chapter 30 and its loose form (each address of a comparison that holds a record lies in the window), whose conditions bind only comparisons.

Theorem 27.47 (The clause can be a world's rule, and no standard world has that rule)**.** *In classical mathematics, for every set of sites, placement σ and partner map π:*

(a) $W_{\sigma,\pi}$ meets the three facts of Proposition 27.45(a), and in each history it permits, a post made with at least three records is the record of $[\, c(\sigma k) = c(\pi\sigma k) \,]$, c the current records: a post of a law that satisfies the locality clause with partner π;

(b) $W_{\sigma,\pi}$ permits every one-post history and no history consisting of four posts; on two sites posted in turn, each the other's partner, it is rich, while with a fresh site for every post it permits no post once three records exist;

(c) no clause world equals a world that forbids some one-post history, permits only finitely many, or permits some history consisting of four posts; no rich world inside a clause world equals a world that permits such a history or bounds the numbers of records or of outcomes of its histories; and some rich world inside a clause world, whose first three acts are fixed, permits exactly one one-post history;

(d) every standard world, for every value of its parameters, meets a condition of each list in (c); so none equals a clause world or a rich world inside one.

Proof. (a) Post 1, post 0, compare $(0, 1)$ is permitted and compares two present records that differ, which gives the facts by Proposition 27.45(a). A permitted post made with $k \geq 3$ records follows the comparison of positions $\ell_k(\sigma k)$ and $\ell_k(\pi\sigma k)$ and is its outcome; the law reads only x and πx. (b) The rule binds only posts made with three or more records, and in four posts the fourth follows a post. On two sites the comparison is of positions $k-2$ and $k-1$, so three posts followed by n rounds of comparing the last two records and posting the outcome give $n+3$ records and n outcomes. A fresh site has no current record. (c) A clause world permits the one-post history of every record, so infinitely many, and no history consisting of four posts; nor does a world inside it, and a rich world bounds neither count. The world of the histories of (b) on two sites that begin post 0, post 0, post 1 (where those acts are present) is inside the two-site clause world, rich, and its only one-post history is post 0. (d) All histories, the probe worlds, the uncompared and free tallies, the patch worlds and both window worlds permit the history of four posts of 1, which meets a condition of both lists; so do the clock and the tally clock, which permit the history of their first four posts. The retain world forbids every post and has no records; the capacity world of B forbids posting 1^{B+1} and has at most B records; the other prefix worlds and the truncated clock permit finitely many one-post histories and bound the length of their histories. □

The separation uses the first four acts of a history; it does not cover encodings of records and histories, intersections or unions of standard worlds, or classes of worlds. The clause is not derived.

In a synchronous tick every site updates at once from the previous tick's records. Take sites $0, \dots, N-1$, seeds c_0 and posting laws F_t (Definition 27.43), and put $c_t(x) = F_t(x, c_{t-1})$. In the *posting run*, records $0, \dots, N-1$ are the seeds and record $Nt + x$ is F_t at x applied to $y \mapsto$ record $(t-1)N + y$. A post *depends on* a site or position when changing that record alone, from some assignment, changes the post, and *depends on it at r* when changing it alone from r does.

Proposition 27.48 (Synchronous ticks run as posts, and who reads whom)**.** *In classical mathematics:*

(a) record $Nt + x$ of the posting run is $c_t(x)$; if F_t reads only $\{x, p_t(x)\}$ at x, post $Nt + x$ reads only the positions $(t-1)N + x$ and $(t-1)N + p_t(x)$;

(b) if a law reads only $\{x, p(x)\}$ at every x with p injective (a pairing, say), at most two posts depend on each site; yet for every site y_0 a law decided by one comparison reads only $\{x, y_0\}$ at every x and has all N posts depending on y_0;

(c) let each site pick its contact from its own record, $F(x, r) = G(x, r(x), r(c(x, r(x))))$. At every r the post of x is fixed by $r(x)$ and $r(c(x, r(x)))$, and in the posting run post $Nt + x$ is fixed by two positions of tick $t-1$; but if no $G(x, u, \cdot)$ is constant and $c(x, \cdot)$ takes two values other than x, no fixed y makes F read only $\{x, y\}$ at x. Where the picks $x \mapsto c(x, r(x))$ are injective, at most two posts depend on each site at r; if the picks pair the sites off at every r, each $c(x, \cdot)$ is constant;

(d) let site x decide from $r(x)$ and $r(q(x))$, by a test a, whether to contact one candidate $q(x)$: $F(x, r) = G(x, r(x), r(qx))$ when the test holds and $H(x, r(x))$ otherwise. Then F satisfies the locality clause with partner q; and if $q(q(x)) = x$ and $a(qx, v, u) = a(x, u, v)$, the contacts made pair the sites off at every r, and for the agreement test they change with the records.

The statements other than the counts of dependent posts hold with no omniscience principle and no choice principle.

Proof. (a) Induction on t: post $Nt + x$ applies $F_t(x, \cdot)$ to the records $(t-1)N + y$, which are $c_{t-1}(y)$. (b) A post of x that depends on y has $y \in \{x, p(x)\}$, and $p(x) = y$ for at most one x. For the hub, post the outcome of the test that $r(x)r(y_0)$ is empty. (c) The first claims are the form of F. Given y, pick u with $c(x,u) \notin \{x, y\}$, give every site u, and change only the record at $c(x,u)$. If $c(x,u) = z \neq x$, the assignments giving x the record u force $c(z, \cdot) = x$, and then for each record b the assignment giving every site b forces $c(x,b) = z$. (d) The test and both branches use only $r(x)$ and $r(qx)$; if the test holds at x it holds at $q(x)$, whose contact is $q(q(x)) = x$. Under the agreement test on two sites, equal records give the contacts $1, 0$ and different ones $0, 1$. □

The run itself has no comparisons, so no clause world permits it: here the clause is a property of the tick law. Injective partners, not the clause alone, keep each record to two readers.

A site may also read its candidates' records before picking. For a posting law F on sites $0, \dots, N-1$ with records finite binary words (Definitions 27.43 and 27.46), the post of x is *on two records at* an assignment r if some site y has $F(x, r') = F(x, r)$ for all r' equal to r at x and y (the locality clause asks for one y for all r).

Proposition 27.49 (Picks that keep each post on two records)**.** *In classical mathematics:*

(a) for three different sites x, c_1x, c_2x, let a test $b(x, r(x), r(c_1x), r(c_2x)) \in \{1, 2\}$ pick c_bx, and let $F(x,r) = G(x, r(x), r(c_bx))$, G any law. The post of x is on two records at every r exactly when, for some map χ from records to $\{1, 2\}$, the tie $G(x, a, d_1) = G(x, a, d_2)$ holds whenever $b(x, a, d_1, d_2) \neq \chi(a)$. If every $G(x, a, \cdot)$ is injective, a tie is $d_1 = d_2$; if $G(x, a, d)$ is the one-letter record of $[\, a = d \,]$ (the comparison), it is $a = d_1 \Leftrightarrow a = d_2$. On sites $0, 1, 2$, with $x = 0$, $c_1x = 1$, $c_2x = 2$, the comparison and the pick of site 1 exactly when $r(1) = r(0)$ leave the post on no two records at some r;

(b) for different sites $c_1, \dots, c_k \neq x$, $k \geq 1$, let $F(x,r) = P(r(x), v)$ with $v_i = r(c_i)$. The post is on two records at every r exactly when for each a some i has $P(a, v) = P(a, w)$ whenever $v_i = w_i$;

(c) let every site x pick $c(x, r(x))$ from its own record and post $F(x,r) = L(x, r(x), r(c(x, r(x))))$, where $L(x, a, d)$ is $G(x, a, d)$ if a test $\mathrm{acc}(x, a, d)$ holds (the site accepts) and $H(x, a)$ if not. At every r each post is on two records; for $y \neq x$ the post of x depends on y at r exactly when $y = c(x, r(x))$ and $L(x, r(x), d) \neq F(x, r)$ for some record d; where $x \mapsto c(x, r(x))$ is injective, at most two posts depend on each site at r, whatever is accepted; and for each site y_0 some such law has, at some r, at most one site accepting and all N posts depending on y_0.

The first two statements of (c) hold with no omniscience principle and no choice principle.

Proof. (a) Given χ, the post is $G(x, r(x), r(c_{\chi(r(x))}x))$, as the values tie where the pick differs from χ. Conversely, fix a, place a, d_1, d_2 at x, c_1x, c_2x, and let $T(d_1, d_2)$ be the post (row d_1, column d_2); so $T(d, d) = G(x, a, d)$. The site kept with x is not both candidates, and changing the other keeps the post, so the row of d_1 or the column of d_2 is constant. If some row is not constant, each column meets it at a point whose row is not, so every column is constant.

Constant rows give $G(x,a,d_1) = T(d_1,d_1) = T(d_1,d_2) = G(x,a,d_2)$ wherever $b = 2$, so $\chi(a) = 1$ serves; constant columns give $\chi(a) = 2$. In the example, the records empty, 1, 0 at sites 0, 1, 2 give the post 0; emptying $r(1)$ makes it 1, as does emptying $r(2)$, and one of the two keeps the record of the site kept with site 0. (b) Given i for $a = r(x)$, the records at x and c_i fix the post. Conversely, fix a; each v has an i that *serves* it: $P(a,w) = P(a,v)$ whenever $w_i = v_i$ (the candidate kept with x, or any i if none is). If $i \neq j$ serve v and w, then $P(a,v) = P(a,u) = P(a,w)$ for u equal to v except $u_j = w_j$. So if $P(a,v) \neq P(a,w)$, one i alone serves both, and also every u, as $P(a,u)$ differs from $P(a,v)$ or $P(a,w)$; if $P(a,\cdot)$ is constant, any i will do. (c) The own record fixes the pick, so it and the picked record fix the post. Changing $r(y)$ alone, $y \neq x$, keeps the pick, so the post stays unless y is the pick, and then becomes $L(x, r(x), d)$ for the new record d. With injective picks only the post of y and the one post that picks y can depend on y. For the hub, every site picks y_0; site z holds 1^z, accepts if its record is the hub's, and posts the hub's record if so and 1 followed by its own if not. Only y_0 accepts; the post of y_0 moves when its record becomes 0, and that of $z \neq y_0$ when the hub's record becomes 1^z, as z then accepts. □

The clause can also carry the golden ratio. On two sites posted in turn, let each post after the third be the partner's current record followed by the site's own, a law that reads only the site and its partner, seeded with 0, 0, 1. Then $R_0 = R_1 = 0$, $R_2 = 1$ and $R_k = R_{k-1}R_{k-2}$ for $k \geq 3$: 10, 101, 10110, ... Write $\#_1 R$ for the number of letters 1, $|R|$ for the length, and $\nu(a + b\varphi) = a^2 + ab - b^2$ for the norm of $\mathbb{Z}[\varphi]$.

Proposition 27.50 (The Fibonacci clause law posts the powers of φ)**.** *In classical mathematics:*

(a) $\#_1 R_n + |R_n|\varphi = \varphi^n$ *in* $\mathbb{Z}[\varphi]$ *and* $\nu(\#_1 R_n + |R_n|\varphi) = (-1)^n$*, for every* $n \geq 1$*;*

(b) $|R_{k+2}|$ *is the number of postings of the* $(k+1)$*st recognition of Definition 21.24, for every* k*;*

(c) $\varphi^n + \varphi^{-n} - 2$*, which is* $2J(\varphi^n)$*, is the integer* $2\#_1 R_n + |R_n| - 2$ *for even* $n \geq 1$ *and* $-|R_n| - 2 + 2|R_n|\varphi = |R_n|\sqrt{5} - 2$ *for odd* n*.*

Proof. (a) $\#_1$ and $|\cdot|$ add over $R_k = R_{k-1}R_{k-2}$, as $\varphi^k = \varphi^{k-1} + \varphi^{k-2}$; for $n = 1, 2$ the values are φ and $1 + \varphi = \varphi^2$. The norm is multiplicative and $\nu(\varphi) = -1$. So $\#_1 R_n = F(n-1)$ and $|R_n| = F(n)$, as $\varphi^n = F(n)\varphi + F(n-1)$ (Section 21.5). (b) $F(k+2)$ is that posting count in Section 21.5. (c) $\varphi^{-1} = -\psi$, so $\varphi^{-n} = (-1)^n\psi^n = (-1)^n(F(n+1) - F(n)\varphi)$; add, and use $2\varphi - 1 = \sqrt{5}$ and $2J(x) = x + x^{-1} - 2$. □

So the locality clause is consistent with everything proved, follows from none of it, is exactly least read, and can be written into a world's rule that no standard world has. It is a named premise of the lattice's gravity sector, in the same position as $\kappa = 1$.

27.10 What reading the cost as the graviton's action needs

The comparison of a geometry with a reference that this chapter began with is *reading one*: for positive definite g_0 and g, $C(g_0, g) = J(g_0^{-1}g)$, J summed over the principal stretches. Reading one is an identification, and we close by stating exactly what it needs. A cost of comparing geometries is *frame-free* when $C(P^{\mathsf{T}}g_0P, P^{\mathsf{T}}gP) = C(g_0, g)$ for every invertible P and all positive definite g_0, g, and *axis-additive* when $C(1, \operatorname{diag}\lambda) = \sum_i J(\lambda_i)$ for all positive λ_i.

On four coordinates with **1** as time, the posting frame is $p_1 = (1,1,-1,-1)$, $p_2 = (1,-1,1,-1)$, $p_3 = (1,-1,-1,1)$, and the two polarizations at the face wave p_1 are $h_+ = p_2 p_2^{\mathsf{T}} - p_3 p_3^{\mathsf{T}}$ and $h_\times = p_2 p_3^{\mathsf{T}} + p_3 p_2^{\mathsf{T}}$. For weights w_k, the *step-class form* is $\sum_S w_{|S|} (\mathbf{1}_S^{\mathsf{T}} H \mathbf{1}_S)^2$, summed over the nonempty sets S of axes.

Proposition 27.51 (The reading is two numbers at one wave)**.** *In classical mathematics:*

(a) a cost is reading one if and only if it is frame-free and axis-additive, and neither property alone suffices;

(b) a quadratic cost $\mathcal{Q}$ of strains with the lattice's symmetry equals J_2 on all TT strains if and only if $\mathcal{Q}(h_+) = 16$ (calibration at the face) and $\mathcal{Q}(h_\times) = \mathcal{Q}(h_+)$ (no birefringence); for the step-class form, this holds exactly when $w_2 = \frac{1}{4}$ and $w_1 + w_3 = 1$, so equal weights fail it, while the per-posting weights $\frac{1}{2}, \frac{1}{4}, \frac{1}{2}$ meet it.

Proof. (a) A positive definite pair is simultaneously diagonalizable: $P^{\mathsf{T}} g_0 P = 1$ and $P^{\mathsf{T}} g P = \operatorname{diag}\lambda$, so frame freedom reduces C to $C(1, \operatorname{diag}\lambda)$, and axis additivity gives $\sum J(\lambda_i) = J(g_0^{-1} g)$. The axis reading $\sum_i J(g_{ii}/(g_0)_{ii})$ is axis-additive and not frame-free; the volume reading $n J(\det(g_0^{-1} g)^{1/n})$ is frame-free and not axis-additive. (b) With $f_a = \frac{1}{2} p_a$, a strain with $H\mathbf{1} = 0$ is $\sum_{a,b} M_{ab} f_a f_b^{\mathsf{T}}$, M symmetric, with $\operatorname{tr} H = \operatorname{tr} M$ and $J_2(H) = \frac{1}{2} \operatorname{tr} M^2$; every TT strain is one with $\operatorname{tr} M = 0$. Exchanging axes 1 and 2, or 1 and 3, exchanges f_1 with f_2, or with f_3, and exchanging 0 with 1 and 2 with 3 negates f_2 and f_3; so relabellings permute the f_a at will and change any two of their signs. Each product of an off-diagonal M_{ab} with another entry is reversed by one of these sign changes, so $\mathcal{Q}$, a quadratic form in the entries M_{ab} ($a \le b$), has none; by the permutations, and as $\sum_{a \ne b} M_{aa} M_{bb} = -\sum_a M_{aa}^2$ when $\operatorname{tr} M = 0$, $\mathcal{Q} = c \sum_a M_{aa}^2 + c' \sum_{a \ne b} M_{ab}^2$ on these strains. Here h_+ has $M = \operatorname{diag}(0,4,-4)$ and $h_\times$ has $M_{23} = M_{32} = 4$, so $\mathcal{Q}(h_+) = 32c$, $\mathcal{Q}(h_\times) = 32c'$ and $J_2(h_+) = J_2(h_\times) = 16$; as both are TT at p_1, $\mathcal{Q} = J_2$ on all TT strains exactly when $\mathcal{Q}(h_+) = \mathcal{Q}(h_\times) = 16$. For the step-class form, $\mathbf{1}_S^{\mathsf{T}} H \mathbf{1}_S$ on the fifteen steps gives $\mathcal{Q}(h_+) = 64 w_2$ and $\mathcal{Q}(h_\times) = 16(w_1 + w_3)$. □

The per-posting weights were selected with the target in view. Each number rests on a premise, through the changes $U \in \mathrm{SU}(2)$ of the coherent record carrier of Section 27.8 or through the per-posting count. The *face frame* $f_0 = \frac{1}{2}\mathbf{1}$, $f_a = \frac{1}{2} p_a$ is orthonormal; for a real 4×4 matrix X put $v_a = f_0^{\mathsf{T}} X f_a$ and $M_{ab} = f_a^{\mathsf{T}} X f_b$ ($a, b = 1, 2, 3$). Let S_U be the rotation with $U \sigma_b U^\dagger = \sum_a (S_U)_{ab} \sigma_a$, $R_U = f_0 f_0^{\mathsf{T}} + \sum_{a,b} (S_U)_{ab} f_a f_b^{\mathsf{T}}$ and $\iota = \frac{1}{2}\mathbf{1}\mathbf{1}^{\mathsf{T}} - 1$. A cost Q of real 4×4 matrices has the *coherent reading* when $Q(R_U^{\mathsf{T}} X R_U) = Q(X)$ for all U and X, and is *quadratic on strains* when $Q(H) = B(H,H)$ for a symmetric bilinear B and all strains H.

Theorem 27.52 (The carrier's changes are exactly the rotations of space that fix time)**.** *In classical mathematics:*

*(a) the R_U are exactly the orthogonal R with $R\mathbf{1} = \mathbf{1}$ and $\det R = 1$; ι is orthogonal, fixes **1** and has determinant -1, and every orthogonal R fixing **1** has $\det R = 1$ or $\det(R\iota) = 1$;*

(b) Q has the coherent reading if and only if $Q(R^{\mathsf{T}} X R) = Q(X)$ for all X and all R as in (a); then $Q(h_\times) = Q(h_+)$;

(c) if Q is quadratic on strains and has the coherent reading, then $Q(R^{\mathsf T}HR) = Q(H)$ for every strain H and every orthogonal R with $R\mathbf{1} = \mathbf{1}$, improper ones included;

(d) the cost $\pi(X) = \det[\,v,\ Mv,\ M^2v\,]$, of degree six, has the coherent reading and $\pi(\iota X\iota) = -\pi(X)$ for every X, and $\pi \neq 0$ on strains.

Proof. With $F = [f_0\ f_1\ f_2\ f_3]$, $R_U = F\,\mathrm{diag}(1, S_U)F^{\mathsf T}$ and $\iota = F\,\mathrm{diag}(1,-1,-1,-1)F^{\mathsf T}$, and every orthogonal R fixing $\mathbf{1}$ is $F\,\mathrm{diag}(1, S)F^{\mathsf T}$ with S orthogonal, $\det S = \det R = \pm 1$. (a) is then the standard fact that $U \mapsto S_U$ maps $\mathrm{SU}(2)$ onto the rotations of $\mathbb{R}^3$ [88]. (b) follows, and the rotation by $\pi/4$ about f_1, $f_2 \mapsto (f_2 + f_3)/\sqrt{2}$, $f_3 \mapsto (f_3 - f_2)/\sqrt{2}$, carries $h_+ = 4(f_2 f_2^{\mathsf T} - f_3 f_3^{\mathsf T})$ to $h_\times = 4(f_2 f_3^{\mathsf T} + f_3 f_2^{\mathsf T})$. (c) It remains to treat ι. Split a strain as $H = E + O$ with $O = \sum_a v_a(f_0 f_a^{\mathsf T} + f_a f_0^{\mathsf T})$; then $\iota H\iota = E - O$ and $Q(H) - Q(\iota H\iota) = 4B(E, O)$. The coherent turns by π and $\pi/2$ about the face axes leave B invariant and reverse each pairing of $f_0 f_a^{\mathsf T} + f_a f_0^{\mathsf T}$ with $f_0 f_0^{\mathsf T}$ or with $f_b f_d^{\mathsf T} + f_d f_b^{\mathsf T}$, so $B(E, O) = 0$. (d) $X \mapsto R^{\mathsf T}XR$ sends $v \mapsto S^{\mathsf T}v$ and $M \mapsto S^{\mathsf T}MS$, so $\pi \mapsto (\det S)\pi$; at a strain with $v = (1,1,1)$ and $M = \mathrm{diag}(1,2,3)$, π is a Vandermonde determinant, 2. □

So for quadratic costs the coherent reading frees the whole posting frame on strains, and π shows that it does not beyond them; we do not prove that six is the least such degree.

The coherent reading is a named premise about frames of the carrier. Let $L_U = \mathrm{diag}(1, S_U)$, so that $UR(p)U^\dagger = R(L_U p)$. As $\sum_i v_i = 2f_0^{\mathsf T}v$ and $(\sum_i v_i u_i)_a = 2f_a^{\mathsf T}v$, $T_1 = DF^{\mathsf T}$ with $D = \mathrm{diag}(2, \frac{2}{\sqrt3}, \frac{2}{\sqrt3}, \frac{2}{\sqrt3})$, so $L_U T_1 = T_1 R_U$; as L_U keeps $\mathscr{K}$, it is a cone identification at $\kappa = 1$ putting posting i at the pure record $UR(T_1 e_i)U^\dagger$ (Theorem 27.39). As $(L_U T_1)^{\mathsf T} X L_U T_1 = R_U^{\mathsf T}(T_1^{\mathsf T} X T_1)R_U$, Q has the coherent reading exactly when the charge $Q(\Lambda^{\mathsf T}X\Lambda)$ of every real 4×4 matrix X is the same in all frames $\Lambda = L_U T_1$, $U \in \mathrm{SU}(2)$. Call Q *quadratic* when $Q(X) = B(X, X)$ for a symmetric bilinear B and every real 4×4 matrix X, *lattice-symmetric* when $Q(X)$ is unchanged by every relabelling $X_{ij} \mapsto X_{\sigma(i)\sigma(j)}$, and say it has *parity* when $Q(\iota X\iota) = Q(X)$ for all X. Under a common relabelling and exchange of the pairs ij, kl, the quadruples $ijkl$ form eleven classes $[ijkl]$, numbered $0, \dots, 10$ by 0000, 0001, 0010, 0011, 0012, 0101, 0102, 0110, 0112, 0121, 0123; put $Q_a(X) = \sum_{ijkl} a_{[ijkl]} X_{ij} X_{kl}$ for $a \in \mathbb{R}^{11}$, $E_2 = a_0 - a_3 - a_5 - a_7 + 2a_{10}$, $E_3 = a_1 - a_2 - a_6 + a_9$ and

$$E_1 = a_0 - 2a_1 - 2a_2 - a_3 + 4a_4 - a_5 + 2a_6 - a_7 + 4a_8 + 2a_9 - 6a_{10}.$$

Let $s_\pm = \mathbf{1}p_1^{\mathsf T} \pm p_1\mathbf{1}^{\mathsf T}$, and let R_* fix f_0, f_1 and send $f_2 \mapsto (f_2 + f_3)/\sqrt{2}$, $f_3 \mapsto (f_3 - f_2)/\sqrt{2}$.

Proposition 27.53 (What the coherent reading adds: three linear numbers)**.** *In classical mathematics:*

(a) Every quadratic lattice-symmetric Q is a Q_a, and for it these are equivalent: the coherent reading; $Q(R_*^{\mathsf T}XR_*) = Q(X)$ for all X; $Q(R^{\mathsf T}XR) = Q(X)$ for all X and all orthogonal R with $R\mathbf{1} = \mathbf{1}$; the three numbers $Q(h_\times) = Q(h_+)$, $Q(s_+ + h_\times) = Q(s_+ - h_\times)$, $Q(s_- + h_\times) = Q(s_- - h_\times)$; $E_1 = E_2 = E_3 = 0$; parity with $Q(h_\times) = Q(h_+)$. Parity is equivalent to the last two numbers, and if $Q(X) = Q(\Pi_{\mathbf{1}} X \Pi_{\mathbf{1}})$ for all X, the coherent reading is equivalent to $Q(h_\times) = Q(h_+)$.

(b) Q_a with $a_4 = 1$, the step-class form with $w_1, \dots, w_4 = \frac12, \frac14, \frac12, 0$, and Q_a with $a_2 = 1$, $a_4 = \frac12$ (other $a_m = 0$) fail exactly the first, the second and the third number.

(c) A step-class form has the coherent reading exactly when $w_1 = 3w_3$ and $w_1 + w_3 = 4w_2$. The weights $\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}$ and $\frac{1}{2}, \frac{1}{4}, \frac{1}{2}, 0$ give nonnegative forms with $Q(h_+) = 16$, the second equal to J_2 on all TT strains, and neither has the coherent reading, so each charges some matrix differently in two frames $L_U T_1$; $\frac{3}{4}, \frac{1}{4}, \frac{1}{4}, 0$ gives both.

Proof. (a) $B(X,Y) = \frac{1}{4}(Q(X+Y) - Q(X-Y))$ inherits both symmetries, so its coefficient of $X_{ij}Y_{kl}$ depends only on $[ijkl]$. Summing 256 terms, $Q_a(h_\times) - Q_a(h_+) = 16E_1$, $Q_a(s_+ + h_\times) - Q_a(s_+ - h_\times) = 64E_2$, $Q_a(s_- + h_\times) - Q_a(s_- - h_\times) = -128E_3$. R_* is an R_U (Theorem 27.52(a)), $R_* h_+ R_*^{\mathsf{T}} = h_\times$, R_*^2 fixes $s_\pm$ and turns $h_\times$ into $-h_\times$, and ι fixes $h_\times$ and turns $s_\pm$ into $-s_\pm$; so the coherent reading gives invariance under R_*, which gives the numbers, and parity gives the last two. The zeros of E_2, E_3 form a space of dimension 9 spanned by $\frac{1}{16}\sum_a (p_a^{\mathsf{T}} X p_a)^2$ ($a_m = \frac{3}{16}$ for $m = 0, 3, 5, 7, 10$, otherwise $-\frac{1}{16}$; $E_1 = -2$) and eight forms with $E_1 = 0$: $(\mathbf{1}^{\mathsf{T}} X \mathbf{1})^2$ (all $a_m = 1$), $(\mathbf{1}^{\mathsf{T}} X \mathbf{1}) \operatorname{tr} X$ ($a_0 = a_3 = 1$, $a_1 = a_2 = a_4 = \frac{1}{2}$), $(\operatorname{tr} X)^2$, $\operatorname{tr} X^2$, $\operatorname{tr} X^{\mathsf{T}} X$ ($a_0 = 1$ and $a_3, a_7, a_5 = 1$ respectively), $|X\mathbf{1}|^2$, $|X^{\mathsf{T}}\mathbf{1}|^2$ ($a_0 = a_5 = 1$ and $a_1 = a_6 = 1$, $a_2 = a_9 = 1$ respectively), $(X\mathbf{1}) \cdot (X^{\mathsf{T}}\mathbf{1})$ ($a_0 = a_7 = 1$, $a_1 = a_2 = a_8 = \frac{1}{2}$); other coefficients are 0. They are independent (in a vanishing combination $a_{10}, a_4, a_6, a_9, a_8$ remove the first, second, sixth, seventh, eighth in turn, and a_3, a_7, a_5 the rest), and are unchanged by every orthogonal R with $R\mathbf{1} = \mathbf{1}$: so the numbers give frame freedom, hence the coherent reading. All nine have parity, and $\Pi_{\mathbf{1}} \iota = -\Pi_{\mathbf{1}}$. (b) (E_1, E_2, E_3) is $(4, 0, 0)$ and $(0, 0, -1)$ for the two Q_a. (c) A step-class form depends only on $X + X^{\mathsf{T}}$, which gives the third number; $Q(h_+) = 64w_2$, $Q(h_\times) = 16(w_1 + w_3)$ (Proposition 27.54). With $(p_a)_S = p_a^{\mathsf{T}} \mathbf{1}_S$, $\mathbf{1}_S^{\mathsf{T}} s_+ \mathbf{1}_S = 2|S|(p_1)_S$ and $\mathbf{1}_S^{\mathsf{T}} h_\times \mathbf{1}_S = 2(p_2)_S(p_3)_S$; as $(p_1)_i(p_2)_i(p_3)_i = 1$, a double step has one nonzero $(p_a)_S$ and $(p_a)_S = 0$ at $|S| = 4$, $Q(s_+ + h_\times) - Q(s_+ - h_\times) = 64(w_1 - 3w_3)$. Apply (a) and Proposition 27.51(b). □

On the per-posting route a step S, $0 < |S| < 4$, is charged $\frac{1}{2}u^2$ on each of $c(|S|)$ postings, with shares u summing to $\mathbf{1}_S^{\mathsf{T}} H \mathbf{1}_S$; even shares give $w_k = 1/(2c(k))$. The four *count rules* are $(c(1), c(2), c(3))$ with $c(2) = 2$ and $c(1), c(3) \in \{1, 3\}$: the *fewest* $(1, 2, 1)$, forward $(1, 2, 3)$, reversed $(3, 2, 1)$ and longest $(3, 2, 3)$. Read each counter as an account's signed balance (an identification), a posting being a debit $+1$ or a credit -1 on one account. A word of postings with $t \in \mathbb{Z}$ ticks *realizes* S when its balance plus $t\mathbf{1}$ is $\mathbf{1}_S$; the *tick-free count* of S is the least length of a realizing word, and the *tick-posted count* the least of the length plus $4|t|$. The named premise *tick-free least postings* for c says that $c(|S|)$ is the tick-free count of every S with $0 < |S| < 4$. With $E_a = f_a f_a^{\mathsf{T}}$, a cost Q is *axis-calibrated* when $Q(\mu E_a) = \frac{1}{2}\mu^2$, has *independent axes* when $Q(E_a + E_b) = Q(E_a) + Q(E_b)$ for $a \neq b$, and is *face-axis additive* when $Q(\sum_a \mu_a E_a) = \frac{1}{2}\sum_a \mu_a^2$.

Proposition 27.54 (What the count and the face calibration rest on)**.** *In classical mathematics:*

(a) a share rule unchanged by relabelling the counters is even inside each step and even outside it, and m shares with sum s cost at least $s^2/(2m)$, with equality exactly at equal shares;

(b) every count rule has the face calibration, and no birefringence holds exactly for the fewest count; least charge picks the longest count, which is birefringent, as are equal weights;

(c) for $0 < |S| = k < 4$ the tick-free count of S is $\min(k, 4-k)$, as for its complement, and the tick-posted count is k; tick-free least postings holds for the fewest count, forces it, and then gives the per-posting form and both numbers, while the forward count fails it;

(d) for Q quadratic on strains: Q is face-axis additive exactly when it is axis-calibrated with independent axes; if it is axis-calibrated, $Q(h_+) = 16$ exactly when $Q(E_2 + E_3) = Q(E_2) + Q(E_3)$, and under the coherent reading exactly when it is face-axis additive; every cost $(\frac{1}{2} - \alpha)\operatorname{tr} M^2 + \alpha(\operatorname{tr} M)^2$ has the coherent reading, is quadratic on strains and axis-calibrated, and has independent axes only at $\alpha = 0$.

Proof. (a) A transposition of two counters both in S, or both outside it, fixes S; and $\sum_i \frac{1}{2}u_i^2 - s^2/(2m) = \frac{1}{2}\sum_i (u_i - s/m)^2$. (b) Number the counters 1 to 4. Only the double steps $\{1,3\}$, $\{1,4\}$, $\{2,3\}$, $\{2,4\}$ strain h_+, by ± 4, and only the single and triple steps strain $h_\times$, by ± 2; so $Q(h_+) = 64w_2 = 16$, while $Q(h_\times) = 16(w_1 + w_3)$ is 16, $\frac{32}{3}$, $\frac{32}{3}$, $\frac{16}{3}$ for the fewest, forward, reversed and longest counts. Least charge minimizes $s^2/(2c)$, so takes $c = 3$. (c) A word is at least as long as $\sum_i |b_i|$ for its balance b, which $|b_i|$ postings on each account attain; with t ticks the balance is $\mathbf{1}_S - t\mathbf{1}$, which needs $k|1-t| + (4-k)|t|$ postings, least at $t = 0$ or $t = 1$, and adding $4|t|$ makes $t = 0$ best. Exchanging debits with credits and t with $1-t$ maps the realizations of S to those of its complement. Then apply (b). (d) $Q(\sum_a \mu_a E_a) = \sum_a \mu_a^2 Q(E_a) + 2\sum_{a<b} \mu_a \mu_b B(E_a, E_b)$, and $Q(h_+) = Q(4E_2 - 4E_3) = 16 - 32B(E_2, E_3)$ for an axis-calibrated Q; the coherent turns by $\pi/2$ about the face axes carry $\{E_2, E_3\}$ to every other pair. The family depends only on $\operatorname{tr} M$ and $\operatorname{tr} M^2$ and charges $1 + 2\alpha$ for $E_a + E_b$. □

A count rule comes from how the ledger writes a step (writing each step by a least writing is an identification, as are the credit conditions of (d)). A *writing* of S is a list of postings (a debit $+1$ or a credit -1 on one counter) and *ticks* (one event adding 1 to every counter) with net change $\mathbf{1}_S$. A *charge* prices events, a writing costs the sum, and a *least writing* of S costs no more than any writing of S. A charge *reads off* c when for every S with $0 < |S| < 4$ least writings exist and all have $c(|S|)$ postings, and has *prices* $p_\mathrm{d}, p_\mathrm{c}, q$ when debits cost p_d, credits p_c and the tick q. The *comparison charge* of a change $\Delta \in \mathbb{R}^4$ is $\sum_{i,j} J(e^{\Delta_i - \Delta_j})$ over ordered pairs; the *retained-count charge* of an event is $\sum_i (J(e^{\delta_i}) + J(e^{\gamma_i}))$, δ_i, γ_i the changes of account i's debit and credit counts, a tick being one debit on each account.

Proposition 27.55 (The price of the tick decides the count)**.** *In classical mathematics:*

(a) for prices $p_\mathrm{d}, p_\mathrm{c} > 0$, $q \geq 0$ and $0 < |S| = k < 4$, least writings of S exist; all have k postings if $p_\mathrm{d} k < p_\mathrm{c}(4-k) + q$, all $4-k$ if $p_\mathrm{c}(4-k) + q < p_\mathrm{d} k$, and some of each at equality. A rule read off it satisfies tick-free least postings exactly when $p_\mathrm{c} + q < 3p_\mathrm{d}$ and $p_\mathrm{d} < 3p_\mathrm{c} + q$;

(b) if $p_\mathrm{d} = p_\mathrm{c} = p > 0$ and $q \geq 0$, the charge reads off the fewest count when $q < 2p$, the forward count when $q > 2p$, and no rule when $q = 2p$;

(c) the comparison charge has prices $6J(e)$, $6J(e)$, 0 and reads off the fewest count, and each such rule satisfies tick-free least postings, has the per-posting form and meets both numbers of Proposition 27.51(b); the retained-count charge has prices $J(e)$, $J(e)$, $4J(e)$ and reads off the forward count, and each such rule fails tick-free least postings and is birefringent;

(d) for a counter a and $\nu \in \mathbb{R}^4$ with $\sum_j \nu_j = 1$ and $(\mathbf{1}_{\{a\}})_i - (\mathbf{1}_{\{a\}})_j + \nu_i - \nu_j = 0$ for all i, j, $\nu = \frac{1}{2}\mathbf{1} - \mathbf{1}_{\{a\}}$; this antipode meets both conditions, $\mathbf{1}_{\{a\}} + \nu = \frac{1}{2}\mathbf{1}$, ν has the differences of the credit $-\mathbf{1}_{\{a\}}$, and the comparison charge is $6J(e)$ at ν and at $\mathbf{1}_{\{a\}}$, 0 at constants.

Proof. (a) A writing with t ticks needs $|(\mathbf{1}_S)_i - t|$ debits or credits on counter i, and more postings cost more, so its least charge is $p_d k$ for $t = 0$, $p_c(4-k)+q$ for $t = 1$, and $p_c(4t-k)+qt$, larger by $(t-1)(4p_c+q)$, for $t \geq 2$: the least writings are the k debits on S or the tick with the $4-k$ credits off S, whichever costs less. Then $c(2) = 2$, $c(1) = 1$ exactly when $p_d < 3p_c + q$, $c(3) = 1$ exactly when $p_c + q < 3p_d$, and tick-free least postings is $c = (1, 2, 1)$ (Proposition 27.54(c)). (b) At $k = 1$, $p < 3p + q$; at $k = 3$ compare $3p$ with $p + q$. (c) A posting on a changes six comparisons by $e^{\pm 1}$, and $J(x) = J(1/x)$; a tick changes none, and $J(1) = 0$. A posting changes one count by one, a tick four. $J(e) = \cosh 1 - 1 > 0$. Apply (b) and Proposition 27.54(b),(c). (d) The condition at (a, j) gives $v_j = v_a + 1$ for $j \neq a$, and the sum $4v_a + 3 = 1$; the rest is direct. □

Independent axes rest on a named statistical premise. A *law* (of probabilities) is $\varpi \in \mathbb{R}^4$ with all $\varpi_i > 0$ and $\sum_i \varpi_i = 1$; the *face bit* a of posting i is $(p_a)_i = \pm 1$, the ath coordinate of u_i. The state $R(1, \vec{r})$ gives the law $\varpi_i(\vec{r}) = \frac{1}{2}\langle T_1 e_i, (1, \vec{r})\rangle = \frac{1}{4}(1 + \vec{r}\cdot u_i/\sqrt{3})$; $\varpi(\vec{0})$ is the *uniform law*. For $\mu \in \mathbb{R}^3$ and a gain γ, $\delta = \frac{\gamma}{4}\sum_a \mu_a p_a$ moves the mean of face bit b by $\gamma\mu_b$; as $J(1+x) = x^2/(2(1+x))$, its charge $\frac{1}{2}\sum_i \delta_i^2/\varpi_i$ is the limit of $\varepsilon^{-2}\sum_i \varpi_i J(1 + \varepsilon\delta_i/\varpi_i)$. A cost Q has the *statistical face reading* at (ϖ, γ) when $Q(\sum_a \mu_a E_a) = \frac{1}{2}\sum_i \delta_i^2/\varpi_i$ for every μ.

Proposition 27.56 (Independent axes are the uniform law of the face bits)**.** *In classical mathematics:*

(a) Under $\varpi(\vec{r})$ face bit a has mean $r_a/\sqrt{3}$, for every $\vec{r}$. The uniform law is the only law unchanged by relabelling the postings, and under it any two face bits are independent.

(b) If Q has the statistical face reading at (ϖ, γ), then $Q(E_a+E_b) - Q(E_a) - Q(E_b) = \frac{\gamma^2}{16}\sum_i (p_c)_i/\varpi_i$ for $\{a, b, c\} = \{1, 2, 3\}$. So if $\gamma \neq 0$, Q has independent axes exactly when ϖ is uniform; if $\varpi = \varpi(u_1/\sqrt{3}) = (\frac{1}{2}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6})$, the law of the pure record $R(T_1 e_1)$, every such cross term is $-\gamma^2/4$.

Proof. (a) $\sum_i (p_a)_i = 0$ and $p_a \cdot p_b = 4\delta_{ab}$. A law unchanged by relabelling is constant. For $a \neq b$ the pairs $((p_a)_i, (p_b)_i)$ are the four sign pairs once each. (b) As $(p_a)_i^2 = 1$ and $(p_1)_i(p_2)_i(p_3)_i = 1$,

$$Q\Big(\sum_a \mu_a E_a\Big) = \frac{\gamma^2}{32}\sum_i \frac{(\sum_a \mu_a (p_a)_i)^2}{\varpi_i} = \frac{\gamma^2}{32}\Big(\sum_a \mu_a^2 \sum_i \frac{1}{\varpi_i} + 2\sum_{a<b} \mu_a\mu_b \sum_i \frac{(p_c)_i}{\varpi_i}\Big);$$

the cross terms vanish exactly when $(1/\varpi_i)_i$ is orthogonal to p_1, p_2, p_3, a multiple of $\mathbf{1}$, so ϖ is uniform. At $(\frac{1}{2}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6})$, $\sum_i (p_c)_i/\varpi_i = 2 - 6$. □

So the face bits read the complementary components $\sigma_1, \sigma_2, \sigma_3$, as $\mathrm{tr}(R(1, \vec{r})\sigma_a) = r_a$, but complementarity alone does not give independent axes.

Two more facts locate the remaining premise. A local lattice cost (Definition 27.9) is *one-contact* when each offset $p_j - q_j$ is a Kuhn step $\mathbf{1}_S$, as for an additive law of posting events that each read one record and one a step away; its coefficients are *bilinear tables* when $c_j(H_0, H_1) = \sum T_{abcd}(H_0)_{ab}(H_1)_{cd}$.

Proposition 27.57 (Locality is the premise; reading one is J_2 at quadratic order only)**.** *In classical mathematics:*

(a) every local lattice cost with bilinear-table coefficients has, on all pairs of matrices and at all waves, the long-wave symbol of a one-contact local cost with bilinear-table coefficients of either sign;

(b) if $1+\varepsilon X$ is invertible, then $J(1+\varepsilon X) = \varepsilon^2 J_2(X) - \frac{1}{2}\varepsilon^3 \operatorname{tr} X^3 + \frac{1}{2}\varepsilon^4 \operatorname{tr}(X^4(1+\varepsilon X)^{-1})$, and $\operatorname{tr} H^3 = 0$ for every strain H that is TT at a wave not a multiple of $\mathbf{1}$.

Proof. (a) The long-wave symbol is $\sum_{e,f} g_{ef} K_e K_f$ with bilinear tables g_{ef}; $K_e^2 = (K\cdot \mathbf{1}_{\{e\}})^2$ and $2K_eK_f = (K\cdot\mathbf{1}_{\{e,f\}})^2 - K_e^2 - K_f^2$, and a table g times $(K\cdot\mathbf{1}_S)^2$ is one term at the offset $\mathbf{1}_S$ with coefficient $-2g$. (b) Expand $(1+\varepsilon X)^{-1}$ one order further than in Theorem 27.2. A TT strain is $\sum_{a,b} M_{ab} f_a f_b^{\mathsf T}$ with M traceless and singular, and $\operatorname{tr} M^3 = 3\det M$ for traceless 3×3 matrices. □

So the premise that selects the Fierz–Pauli trace coefficient (Theorem 27.12(d)) is locality, and that the ledger's charge is local is not derived. At cubic order reading one parts from the static form $V(h_1,h_2,h_3) = -\frac{1}{4}\sum k_b^{\mathsf T} h_a h_b h_c k_b$, summed like reading one's cubic term $-\frac{1}{2}\sum \operatorname{tr}(h_a h_b h_c)$ over the six orderings (a,b,c) of three legs. Take the space waves $k_1=(1,0,0)$, $k_2=(0,1,0)$, $k_3=(-1,-1,0)$ and the transverse-traceless legs $h_1^+ = \operatorname{diag}(0,1,-1)$, $h_2^+ = \operatorname{diag}(1,0,-1)$, $h_3^+ = \left(\begin{smallmatrix} 1 & -1 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & -2 \end{smallmatrix}\right)$, $h_2^\times = \left(\begin{smallmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{smallmatrix}\right)$ and $h_3^\times = \left(\begin{smallmatrix} 0 & 0 & 1 \\ 0 & 0 & -1 \\ 1 & -1 & 0 \end{smallmatrix}\right)$. On (h_1^+,h_2^+,h_3^+), V is $\frac{1}{2}$ and reading one is 6; on $(h_1^+,h_2^\times,h_3^\times)$ they are 1 and 3. The ratios $\frac{1}{12}$ and $\frac{1}{3}$ differ, so no constant turns one form into the other. That V is the static cubic vertex of Einstein's action, the coefficient of $\mu_1\mu_2\mu_3$ in $\sqrt{\gamma}\,R(\gamma)$ for the spatial metric $\gamma = 1 + \sum_a \mu_a h_a e^{ik_a\cdot x}$, rests on an expansion we do not reproduce, and we do not claim it; read with it, reading one matches Einstein's graviton at quadratic order only. The coherent reading (three linear numbers, Proposition 27.53), independent axes (the statistical face reading at the uniform law, Proposition 27.56), the per-posting charge, tick-free least postings (a tick cheaper than two postings, Proposition 27.55) and locality (a depth bound or an order of limits, Theorem 27.13) are named premises, each sharpened here and none derived; the preprint [95] develops linear gravity on them, and Section 27.16 states where each premise stands.

27.11 Regge's action is one half of Einstein's through quartic order

The earlier sections compared Regge's action with linearized gravity: its Hessian is the Fierz–Pauli form at long wavelength (Proposition 27.21, Theorem 27.30). Gravity is not linear. A graviton scatters off a graviton through the cubic and quartic terms of the action, and those terms decide whether a lattice action is Einstein's theory or only shares its propagator. So the question here is the next one: are the cubic and quartic long-wave vertices of Regge's action on the Kuhn lattice those of $\sqrt{|g|}\,R$?

They are, each with the factor $\frac{1}{2}$, the same at every order. On every Euclidean background g_κ, $\kappa < \frac{1}{4}$, this holds with Regge's own derivatives at quadratic, cubic and quartic order; on the

Lorentzian backgrounds it holds for the continued tables; and the identities of the tables hold on every background g_κ off three degenerate values. The full treatment is the preprint [196] (Zenodo, 2026), and the tables, with programs that check the identities exactly, are the data set [210]; this section states the results, proves the steps that fit on a page, and describes the finite computations that close the rest. Everything here is proved in classical mathematics: the identities are identities of polynomials and rational functions over a field, and the derivatives are derivatives of real functions.

Definition 27.58 (Tables, long-wave vertices and Einstein's vertices)**.**

1. A *table* of degree n is a homogeneous polynomial $T(\lambda)$ of degree n in the ten slot variables $\lambda = (\lambda_f)$ of one Kuhn simplex (slots as in Definition 27.19). For n plane waves $H_i e^{iK_i\cdot x}$ with H_i symmetric, the Taylor amplitudes $a^i_{\sigma,m}(f) = (s_f^{\mathsf T} H_i s_f)(K_i\cdot x_f)^m/m!$ are those of Definition 27.23, and $\hat T(b_1,\dots,b_n)$ is the coefficient of $\epsilon_1\cdots\epsilon_n$ in $T(\epsilon_1 b_1+\cdots+\epsilon_n b_n)$. The *long-wave vertex* of T is

$$\mathscr{V}[T](H;K) = \frac{1}{n!}\sum_{m_1+\cdots+m_n=2}\ \sum_{\sigma}\hat T\big(a^1_{\sigma,m_1},\dots,a^n_{\sigma,m_n}\big),$$

   summed over the 24 simplices and the ways of putting two momentum factors on the legs. For $n=3$ it is the vertex V_T of Definition 27.23.

2. For a density $\mathscr{L}(g,\partial g,\partial\partial g)$ and a constant symmetric g_0, the *vertex* $V_n[\mathscr{L}](H;K)$ is the coefficient of $\epsilon_1\cdots\epsilon_n$ in $\mathscr{L}$ at the metric $g = g_0+\sum_i \epsilon_i H_i e^{iK_i\cdot x}$; when $K_1+\cdots+K_n=0$ it does not depend on x.

3. With $\Gamma_{e,ab} = \tfrac12(\partial_a g_{eb}+\partial_b g_{ea}-\partial_e g_{ab})$, *Einstein's first-order Lagrangian* is

$$\mathscr{L}_{\Gamma\Gamma} = \sqrt{|\det g|}\; g^{ab}g^{ce}g^{df}\big(\Gamma_{e,ad}\Gamma_{f,bc}-\Gamma_{e,ab}\Gamma_{f,cd}\big),$$

   and *Einstein's vertices* on the background with inverse metric $\gamma = g_0^{-1}$ are $W_n(\gamma;H;K) = V_n[\mathscr{L}_{\Gamma\Gamma}](H;K)/\sqrt{|\det g_0|}$.

4. Let Ψ be the *simplex function*, the share $\sum_t A_t(\theta_t-\theta_t^0)$ of one Kuhn simplex, so that Regge's action near the flat lattice is $-\sum_\sigma \Psi_\sigma$, and let ℓ_κ be the squared edge lengths of the Kuhn simplex at g_κ. For $\kappa<\frac14$, $n=2,3,4$ and $\lambda\in\mathbb{R}^{10}$ the *Regge tables* of the background g_κ are

$$T_n(\kappa;\lambda) = (1-4\kappa)^{-1/2}\,\frac{d^n}{dr^n}\Psi(\ell_\kappa+r\lambda)\Big|_{r=0}.$$

   By Theorem 27.59 each $T_n(\kappa)$ is a table of degree n whose coefficients are rational functions of κ: $T_2(\kappa;\lambda) = -\lambda^{\mathsf T}R(\kappa)\lambda$, with $R(\kappa)$ the rational family of Theorem 27.28; the coefficients of $T_3(\kappa)$ have poles only at $\frac14,\frac13,\frac12$, and $T_3(0)=r$, the form of Table 27.2; and the coefficients of $T_4(\kappa)$ are $N_\mu(\kappa)/D(\kappa)$ with integer polynomials N_μ and

$$D(\kappa) = 1536\,(2\kappa-1)^3(3\kappa-1)^3(4\kappa-1)^3.$$

   At every other real or complex κ off these poles, $T_n(\kappa)$ is the table of the continued rational functions, which is unique. The coefficients of T_2, T_3 and T_4 are listed in the data set [210].

The vertex of a density is an actual coefficient of the action: one cell of the lattice and one unit of coordinate volume are the same region, and a vertex with two derivatives is of second order in the momenta. For a lattice action whose simplex shares are $-\Psi_\sigma$, the part of second order in the momenta of the $\epsilon_1 \cdots \epsilon_n$ coefficient of one cell is $\mathscr{V}[Q_n]$ when the share's part of order n is $-Q_n/n!$. So the vertices of Regge's action are those of the tables once the tables, which are defined from its derivatives, are known to be the rational tables described above. That is the first theorem.

Theorem 27.59 (Regge's derivatives on every Euclidean background)**.** *In classical mathematics, for every $\kappa < \frac{1}{4}$, every direction $\lambda \in \mathbb{R}^{10}$ and $n = 2, 3, 4$,*

$$\frac{d^n}{dr^n}\Psi(\ell_\kappa + r\lambda)\Big|_{r=0} = \sqrt{1-4\kappa}\; T_n(\kappa;\lambda),$$

where $T_n(\kappa;\lambda)$ is a homogeneous polynomial of degree n in λ whose coefficients are rational functions of κ: $T_2(\kappa;\lambda) = -\lambda^{\mathsf{T}} R(\kappa)\lambda$; the coefficients of T_3 have poles only at $\frac{1}{4}, \frac{1}{3}, \frac{1}{2}$, and $T_3(0) = r$; and the coefficients of T_4 are $N_\mu(\kappa)/D(\kappa)$ with integer polynomials N_μ.

Conditions and scope.

Base and premises

The Kuhn simplex at the Euclidean backgrounds g_κ, $\kappa < \frac{1}{4}$; classical real numbers.

Conclusion

The three tables are Regge's own second, third and fourth derivatives, with the volume factor $\sqrt{\det g_\kappa}$ in front, on every Euclidean member of the family. With Definition 27.58 the long-wave vertices of Regge's action at g_κ are $V_n[S_{\mathrm{R}}] = \sqrt{\det g_\kappa}\,\mathscr{V}[T_n(\kappa)]$.

Exact computation

The third- and fourth-order identities are long polynomial identities, checked by exact computation as the proof describes and not reproduced here; the coefficients of $T_3(\kappa)$ and $T_4(\kappa)$ as rational functions of κ, and programs that check the identities exactly, are in the data set [210].

Not claimed

True derivatives for $\kappa > \frac{1}{4}$, where the angles are Lorentzian; there the tables are continued as rational functions.

Proof. For $n = 2$ this is Theorem 27.29, since $S = -\Psi$ there and $\Psi'' = \sum_t A_t'\theta_t'$. For $n = 3$ and $n = 4$ the route is the same, carried further. Schläfli's identity (Theorem 27.27) gives $\Psi' = \sum_t A_t'(\theta_t - \theta_t^0)$ along every line, and differentiating it again,

$$\Psi'' = \sum_t A_t'\theta_t', \qquad \Psi''' = \sum_t \big(2A_t''\theta_t' + A_t'\theta_t''\big), \qquad \Psi^{(4)} = \sum_t \big(3A_t'''\theta_t' + 3A_t''\theta_t'' + A_t'\theta_t'''\big)$$

at $r = 0$, where the angles' flat values drop out. Each derivative of an area or an angle comes from the Gram algebra of Theorem 27.26: rational functions of κ and λ times the square roots $\sqrt{Q_t}$ and $\sqrt{W_{ll}W_{mm} - W_{lm}^2}$, and by part (c) of that theorem every product above carries the square roots in pairs that reduce to one factor $\sqrt{1-4\kappa}$. So each identity, cleared

of denominators, is a polynomial identity in κ and the ten λ_f, one per triangle. At third order the ten triangles give an exact computation of moderate size. At fourth order the reversal of the simplex's vertex order maps four of the ten triangles onto four others, so six identities remain; each expands, after clearing denominators, into a polynomial in eleven variables whose verification by exact computation takes between one and one and a half million monomial merges, and all six vanish identically. □

The second step moves from Einstein's first-order Lagrangian to $\sqrt{|g|}\,R$ itself.

Theorem 27.60 (The vertices of $\sqrt{|g|}\,R$ are Einstein's first-order vertices)**.** *In classical mathematics, let $\sigma \in \{1,-1\}$ and let g_0 be a symmetric 4×4 real matrix with $\sigma \det g_0 > 0$, $\gamma = g_0^{-1}$. For symmetric H_i and momenta with $\sum_i K_i = 0$, and $n = 2,3,4$,*

$$V_n\big[\sqrt{\sigma \det g}\,R\big](H;K) = \sqrt{\sigma \det g_0}\; W_n(\gamma;H;K),$$

and $W_2(\gamma;X,X';k,-k) = -\frac{1}{2}\mathrm{FP}_\gamma(k;X,X')$, with FP_S the form of Section 27.2. In particular, for every $\kappa < \frac{1}{4}$ the quartic vertex of $\sqrt{\det g}\,R$ around g_κ is $\sqrt{1-4\kappa}\,W_4(g_\kappa^{-1})$, and around g_1 the vertices of $\sqrt{-\det g}\,R$ are $\sqrt{3}\,W_n(g_1^{-1})$.

Proof. Three links. First, the classical identity $\sqrt{|g|}\,R = \mathscr{L}_{\Gamma\Gamma} + \partial_c\big(\sqrt{|g|}\,Y^c\big)$ with $Y^c = g^{bd}\Gamma^c_{bd} - g^{bc}\Gamma^a_{ba}$ [200, §93], which holds over every commutative ring with derivations once $\partial g^{-1} = -g^{-1}(\partial g)g^{-1}$ and Jacobi's formula $\partial\sqrt{|g|} = \sqrt{|g|}\,\Gamma^e_{ec}$ are supplied. Second, on plane waves the derivative ∂_c acts on the coefficient of $\epsilon_1\cdots\epsilon_n$ as multiplication by $i\sum_i K_{i,c}$, so a total derivative has no vertex when the momenta sum to zero. Third, the vertex is the top coefficient of the density in the ring $\mathbb{R}[\epsilon_1,\dots,\epsilon_n]/(\epsilon_1^2,\dots,\epsilon_n^2)$ with $g = g_0 + \sum \epsilon_i H_i$, $\partial_c g = \sum \epsilon_i\, iK_{i,c}H_i$: the map that sends a smooth function to this jet is a ring homomorphism, it sends $\sqrt{\sigma\det g}$ to a square root of $\sigma\det g$ and g^{-1} to the inverse, and so the mixed derivative is computed inside that ring. The quadratic case is a direct expansion of $\mathscr{L}_{\Gamma\Gamma}$ to second order; for the two backgrounds use $\det g_\kappa = 1-4\kappa$ (Theorem 27.26(a)). □

Theorem 27.61 (Regge's tables are one half of Einstein's through quartic order)**.** *In classical mathematics:*

(a) Quartic, every background. *Let F be a field of characteristic zero and $\kappa \in F$ with $(2\kappa-1)(3\kappa-1)(4\kappa-1)\neq 0$. For all symmetric $H_1,\dots,H_4$ over F and all $K_1,\dots,K_4 \in F^4$ with $K_1+\cdots+K_4 = 0$,*

$$\mathscr{V}[T_4(\kappa)](H;K) = \tfrac{1}{2}\,W_4\big(g_\kappa^{-1};H;K\big), \qquad g_\kappa^{-1} = 1 + \tfrac{\kappa}{1-4\kappa}\mathbf{1}\mathbf{1}^{\mathsf T}.$$

(b) Cubic, every background. *For every real κ with $(2\kappa-1)(3\kappa-1)(4\kappa-1)\neq 0$, all complex symmetric H_1,H_2,H_3 and all $K_1,K_2,K_3 \in \mathbb{C}^4$ with $K_1+K_2+K_3 = 0$, $\mathscr{V}[T_3(\kappa)](H;K) = \frac{1}{2}W_3(g_\kappa^{-1};H;K)$; in particular $\mathscr{V}[T_3(0)] = \frac{1}{2}W_3(1)$ and $\mathscr{V}[T_3(1)] = \frac{1}{2}W_3(g_1^{-1})$, with $g_1^{-1} = 1 - \frac{1}{3}\mathbf{1}\mathbf{1}^{\mathsf T}$.*

(c) Quadratic, every background. *For every real κ with $(2\kappa-1)(3\kappa-1)(4\kappa-1)\neq 0$ and all complex symmetric X, X' and $P \in \mathbb{C}^4$, $\mathscr{V}[T_2(\kappa)](X,X';P,-P) = -\frac{1}{4}\mathrm{FP}_{g_\kappa^{-1}}(P;X,X')$, which is $\frac{1}{2}W_2(g_\kappa^{-1})$.*

Conditions and scope.

Base and premises
The Kuhn simplex and its tables; classical algebra over a field. Part (a) holds over $\mathbb{Q}(\kappa)$, $\mathbb{R}$ and $\mathbb{C}$, so for complex momenta too; parts (b) and (c) hold at every real κ off the poles, for complex legs.

Conclusion
At every order through four, on every background g_κ off the poles, the long-wave vertex of the lattice tables is one half of Einstein's. With Theorems 27.59 and 27.60, Regge's action on the Kuhn lattice is $\frac{1}{2}\int \sqrt{g}\,R$ through quartic order at long wavelength around every Euclidean background g_κ, $\kappa < \frac{1}{4}$ (Corollary 27.62).

Exact computation
Each part ends in a finite computation that the proof describes and does not reproduce: for (a), fifty-three comparisons of integers of about 200,000 digits; for (b), polynomial identities in κ and the eight free momentum components on the 20 representative triples of basis matrices; for (c), the same on the 100 ordered pairs. The tables are part S1 of the data set [210]; its parts S4 and S3 hold programs that check the identities of (a) on the fifty-three representatives, and those of (b) and (c) with κ kept as a variable, exactly.

Identification
The midpoint rule that turns a metric wave into edge lengths, $d^{\mathsf{T}} H d\, e^{iK\cdot(y+d/2)}$, and Regge's action as the gravitational action.

Not claimed
The metric's five missing edge modes, which Section 27.14 treats.

Proof. (a) Both sides are linear in each leg, invariant under permutations of the legs and under the 24 relabellings of the axes, which permute the simplices of a cell and fix g_κ; and W_4 is homogeneous of degree five in γ and bilinear in the two Christoffel factors. A functional with these properties that vanishes on 53 representative 4-tuples of basis polarizations $E_{ab}+E_{ba}$, with the fourth momentum eliminated, vanishes on all symmetric legs and conserved momenta; that the 53 representatives reach all 10^4 ordered tuples is a finite check. On a representative, the lattice side times $192\,D(\kappa)$ is a polynomial of degree below ten in κ and quadratic in the free momentum components, and Einstein's side times $16(1-4\kappa)^5$ is a polynomial of degree at most five in κ; the identity $(1-4\kappa)^5 \cdot 192 D(\kappa) \cdot \big(\mathscr{V}[T_4] - \frac{1}{2}W_4\big) = 0$ is checked by exact computation for each of the 53 representatives. Each check packs all coefficients of both polynomials into one integer, with distinct monomials at distinct powers of a large base, and compares two integers of about 200,000 decimal digits; bounds on the coefficients make the comparison equivalent to the polynomial identity. Since $(1-4\kappa)D(\kappa) \neq 0$, the identity follows. (b) Both sides are trilinear and symmetric in the legs and quadratic in the momenta. Take real data first. Both sides are sums, over the entries of the three legs, of quadratic forms in the momenta whose coefficients are rational in κ; with the third momentum eliminated only the projected coefficients count, and clearing the denominators $(4\kappa-1)^4$ on Einstein's side and those of $T_3(\kappa)$ on the lattice side turns the identity into finitely many polynomial identities in κ with integer coefficients, checked by exact computation; they hold at every real κ, so the identity holds wherever both sides are defined. Both sides are then polynomials

in the entries of the legs and two free momenta, with real coefficients, that agree at every real point; so they agree at every complex point. At $\kappa = 0$ the table is that of Table 27.2. (c) At each κ the quadratic vertex of $T_2(\kappa)$ and $-\frac{1}{4}\mathrm{FP}$ are polynomials in the entries of X, X', P whose coefficients are rational in κ; clearing the poles of $R(\kappa)$ turns the identity into finitely many polynomial identities in κ, checked by exact computation. The last equality is Theorem 27.60. At $\kappa = 0$ the quadratic identity can be read off Proposition 27.21: since $\hat{T}_2(b, b') = -2\, b^{\mathsf{T}} R(0) b'$, $48R(0) = E$ and the two momentum factors give $\frac{1}{2}\big(K \cdot (x_f - x_{f'})\big)^2$, the vertex is $-\frac{1}{96}\sum_\sigma \sum_{f,f'} E_{ff'} (s_f^{\mathsf{T}} X s_f)(s_{f'}^{\mathsf{T}} X' s_{f'}) \big(K \cdot (x_f - x_{f'})\big)^2 = -\frac{24}{96}\mathrm{FP}_1(K; X, X')$. □

Corollary 27.62 (One half of Einstein–Hilbert, through quartic order)**.** *In classical mathematics, on the Kuhn lattice, for $n = 2, 3, 4$, all real symmetric polarizations and real momenta summing to zero,*

$$V_n[S_{\mathrm{R}}](H; K) = \tfrac{1}{2}\, V_n\big[\sqrt{\det g}\, R\big](H; K) \quad \text{around every Euclidean member } g_\kappa,\ \kappa < \tfrac{1}{4},$$

in particular around $g_0 = 1$. On the Lorentzian member $\kappa = 1$ the same holds for the tables continued to $\kappa = 1$: $\sqrt{3}\, \mathscr{V}[T_n(1)] = \frac{1}{2} V_n[\sqrt{-\det g}\, R]$ around g_1, $n = 2, 3, 4$.

Proof. Theorem 27.59 gives $V_n[S_{\mathrm{R}}] = \sqrt{\det g_\kappa}\, \mathscr{V}[T_n(\kappa)]$, Theorem 27.61 gives $\mathscr{V}[T_n] = \frac{1}{2} W_n$, and Theorem 27.60 gives $\sqrt{|\det g_\kappa|}\, W_n = V_n[\sqrt{|g|}\, R]$; at $\kappa = 1$, $\sqrt{|\det g_1|} = \sqrt{3}$. □

The tables at $\kappa = 1$ are the Lorentzian lattice's own. The cell forms of Section 27.7, built on the $\kappa = 1$ cell from the rates of its areas and angles, are at orders two, three and four the forms of $T_2(1)$, $T_3(1)$ and $T_4(1)$ times one and the same factor, of absolute value $\sqrt{3} = \sqrt{|\det g_1|}$; and for every $\kappa > \frac{1}{2}$ the cell forms of the background g_κ are the continued tables times one factor of absolute value $\sqrt{4\kappa - 1}$ (Proposition 27.63). That the quartic cell form at $\kappa = 1$ is the fourth derivative of δ's own Regge action on $\mathbb{R}_\delta$ rests, as before, on its third-order rates, whose identification with third derivatives is open.

Proposition 27.63 (One normalization at every order)**.** *In classical mathematics: on the $\kappa = 1$ cell, the quadratic, cubic and quartic cell forms equal $\sqrt{3}$ times the forms of the tables $-T_2(1)$, $-T_3(1)$ and $-T_4(1)$, for every argument; and for every $\kappa > \frac{1}{2}$ the corresponding cell forms of the background g_κ equal $\sqrt{4\kappa - 1} = \sqrt{|\det g_\kappa|}$ times the forms of $-T_n(\kappa)$.*

Proof. Each cell form is assembled from closed forms for the first, second and third rates of the Lorentzian areas $\frac{1}{4}\sqrt{-Q_t}$ and angles of the cell, as the Euclidean derivatives are in the proof of Theorem 27.59. Jacobi's identity gives $A_t/\sqrt{|D_t|} = \frac{1}{2}\sqrt{|\det G|}$ on both sides of the light cone, so the square roots again collect into one factor, $\sqrt{4\kappa - 1}$, and the remaining identities are polynomial identities in κ and the slot variables, checked by exact computation; at $\kappa = 1$ they are integer identities. □

Remark 27.64 (Why the half is a normalization and not a change of coupling)**.** The factor $\frac{1}{2}$ is the classical normalization of Regge calculus, in which $\sum_h A_h \delta_h$ corresponds to $\frac{1}{2}\int \sqrt{g}\, R$ [199]. It is the same at orders two, three and four. A common factor in front of an action fixes its units; a factor that differed between orders would change the ratio of the cubic to

the quadratic vertex, which is the gravitational coupling. With an action scale s, $s\sum_h A_h\delta_h = \frac{s}{2}\int\sqrt{|g|}\,R = (16\pi G)^{-1}\int\sqrt{|g|}\,R$ at $G = 1/(8\pi s)$. On the Euclidean members the identities also follow from the convergence theorem of Cheeger, Müller and Schrader [199], by an argument that uses fatness bounds and the analyticity of the action in the wave amplitudes; the proofs above use no convergence theorem, and that theorem does not reach the Lorentzian member.

The answer to the opening question is therefore yes, at the order Einstein's theory is written in. Reading the lattice action as gravity's action remains an identification, and the factor $\kappa = 1$ remains the named premise of Section 27.8; given both, the lattice's gravitons interact at long wavelength through cubic and quartic order as general relativity's do.

27.12 Among area charges, gauge consistency selects Regge's action through cubic order

Section 27.5 showed that the hinge cost built from J fails at third order: its cubic vertex breaks gauge invariance, and Proposition 27.25 showed that a hinge cost linear in the deficit matches Regge's derivatives exactly when its area factor is linear to second order. This section turns the question around. Which hinge costs pass the gauge tests at all, and what exactly is wrong with J's? The answers are: among hinge charges built from one function of the area, through cubic order only Regge's charge passes, up to its scale, and for shape costs the tests fix Regge's action up to its coupling; J's cubic vertex is one quarter of Einstein's plus a gauge-breaking part Δ that we write out; and one hinge-local correction removes Δ and leaves exactly half of Regge's cubic vertex. All results are proved in classical mathematics, on the Euclidean Kuhn lattice.

Definition 27.65 (Hinge charges, jets and the gauge tests)**.**

1. A *hinge charge* built from one function of the area is the cost $\sum_h \varphi(A_h)\,\delta_h$, δ_h the deficit. At the Euclidean flat lattice the hinges have the four areas $a \in \{\frac{1}{2}, \frac{\sqrt{2}}{2}, \frac{\sqrt{3}}{2}, 1\}$, and the *jets* of φ are $\big(\varphi(a)/a, \varphi'(a), \varphi''(a)\big)$ at these four areas. Regge's charge $\lambda A\delta$ has the jets $(\lambda, \lambda, 0)$ at every area. A *ratio charge* is $a_0\psi(A/a_0)\,\delta$, a_0 the flat area of the hinge, with jets $(c_0, c_1, c_2) = (\psi(1), \psi'(1), \frac{1}{2}\psi''(1))$; Regge's are $(1, 1, 0)$.

2. The *quadratic test*: the charge's per-simplex quadratic table is gauge null (Definition 27.19) at every momentum. The *cubic test at a witness*: on a configuration of three legs, two of them solutions of the linearized field equations and one a pure-gauge leg, the long-wave cubic vertex of the charge's cubic table vanishes. The three *witnesses*, with Gaussian-integer null momenta for the Euclidean form, are: W_1, the legs $(\eta', \eta', K_3 \otimes e_1 + e_1 \otimes K_3)$ with $\eta' = \mathrm{diag}(-1, 1, 1, 1)$ at the static momenta $K_1 = (0, 3, 4, 5i)$, $K_2 = (0, 5, 12, 13i)$, $K_3 = -K_1 - K_2$; W_2, the same with e_2 in place of e_1; and W_3, the transverse-traceless legs

$$h_1 = \begin{pmatrix} -321 + 240i & -228 + 70i & -100 - 125i & -200 - 375i \\ -228 + 70i & 171 - 240i & 75 & 150 \\ -100 - 125i & 75 & -75 & 75 \\ -200 - 375i & 150 & 75 & 225 \end{pmatrix},$$

$$h_2 = \begin{pmatrix} 482+312i & -120+65i & -60-65i & -60+130i \\ -120+65i & -457-312i & 50 & -25 \\ -60-65i & 50 & 25 & 25 \\ -60+130i & -25 & 25 & -50 \end{pmatrix}$$

at $K_1 = (3,4,0,5i)$, $K_2 = (5,0,12,13i)$, with the gauge leg $K_3 \otimes e_1 + e_1 \otimes K_3$, $K_3 = -K_1 - K_2$. Each h_j is traceless and transverse to its momentum, $\sum_a K_{j,a} h_{j,ab} = 0$ for every b, and both momenta are null, $\sum_a K_{j,a}^2 = 0$.

The tests read a charge only through its jets: along a line of squared lengths the quadratic and cubic parts of $\varphi(A)\delta$ involve φ, φ' and φ'' at the flat areas and nothing else, since δ vanishes on the flat lattice.

Theorem 27.66 (Regge is the only consistent area charge through cubic order)**.** *In classical mathematics, for hinge charges built from one function of the area on the Euclidean Kuhn lattice:*

(a) the quadratic table is gauge null at every momentum exactly when the value-and-slope jets $(\varphi(a)/a, \varphi'(a))$, listed over the four areas, lie in the span of $v_1 = (2,1\,|\,2,1\,|\,2,1\,|\,2,1)$, $v_2 = (1,0\,|\,1,0\,|\,1,0\,|\,1,0)$ and $v_3 = (2,1\,|\,\frac{5}{2},\frac{1}{2}\,|\,3,0\,|\,3,0)$; the table of v_1 has zero symbol, that of v_2 is $-\frac{1}{48}E$ and that of v_3 is $-\frac{1}{16}R_1$, each up to a table of zero symbol, and the table of the constant jets $(1,1)$ is $\frac{1}{48}E$;

(b) the charge passes the quadratic test and the cubic test at W_1, W_2 and W_3 if and only if its jets are $(\lambda,\lambda,0)$ at all four areas for one real λ: Regge's jets at scale λ.

Conditions and scope.

Base and premises

The Euclidean Kuhn lattice; hinge charges built from one function of the area; classical real numbers.

Conclusion

Among these charges, the quadratic test and the cubic test at three witnesses leave exactly Regge's charge, up to its scale.

Exact computation

Part (a) is exact linear algebra on eight rational 10×10 tables; part (b) evaluates the per-area cubic tables exactly at the three witnesses of Definition 27.65 and checks that the six real linear equations of Table 27.5 have full rank: their determinant, computed exactly from the printed coefficients, is $-27\,866\,927\,400\,397\,976\,309\,514\,240$. The witnesses and the coefficients are printed here; the evaluation of the tables at the witnesses that produces the coefficients is the exact computation of [197, Table 1].

Not claimed

Charges with one function for each class of hinge, and shape costs (Proposition 27.67); costs nonlinear in the deficit.

Table 27.5. The cubic test of Theorem 27.66(b) as six real equations. Each row is the real or imaginary part of the test at one witness of Definition 27.65; the columns multiply $u_1 + u_2$, u_3 and the four curvature jets z_a. The static witnesses do not see the curvature jet at area 1; the transverse-traceless witness does. The determinant is $-27\,866\,927\,400\,397\,976\,309\,514\,240 \neq 0$.

	$u_1 + u_2$	u_3	$z_{1/2}$	$z_{\sqrt{2}/2}$	$z_{\sqrt{3}/2}$	z_1
W_1, real	-56	-360	-8	0	48	0

W_3, real	$-\frac{946463965}{8}$	$-\frac{1504452249}{4}$	14665886	$\frac{971809893}{8}$	$-\frac{37294969}{2}$	$\frac{55612715}{2}$
W_3, imag.	$-\frac{998974207}{8}$	$-\frac{41233057}{4}$	390527308	$-\frac{1786358293}{8}$	1780182	$-\frac{68444255}{2}$

Proof. (a) The quadratic table is linear in the eight value-and-slope jets, through eight rational 10×10 tables obtained from the first derivatives of the areas and angles of Theorem 27.26. Gauge nullity at every momentum is, after the phases are factored, a finite set of linear conditions (Theorem 27.20(d)), and the span is exact linear algebra on them. (b) Write the value-and-slope jets as $u_1 v_1 + u_2 v_2 + u_3 v_3$ and the curvature jets as z_a. The cubic table is linear in the twelve jets, and three exact identities among the per-area cubic tables reduce the cubic test at a witness to $\frac{3}{2}(u_1 + u_2)\mathscr{V}(X_1) + u_3\mathscr{V}(V_3) + \sum_a z_a \mathscr{V}(S_{2,a})$, with fixed tables X_1, V_3, $S_{2,a}$ evaluated exactly at the witness. The real and imaginary parts at the three witnesses are six real linear equations in $u_1 + u_2$, u_3 and the four z_a, of full rank (Table 27.5). So $u_1 + u_2 = u_3 = 0$ and every $z_a = 0$, which is $(\lambda, \lambda, 0)$ with $\lambda = u_1$. Conversely Regge's charge passes both tests (Theorem 27.20(e) and Theorem 27.24(b),(c)). □

The tests see the jets and nothing more: $[A + (A - a_0)^3/a_0^2]\,\delta$ has Regge's jets at the flat area a_0 without being Regge's charge. Rotation invariance does not do the selecting either: J's own cubic vertex below is rotation invariant and still fails. The gravity preprint [197] adds a second route, the record clause, which fixes the whole function and its scale [197, Theorem 5.5]. Wider classes behave as one expects once the inversion symmetry of the cell is taken into account.

Proposition 27.67 (Wider classes of hinge costs)**.** *In classical mathematics, on the Euclidean Kuhn lattice:*

(a) the central inversion of the cell leaves the long-wave cubic vertex of every cubic table unchanged under the reversal of its slots, at every momentum-conserving triple of legs;

(b) with one function of the area for each class of hinge, the quadratic test and the cubic test at W_1, W_2, W_3 leave exactly Regge's jets on the inversion-even part and three inversion-odd terms that neither test can see;

(c) for shape costs, $\sum_h f_c(L_h)\delta_h$ with one smooth function of the hinge's three squared lengths for each of its six classes, the quadratic test and the cubic test at eleven on-shell witnesses leave, on the inversion-even part, exactly λ times Regge's action plus μ times the coupling direction Y of Proposition 27.70, and inversion-odd terms of zero symbol.

Proof. (a) The inversion $x \mapsto \mathbf{1} - x$ maps the simplices of a cell to simplices, reverses the slots by the permutation $(0\,9)(1\,8)(2\,6)(4\,7)$ and reflects the midpoints; reindexing the cell sum as in Theorem 27.24(a) changes the phases $K_i \cdot x_f$ into $K_i \cdot \mathbf{1} - K_i \cdot x_f$, and the vertex, quadratic in the momenta, is unchanged when $\sum K_i = 0$. (b) and (c) The tests are linear in the jets; an inversion-odd table has, by (a), no long-wave vertex. The even part reduces to exact linear algebra on rational tables at the witnesses, as in Theorem 27.66. □

Now $\mathcal{J}$'s charge. By (27.1), $\mathcal{J}$'s odd hinge cost has the cubic form $-(r + d)$ per simplex, with r Regge's and d the extra term of Table 27.2. For a cubic monomial m in two momenta and three polarizations, write

$$\langle m \rangle = - \sum_{(i,j,k)} m(K_i, H_i, K_j, H_j, H_k),$$

summed over the six orderings of the legs; the sign is the i^2 of two derivatives.

Theorem 27.68 ($\mathcal{J}$'s cubic vertex is one quarter of Einstein's plus Δ)**.** *In classical mathematics, for all real symmetric H_1, H_2, H_3 and real momenta with $K_1+K_2+K_3 = 0$, with $W_3 = W_3(1; H; K)$:*

(a) $V_r = \frac{1}{2}W_3$, $V_d = -\frac{1}{4}W_3 + \Delta$ *and so* $V_r + V_d = \frac{1}{4}W_3 + \Delta$, *where*

$$\Delta = \tfrac{1}{8}\big\langle (K_i^{\mathsf{T}} H_i K_j)\,\mathrm{tr}\,H_j\,\mathrm{tr}\,H_k \big\rangle - \tfrac{1}{8}\big\langle (K_i^{\mathsf{T}} H_i H_j K_j)\,\mathrm{tr}\,H_k \big\rangle - \tfrac{1}{8}\big\langle (H_i K_i)^{\mathsf{T}} H_k (H_j K_j) \big\rangle$$
$$- \tfrac{1}{16}\big\langle (K_i \cdot K_j)\,\mathrm{tr}\,H_i\,\mathrm{tr}\,H_j\,\mathrm{tr}\,H_k \big\rangle + \tfrac{1}{16}\big\langle (K_i \cdot K_j)\,\mathrm{tr}(H_i H_j)\,\mathrm{tr}\,H_k \big\rangle + \tfrac{1}{8}\big\langle K_i^{\mathsf{T}} H_j H_k H_i K_j \big\rangle;$$

(b) $\Delta = -\frac{1}{8}\mathscr{E}_1 - \frac{1}{32}\mathscr{E}_3 + \mathscr{R}$, *where* $\mathscr{E}_1 = \sum \mathrm{tr}\,H_i\,(H_j : G^1(H_k))$ *and* $\mathscr{E}_3 = \sum \mathrm{tr}\,H_i\,\mathrm{tr}\,H_j\,S^1(H_k)$ *are field-equation vertices (G^1, S^1 the linearized Einstein tensor and scalar of a leg, summed over the leg assignments) and $\mathscr{R}$ is a sum of five invariant monomials; and Δ is not a combination of W_3 and the four field-equation vertices.*

Conditions and scope.

Base and premises

The Euclidean Kuhn lattice; classical real numbers.

Conclusion

Regge's cubic vertex is one half of Einstein's. $\mathcal{J}$'s odd hinge cost has the cubic form $-(r+d)$ and so the vertex $-(\frac{1}{4}W_3 + \Delta)$, against Regge's $-\frac{1}{2}W_3$: half of Regge's coupling plus a part Δ that no redefinition of the metric (which adds field-equation vertices) and no change of the coupling (which adds multiples of W_3) removes. This is the defect that Theorem 27.24 detected on two configurations.

Proof. (a) $V_r = \frac{1}{2}W_3$ is Theorem 27.61(b) at $\kappa = 0$. For d, both sides are trilinear in the legs, symmetric under their permutations and quadratic in the momenta; as in Theorem 27.61(a) they agree once they agree on representative triples of basis polarizations with two free momenta, and there both are explicit polynomials compared by exact computation. (b) The field-equation vertices and the five monomials of $\mathscr{R}$ are explicit; the identity is again a polynomial identity. For the last claim, one configuration makes W_3 and all four field-equation vertices vanish while $\Delta = -\frac{1}{4}$. □

A ratio correction can repair $\mathcal{J}$'s jets, and a hinge-local correction can do better.

Theorem 27.69 (The counterterm, and J without Δ)**.** *In classical mathematics, on the Euclidean Kuhn lattice:*

(a) a ratio charge passes the cubic test at W_1 if and only if $c_0 = c_1$ and $c_2 = 0$;

(b) J's charge has the ratio jets $(0, \frac{1}{2}, -\frac{1}{4})$; a ratio correction with jets (c_0^*, c_1^*, c_2^*) has a quadratic table of zero symbol exactly when $c_0^* = 2c_1^*$, and the only such correction with which J's charge passes the cubic test at W_1 is $(1, \frac{1}{2}, \frac{1}{4})$, for example $\big[a_0 + \frac{1}{2}(A-a_0) + \frac{1}{4}(A-a_0)^2/a_0\big]\delta$; J plus it has Regge's jets $(1, 1, 0)$, so the halved coupling is lost;

(c) the hinge-local correction $C^* + \frac{1}{2}Y$, with C^* the ratio correction of (b) and Y the coupling direction of Proposition 27.70, has a quadratic table of zero symbol and the cubic form $d + \frac{1}{2}r$; J's charge plus it has the cubic form $-\frac{1}{2}r$, exactly one half of Regge's form $-r$, so its cubic vertex is one half of Regge's with Δ removed, and it passes the cubic test at W_1, W_2 and W_3.

Proof. (a) A ratio charge has the per-simplex cubic table $c_0(Y_1 + 2X_1) - 3c_1(X_1 + Y_1) - 6c_2 Z_1$ with $X_1 = \sum_t A_t' \theta_t''$, $Y_1 = \sum_t A_t'' \theta_t'$ and $Z_1 = \sum_t A_t'^2 \theta_t' / A_t$, by Leibniz's rule and the twice differentiated Schläfli identity. At W_1 the three vertices are $\mathscr{V}(X_1) = -\frac{112}{3} - \frac{160}{9}i$, $\mathscr{V}(Y_1) = \frac{56}{3} + \frac{80}{9}i$ and $\mathscr{V}(Z_1) = -\frac{40}{3} - \frac{80}{9}i$, exact sums over the 24 simplices; so the witness value is $(c_0 - c_1)(-56 - \frac{80}{3}i) + c_2(80 + \frac{160}{3}i)$, whose imaginary part vanishes exactly when $c_0 - c_1 = 2c_2$, and then its real part is $-32c_2$. (b) $J_{\mathrm{odd}}(x, e^{\delta}) = \frac{1}{2}(x - x^{-1})\sinh\delta$ (Proposition 27.16(b)), whose ratio part $\psi_J(x) = \frac{1}{4}(x - x^{-1})$ has $\psi_J(1) = 0$, $\psi_J'(1) = \frac{1}{2}$, $\psi_J''(1) = -\frac{1}{2}$; the rest, $\psi_J(\sinh\delta - \delta)$, enters neither the quadratic nor the cubic action. The zero-symbol condition is the direction v_1 of Theorem 27.66(a), and (a) applied to $(c_0^*, c_1^* + \frac{1}{2}, c_2^* - \frac{1}{4})$ with $c_0^* = 2c_1^*$ gives $(1, \frac{1}{2}, \frac{1}{4})$. (c) In the sign of the cost forms Regge's charge has the cubic form $-r$ and J's the form $-(r + d)$ (by (27.1)); C^* has the form d, since J's charge plus C^* has Regge's jets, and Y has no quadratic part and the form r, minus Regge's (Proposition 27.70). So $C^* + \frac{1}{2}Y$ has the form $d + \frac{1}{2}r$, and J's form plus it is $-\frac{1}{2}r$, whose vertex is $-\frac{1}{2}V_r = -\frac{1}{4}W_3$ by Theorem 27.68, one half of Regge's $-\frac{1}{2}W_3$. The witness values are exact evaluations. □

The coupling direction behind part (c) is a change of Regge's coupling, and it is a hinge cost to first order.

Proposition 27.70 (The coupling direction)**.** *In classical mathematics, let L_0 be a reference simplex, L a nondegenerate simplex near it, $\Psi_{L_0}(L) = \sum_t A_t(L)(\theta_t(L) - \theta_t(L_0))$ and $\Psi_Y(L) = \sum_t \big(A_t(L) + L_0 \cdot \nabla A_t(L)\big)\big(\theta_t(L) - \theta_t(L_0)\big)$.*

(a) $\dfrac{d}{dg}\Big[g^{-2}\Psi_{L_0}\big(L_0 + g(L - L_0)\big)\Big]_{g=1} = -\Psi_Y(L)$. Hence the hinge cost $Y = \sum_h (A_h + L_0 \cdot \nabla A_h)\delta_h$, with L_0 the flat squared lengths of each hinge, has an identically zero quadratic table and minus Regge's cubic table: $S_{\mathrm{R}} + (1 - \nu)Y$ has Regge's quadratic action and ν times Regge's coupling through cubic order.

(b) The second derivative at $g = 1$ of $g^{-2}\Psi_{L_0}(L_0 + g(L - L_0))$ is a hinge cost plus the simplex-local product $\sum_t (D_{L_0} A_t)(D_{L_0}\theta_t)$, with D_{L_0} the derivative in the direction L_0 at L.

Proof. (a) Put $F(g) = \Psi_{L_0}(L_0 + g\ell)$, $\ell = L - L_0$. Then $\frac{d}{dg}[g^{-2}F]_{g=1} = F'(1) - 2F(1)$ and $F'(1) = \sum_t [A_t'(\theta_t - \theta_t(L_0)) + A_t\theta_t']$; Schläfli's identity removes $\sum_t A_t\theta_t'$. Heron's area is homogeneous of degree one in the squared lengths, so $L \cdot \nabla A_t = A_t$ by Euler's identity and $A_t' = A_t - L_0 \cdot \nabla A_t$; hence $F'(1) - 2F(1) = -\Psi_Y(L)$. Summed over the simplices at $L_0 = \ell_\kappa$, the function $\nu \mapsto \nu^{-2} S_{\mathrm{R}}(\ell_\kappa + \nu\lambda) = \sum_n \nu^{n-2} S_n$ has derivative $-Y$ at $\nu = 1$, so $Y_n = -(n-2)S_n$: zero at $n = 2$ and $-S_3$ at $n = 3$. (b) Differentiating once more, Euler's identity for the homogeneous functions A_t and ∇A_t turns every term but one into a function of the triangle's squared lengths times $\theta_t(L) - \theta_t(L_0)$, a hinge cost; the remaining term is $\sum_t (D_{L_0} A_t)(D_{L_0}\theta_t)$. □

So Y is exactly as consistent as Regge's action to first order in the change of coupling, and part (b) shows why it stops there: the second-order term contains a product of two rates on the same simplex, which no hinge cost has. The next section proves that at quartic order no hinge shape cost makes up the difference.

27.13 Hinge shape costs cannot complete a changed coupling

Rescaling every departure from flat space by ν and the action by ν^{-2} gives $\nu^{-2} S_{\mathrm{R}}(\ell_\kappa + \nu\lambda) = S_2 + \nu S_3 + \nu^2 S_4 + \dots$, Regge's action with ν times its coupling. The hinge cost Y gives $S_{\mathrm{R}} + (1-\nu)Y = S_2 + \nu S_3 + (2\nu - 1)S_4 + \dots$, since $Y_n = -(n-2)S_n$, which falls short at quartic order by $(1-\nu)^2 S_4$; at $\nu = \frac{1}{2}$, the coupling that J's charge carries, the shortfall is one quarter of Regge's quartic part. Can hinge costs supply it? A *shape cost* gives each hinge h of class c the cost $f_c(L_h)\delta_h$, with L_h its three squared lengths and one smooth function f_c for each of the six classes $(|a|, |b|) \in \{(1,1), (1,2), (1,3), (2,1), (2,2), (3,1)\}$ of hinges with vertices y, $y + a$, $y + a + b$. The values, gradients and Hessians of the f_c fix the quadratic and cubic parts; their third derivatives first enter at quartic order, through sixty *third-derivative directions* (c, j), one for each class and each of the ten cubic monomials in the three changes of squared length. Let $F_{c,j}(\kappa)$ be their per-simplex quartic tables divided by $\frac{1}{2}\sqrt{|1 - 4\kappa|}$, the normalization in which Regge's quartic part per simplex is $-\frac{1}{12} T_4(\kappa)$; they are rational in κ. A *physical configuration* on $\gamma = g_\kappa^{-1}$ has three gravitons, K_i null for γ and H_i symmetric, transverse and traceless for γ $(i = 1, 2, 3)$, and one pure-gauge leg $H_4 = K_4 \xi^{\mathsf{T}} + \xi K_4^{\mathsf{T}}$ with $K_4 = -K_1 - K_2 - K_3$ null.

Theorem 27.71 (The quartic obstruction). *In classical mathematics, let $\kappa \in \{0, \frac{1}{10}, 1\}$.*

(a) No complex numbers $z_{c,j}$ satisfy $\sum_{c,j} z_{c,j} \mathscr{V}[F_{c,j}(\kappa)](H; K) = \mathscr{V}[-\frac{1}{48} T_4(\kappa)](H; K)$ on every physical configuration.

(b) At $\kappa = 1$ and $\kappa = \frac{1}{10}$ the same holds with the lattice's five non-metric edge modes included, in the corrected gauge variation of each table (the variation with the gravitons' non-metric admixtures and the gauge leg's non-metric part, which solve the lattice's field equation to the needed order); the corrected variation does not depend on how the admixtures and the gauge part are chosen, and at $\kappa = 1$ it is the leading Taylor coefficient, of third order in the momenta, of the exact lattice vertex.

Conditions and scope.

Base and premises
The Kuhn lattice at $\kappa = 0, \frac{1}{10}, 1$; classical algebra over the Gaussian rationals and the integers.

Conclusion
The space of the sixty shape variations is linear, so no nonzero multiple of Regge's quartic variation lies in it: no change of the coupling, $\nu \neq 1$, is completed by shape costs at quartic order.

Inference
Reading (a) as the impossibility of a changed coupling uses one stated inference, which this book does not prove: that completing the coupling requires exactly the quartic shortfall in the gauge variation on physical configurations. The preprint argues it [196, Remark 10.4].

Exact computation
Each claim is an exact rank certificate on 17 or 33 explicit configurations, described in the proof and not printed. The quartic tables and the sixty shape-cost tables are parts S1 and S2 of the data set [210]; its part S8 holds the configurations and certificates of (a) at $\kappa = 0, \frac{1}{10}, 1$ and a program that recomputes every vertex and checks $y^{\mathsf{T}} M = 0$ and $y^{\mathsf{T}} t \neq 0$ exactly.

Not claimed
Costs nonlinear in the deficit, or depending on more than a hinge's three squared lengths.

Proof. Each claim is an exact certificate. Choose finitely many physical configurations, evaluate the sixty-one vertices exactly, and form the matrix M with one column per direction and the target column t. An integer vector y with $y^{\mathsf{T}} M = 0$ and $y^{\mathsf{T}} t \neq 0$ excludes every combination with real coefficients, since applying y to the supposed equalities gives $0 = y^{\mathsf{T}} t$. At $\kappa = 0$ and $\kappa = \frac{1}{10}$ the metric is Euclidean, null momenta are complex, and 17 configurations with Gaussian-integer entries suffice; each contributes a real and an imaginary row, and the sixty columns have rank 32, raised to 33 by the target. Complex coefficients are excluded through real ones: the complex conjugate of a physical configuration is physical and the tables are rational, so the real part of a complex solution would be a real solution. At $\kappa = 1$ real null momenta exist and 33 real integer configurations are used. For (b) the admixtures are computed exactly from the 15×15 form of the lattice at zero momentum, which is nondegenerate on the five non-metric classes (Theorem 27.74(e)), and the same kind of certificate excludes the target. □

At $\kappa = 0$ the lattice has one further mode with no quadratic term, the body diagonal of the cube.

Proposition 27.72 (The body diagonal at the Euclidean background)**.** *In classical mathematics, at* $\kappa = 0$*: every triangle of a Kuhn simplex that contains the body diagonal* 04 *is right-angled opposite it, so the first derivatives of the areas along the diagonal, the row and column* 04 *of the Euclidean table E and the true second derivatives of the simplex function along the diagonal vanish; the edge field with amplitude one on the class* 1111 *is a zero mode of the plane-wave form*

of E at every momentum, and it is no gauge amplitude at any wave with every $\sin(K_a/2) \neq 0$. *Two constant metric strains do not couple to it, while at an explicit on-shell configuration two graviton waves give it a nonzero source at long wavelength. At $\kappa = 1$ the row 04 of R_1 is not zero.*

Proof. The triangle $0j4$ has squared sides j, $4-j$ and 4, and $j+(4-j) = 4$: by Thales it is right-angled at v_j, since the steps $v_j - v_0$ and $v_4 - v_j$ have disjoint supports. As $\partial A/\partial z = (x+y-z)/(16A)$ for squared sides x, y, z, the areas are stationary in ℓ_{04}, and by Schläfli's identity the Hessian $\sum_t \partial A_t \, \partial\theta_t$ has a zero row and column 04. The body diagonal is slot 04 of every simplex and of no other slot, so its column of the plane-wave form vanishes. A gauge amplitude vanishing on the four axis classes has $\eta_a \sin(K_a/2) = 0$, hence is zero. The source values are exact sums over the 24 simplices with the cubic table r. Finally $(R_1)_{04,04} = 2$ (Table 27.1). □

So the flat $\kappa = 0$ lattice is a degenerate critical point on the fifteen-class space, and statements there about four-point amplitudes are statements about the metric truncation. At $\kappa = 1$ and, as the next section shows, at every other admissible background the five non-metric modes are massive.

27.14 Four gravitons at tree level

Once the quadratic form, the cubic vertex and the quartic vertex are fixed, the tree-level scattering of four gravitons is fixed. Since the lattice's vertices are one half of Einstein's, its amplitude should be general relativity's at one half of Einstein's normalization, gauge invariant and with general relativity's helicity structure. This section proves that, on every flat background g_κ of the lattice family off its poles, at long wavelength (second order in the momenta), for the amplitude built from the tables and for the one built from the Lorentzian lattice's own cell forms. The backgrounds g_κ are related by linear changes of coordinates in the continuum theory, and the proofs use that. All statements are proved in classical mathematics over the complex numbers.

Definition 27.73 (The tree four-graviton amplitude)**.** Fix a real κ with $(2\kappa-1)(3\kappa-1)(4\kappa-1) \neq 0$, $\gamma = g_\kappa^{-1}$, $g = g_\kappa$ and $P^2 = P^{\mathsf{T}} \gamma P$. For four legs (H_i, K_i), H_i complex symmetric and $\sum K_i = 0$: the *contact term* is $\mathscr{V}[T_4(\kappa)](H;K)$; the *current* J^{ij} of legs i, j is the matrix with $\mathscr{V}[T_3(\kappa)](H_i, H_j, Z; K_i, K_j, -K_i - K_j) = \sum_{ab} J^{ij}_{ab} Z_{ab}$ for every symmetric Z; the *propagator* of a current is $\Pi(J;P) = \frac{4}{P^2}\big(gJg - \frac{1}{2}(g:J)\,g\big)$, $g:J = \sum g_{ab}J_{ab}$ (the gauge-fixed inverse of the quadratic vertex in de Donder gauge); and the *amplitude* is

$$\mathscr{A}(H;K) = \mathscr{V}[T_4(\kappa)](H;K) + E(J^{12}, J^{34}; K_1+K_2) + E(J^{14}, J^{23}; K_1+K_4) + E(J^{13}, J^{24}; K_1+K_3),$$

$E(J, J'; P) = \sum_{ab} J_{ab} \Pi(J'; P)_{ab}$, defined when $s = (K_1+K_2)^2$, $t = (K_1+K_4)^2$ and $u = (K_1+K_3)^2$ are nonzero.

The exchange is the stationary value of the channel's gauge-fixed quadratic-plus-cubic action, so contact and exchanges enter with weight one, and the amplitude is the coefficient of $\epsilon_1 \cdots \epsilon_4$ in the tree-level effective action of one cell of the metric sector at second order in the momenta. On the Euclidean lattice the null momenta are complex and spinors describe them. For $a, b \in \mathbb{C}^2$, $v(a,b) \in \mathbb{C}^4$ is the vector y whose matrix $\left(\begin{smallmatrix} y_4+iy_3 & y_2+iy_1 \\ iy_1-y_2 & y_4-iy_3 \end{smallmatrix}\right)$ is ab^{T}; the

brackets are $\langle ac\rangle = a_1c_2 - a_2c_1$ and $[bd] = b_1d_2 - b_2d_1$, so that $v(a,b)\cdot v(c,d) = \frac{1}{2}\langle ac\rangle[bd]$. Leg i has $K_i = v(\lambda_i, \tilde{\lambda}_i)$; with reference spinors μ_i, $\tilde{\mu}_i$ its polarizations are $\epsilon_i^+ = v(\mu_i, \tilde{\lambda}_i)/\langle \mu_i\lambda_i\rangle$ and $\epsilon_i^- = v(\lambda_i, \tilde{\mu}_i)/[\tilde{\lambda}_i\tilde{\mu}_i]$, the graviton of helicity $\pm$ is $H_i = \epsilon_i^{\pm} \otimes \epsilon_i^{\pm}$, and $s = \langle 12\rangle[12]$, $t = \langle 14\rangle[14]$, $u = \langle 13\rangle[13]$. These are the conventions of [196, Section 9.3] and of part S7 of the data set [210]. The data are *generic* when momentum is conserved, $s, t, u \neq 0$, and every reference bracket is nonzero.

Theorem 27.74 (Gauge invariance, helicity selection and the MHV amplitude)**.** *In classical mathematics:*

(a) Noether identities. *For every invertible complex symmetric γ, Einstein's vertices obey the order-by-order identities of invariance under a change of coordinates: W_2 vanishes on a pure-gauge leg, and W_3, W_4 with one pure-gauge leg equal minus the lower vertex applied to the linear gauge variations of the other legs.*

(b) Gauge invariance. *For every real κ off the poles, the amplitude vanishes on every physical configuration with $s, t, u \neq 0$ (pure-gauge gravitons decouple); at $\kappa = 0$ and $\kappa = 1$ it does not depend on the gauge parameter of the propagator.*

(c) Helicity selection and MHV. *At $\kappa = 0$, for generic spinor data, the amplitude vanishes unless exactly two of the four helicities are positive, and if legs m, m' are negative and p, p' positive,*

$$\mathcal{A} = -\frac{1}{256}\,\frac{\langle mm'\rangle^4\,[pp']^4}{stu}.$$

The same selection rule and the same MHV value hold at every real κ off the poles, for spinor data carried to the background g_κ by a complex frame of g_κ.

(d) The lattice's own amplitude. *For every real κ with $(2\kappa-1)(3\kappa-1)(4\kappa-1) \neq 0$ the lattice's own long-wave quadratic form is one half of Einstein's, so the amplitude built from the lattice's own propagator is the amplitude above: general relativity's tree amplitude at one half of Einstein's normalization. For every $\kappa > \frac{1}{2}$ the amplitude built from the Lorentzian lattice's own Feynman rules, its cell forms of orders two, three and four, contact term included, is $\sqrt{4\kappa-1} = \sqrt{|\det g_\kappa|}$ times it, for all real legs whose channel momenta are off the cone; it is gauge invariant.*

(e) The other five edge modes. *For every $\kappa \notin \{0, \frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$ the five non-metric edge modes (the four classes with three steps and the class 1111) are nondegenerate at zero momentum; eliminating them at tree level is solvable in every channel with nonzero invariant, and the amplitude with all fifteen edge classes on the internal lines and in the legs equals the amplitude of the metric sector above, so it is Einstein's and gauge invariant. At $\kappa = 0$ the decoupling fails (Proposition 27.72).*

Conditions and scope.

Base and premises

The Kuhn lattice on every flat background g_κ off the poles; complex legs; classical algebra.

Conclusion

The lattice's gravitons scatter at tree level and long wavelength (second order in the momenta) exactly as general relativity's do, on every flat background g_κ of the family off the poles, the Lorentzian $\kappa = 1$ lattice included; and for $\kappa < \frac{1}{4}$ (Theorem 27.59) and $\kappa > \frac{1}{2}$ (part (d)), with the lattice's own Feynman rules the only change is the volume factor $\sqrt{|\det g_\kappa|}$, the same at every order.

Exact computation

The proofs end in finite computations that they describe and do not reproduce: the 40, 400 and 4000 polynomial identities of (a), the canonical MHV value $-\frac{1}{256}$ of (c), the contact-term identity of (d) and the determinant and Schur complement of (e). The tables are part S1 of the data set [210]. Its part S7 holds programs that check (a) on every basis case at three backgrounds, (b) at $\kappa = 0$ and $\kappa = 1$, and (c) at $\kappa = 0$ and $\kappa = 1$ exactly, with the spinor conventions of Definition 27.73; its part S6 holds the fifteen-class quadratic form and its determinant used in (e). The contact-term identity of (d) is not in the data set.

Not claimed

Loops; amplitudes at higher order in the momenta (Section 27.15).

Proof. (a) At $\gamma = 1$ each identity is linear in every polarization and in the gauge vector and polynomial in the momenta, so it holds once it holds for basis polarizations and unit gauge vectors with the last momentum eliminated: 40, 400 and 4000 polynomial identities of degree three, checked by exact expansion. Every invertible complex symmetric γ is $E^{-\mathsf{T}}E^{-1}$ for an invertible complex E, and the vertices transform covariantly under the change of coordinates E, which carries the identities from $\gamma = 1$ to γ. (b) The tables' vertices are one half of Einstein's at every κ off the poles, at all three orders (Theorem 27.61(a)–(c)); the Ward reduction expresses the amplitude with a gauge leg through the identities of (a), and every term cancels once the gravitons are on shell, the gauge-fixed form annihilates the external legs (K_4 null) and the propagator solves the gauge-fixed equation. Independence of the gauge parameter is the same cancellation with the gauge term varied. (c) The amplitude does not depend on the reference spinors, since changing a reference spinor adds a pure-gauge part to that leg and (b) applies. Choosing the references adapted to the helicities makes every non-MHV configuration vanish term by term after the spinor identities, and reduces the MHV case to one canonical configuration, where the value is computed exactly; covariance under the action of $\mathrm{SL}(2,\mathbb{C}) \times \mathrm{SL}(2,\mathbb{C})$ on the spinors carries it to all generic data, and the complex change of coordinates of (a) carries it to every background. (d) The lattice's quadratic vertex is the identity of Theorem 27.61(c). For the Lorentzian cell forms, Proposition 27.63 gives each of the three vertices as $\sqrt{4\kappa - 1}$ times the tables' vertex; in the amplitude the propagator carries $(\sqrt{4\kappa - 1})^{-1}$ and each exchange two cubic vertices, so each exchange and the contact term scale by $\sqrt{4\kappa - 1}$. The contact term needs one algebraic identity in κ and the slot variables, proved by exact computation. (e) On the five classes the zero-momentum form has determinant $3\kappa(2\kappa - 1)^3/(16(4\kappa - 1)^4)$, defined for $\kappa \neq \frac{1}{4}$ and nonzero exactly off $\{0, \frac{1}{2}\}$; at $\kappa = \frac{1}{3}$ it is $-\frac{3}{16}$, and $\kappa = \frac{1}{3}$ is excluded as a pole of the tables, not as a zero of the determinant. A Schur complement onto the metric sector then changes the quadratic, cubic and quartic terms in the metric fields only at fourth order in the momenta, because the zero-momentum form annihilates the metric fields and a cell vertex with all legs metric but one is of second order

in the momenta; so the fifteen-class amplitude at second order in the momenta is the metric one. □

27.15 The graviton's dispersion beyond long wavelength

At order K^2 every lattice of the family is one half of Einstein's theory on its background g_κ, so its graviton travels on the light cone $P^{\mathsf T} g_\kappa^{-1} P = 0$. The next order decides whether the lattice keeps Lorentz invariance at all and whether the two polarizations travel alike. Real light-cone directions exist only on the Lorentzian backgrounds $\kappa > \frac{1}{4}$, where g_κ has the one negative eigenvalue $1 - 4\kappa$. Take a real null covector $P \neq 0$ of g_κ, a direction Q with $g_\kappa^{-1}(P,Q) \neq 0$ and the momentum $K(s) = sP + s^3 tQ$. A *non-gauge wave through order* s^4 at (P,Q,t) is a symmetric polarization H that is not a pure-gauge polarization at P, with edge amplitude $\Phi(H) + s^2 a_2 + s^4 a_4$ on all fifteen classes (a_2, a_4 arbitrary, the non-metric admixtures included), whose plane-wave form of the background's table $R(\kappa)$ against every test amplitude vanishes at orders s^2 and s^4. Along $K(s)$ the dispersion is $K(s)^{\mathsf T} g_\kappa^{-1} K(s) = s^4 \mu + O(s^6)$ with $\mu = 2t\, g_\kappa^{-1}(P,Q)$, the *branch value*: Lorentz invariance at this order means $\mu = 0$, and no birefringence means one value for both polarizations. With $p_k = \sum_a P_a^k$ put

$$
\begin{aligned}
A_\kappa(P) &= f_1(\kappa)\, p_4 + f_2(\kappa)\, p_1 p_3 + f_3(\kappa)\, p_1^4, \qquad \operatorname{disc}_\kappa(P) = f_2(\kappa)^2\, B_\kappa(P),\\
f_1(\kappa) &= \frac{60\kappa^3 - 40\kappa^2 + 10\kappa - 1}{12(2\kappa - 1)}, \qquad f_2(\kappa) = -\frac{\kappa(3\kappa - 1)(5\kappa - 1)}{3(2\kappa - 1)},\\
f_3(\kappa) &= \frac{\kappa^3(45\kappa^2 - 22\kappa + 2)}{12(2\kappa - 1)(4\kappa - 1)^2},\\
B_\kappa(P) &= p_4^2 - 2 p_1 p_3 p_4 + \frac{4(3\kappa - 1)}{3(4\kappa - 1)} p_1^2 p_3^2 + \frac{6\kappa^2 - 1}{4(4\kappa - 1)^2} p_1^4 p_4\\
&\quad - \frac{9\kappa^2 - \kappa - 2}{6(4\kappa - 1)^2} p_1^5 p_3 + \frac{27\kappa^4 - 4\kappa^3 - 12\kappa^2 + 1}{48(4\kappa - 1)^4} p_1^8 .
\end{aligned}
$$

At $\kappa = 1$ these are

$$
a(P) = \tfrac{29}{12} p_4 - \tfrac{8}{3} p_1 p_3 + \tfrac{25}{108} p_1^4, \quad \operatorname{disc}(P) = \tfrac{16}{729} p_1^8 - \tfrac{64}{81} p_1^5 p_3 + \tfrac{80}{81} p_1^4 p_4 + \tfrac{512}{81} p_1^2 p_3^2 - \tfrac{128}{9} p_1 p_3 p_4 + \tfrac{64}{9} p_4^2 .
$$

Theorem 27.75 (The graviton's order-K^4 dispersion on the lattice family)**.** *In classical mathematics:*

(a) for every real $\kappa \notin \{0, \frac{1}{4}, \frac{1}{2}\}$, every real null $P \neq 0$ of g_κ, every real Q with $g_\kappa^{-1}(P,Q) \neq 0$ and every complex t, a non-gauge wave through order s^4 exists at (P,Q,t) exactly when $\mu = 2t\, g_\kappa^{-1}(P,Q)$ is a root of $\mu^2 - 2A_\kappa(P)\mu + A_\kappa(P)^2 - \operatorname{disc}_\kappa(P)$, that is, $\mu = A_\kappa(P) \pm \sqrt{\operatorname{disc}_\kappa(P)}$. The two branch values differ by $2 f_2(\kappa)\sqrt{B_\kappa(P)}$, up to sign, so the polarization splitting is proportional to $\kappa(3\kappa - 1)(5\kappa - 1)/(2\kappa - 1)$ times a function of the direction; at $\kappa = \frac{1}{3}$ the two values coincide in every direction;

(b) at $\kappa = 1$, where $A_1 = a$ and $\operatorname{disc}_1 = \operatorname{disc}$: along $P = (1,4,1,3)$ with $Q = e_1$ ($g_1^{-1}(P,Q) = 1$) such a wave exists exactly for $t = 109$ and $t = -3$, so the branch values are 218 and -6, the two polarizations disperse differently and neither follows the light cone at this order; along the three-fold axis $(1,1,1,0)$ the two share one value; and the odd orders of the expansion vanish;

(c) every background with $\kappa > \frac{1}{2}$ is birefringent at order K^4: for $0 < x < \sqrt{2}$ the covector $P(x) = (1 + x, 1 - x, 1, 1)$ is null for g_κ at $\kappa = \frac{1}{4} + 1/(2x^2)$, the direction $Q = (1, 1, 1, 1)$ has $g_\kappa^{-1}(P(x), Q) = -2x^2$, and non-gauge waves through order s^4 exist at the two different shifts

$$t_1 = -\frac{x^6 + 3x^4 - 34x^2 - 48}{24x^2(x^2 - 2)}, \qquad t_2 = -\frac{5x^6 + 6x^4 - 116x^2 - 24}{192x^2(x^2 - 2)};$$

as x runs over $(0, \sqrt{2})$, κ runs over every value above $\frac{1}{2}$.

At the background $\kappa = \frac{3}{4}$, the point $x = 1$ of (c), the branch values along $(2, 0, 1, 1)$ are 13 and $\frac{43}{16}$.

Conditions and scope.

Base and premises

The linearized lattice action of the background g_κ (the continued Regge table $R(\kappa)$) with all fifteen edge classes and its gauge modes; classical algebra over $\mathbb{C}$.

Conclusion

The long-wave results of the earlier sections are unchanged: they concern order K^2. At order K^4, which on a lattice of spacing a is order k^2a^2, the two branch values of every Lorentzian background off $\kappa = \frac{1}{2}$ are $A_\kappa \pm \sqrt{\mathrm{disc}_\kappa}$; every background with $\kappa > \frac{1}{2}$, the $\kappa = 1$ lattice included, is birefringent and not Lorentz invariant; the $\kappa = 1$ lattice is anisotropic and birefringent wherever disc $\neq 0$; and at $\kappa = \frac{1}{3}$ the two polarizations travel alike at this order.

Exact computation

The identities behind (a) and (c) are polynomial identities, in the direction after the normalization of the proof and in x, checked by exact computation as the proof describes; they are not reproduced here. The data: the table $R(\kappa)$ is this book's (Theorem 27.28); the fifteen-class quadratic form at zero momentum is part S6 of the data set [210]; the metric polarizations of the two waves of (c) are printed in the proof. Their admixtures, and the computation of (a) and (c), are not printed and are not part of that data set. Part (b) is checked by hand in the proof from the closed forms.

Proof. (a) The branch does not change under $(P, Q) \mapsto (cP, c^3Q)$, $c \neq 0$. On the cone $p_2 = \kappa p_1^2/(4\kappa - 1)$, so $p_1 \neq 0$ when $P \neq 0$; take $p_1 = 4$ and write $P = \mathbf{1} + w$ with $\sum_a w_a = 0$, so that the cone is $|w|^2 = 4/(4\kappa - 1)$. Every Taylor part of the plane-wave form of $R(\kappa)$ is affine in $1/(\kappa - \frac{1}{4})$ (Theorem 27.28(b)), so with $|w|^2$ in its place every identity below is a polynomial identity in w. The order-s^2 equation is the admixture equation: the zero-momentum form on the five non-metric classes is invertible for $\kappa \notin \{0, \frac{1}{4}, \frac{1}{2}\}$, its inverse being polynomial after one scalar factor, and the metric leg is on shell, since the order-K^2 form is $-\frac{1}{4}$ times the Fierz–Pauli form of g_κ. Projecting the order-s^4 equation onto the metric sector by the Schur complement leaves a linear condition on the polarization modulo gauge, the gauge modes decoupling; a non-gauge solution exists exactly when the determinant of that condition on the two physical polarizations vanishes, and that determinant is a nonzero multiple of $\mu^2 - 2A_\kappa\mu + A_\kappa^2 - \mathrm{disc}_\kappa$ at $\mu = 2t\, g_\kappa^{-1}(P, Q)$. These are polynomial identities, proved by exact computation. At $\kappa = \frac{1}{3}$, $f_2 = 0$ and $\mathrm{disc}_\kappa = 0$. (b) At $\kappa = 1$ the odd Taylor orders of the plane-wave form vanish by the

central inversion. At $P = (1, 4, 1, 3)$, $p_1 = 9$ and $p_2 = 27$, so P is null; $p_3 = 93$ and $p_4 = 339$ give $a(P) = 106$ and $\mathrm{disc}(P) = 12544 = 112^2$, so the roots are 218 and -6; and the background identity $K(s)^{\mathsf{T}} g_1^{-1} K(s) = 2ts^4 + \frac{2}{3}t^2 s^6$ is direct. (c) Here $p_1 = 4$ and $p_2 = 4 + 2x^2$, which is $\kappa p_1^2/(4\kappa - 1)$ at $\kappa = \frac{1}{4} + 1/(2x^2)$, so $P(x)$ is null; and $g_\kappa^{-1}(P, Q) = p_1/(1 - 4\kappa) = -2x^2$. The waves at t_1 and t_2 are explicit. Their metric polarizations are

$$H_1(x) = \begin{pmatrix} -(x^2+3x+2) & x^2-2 & -(x+2) & 0 \\ x^2-2 & -(x^2-3x+2) & x-2 & 0 \\ -(x+2) & x-2 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$H_2(x) = \begin{pmatrix} x^2-2 & -(x^2+2) & 4(x+1) & 0 \\ -(x^2+2) & x^2-2 & 4(1-x) & 0 \\ 4(x+1) & 4(1-x) & 8 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

and neither is pure gauge at $P(x)$: a polarization $P \otimes \xi + \xi \otimes P$ whose fourth row vanishes has $2\xi_4 = 0$ and then $\xi_a = 0$ for every a, since $P_4 = 1$, so it is zero, and $H_1(x)$, $H_2(x)$ are not ($8 \neq 0$ and $x^2 - 2 \neq 0$). Their admixtures on the fifteen edge classes, at orders s^2 and s^4, are polynomials in x over the common denominator $192x^2(x-2)(x^2-2)^2$; checking the waves is a polynomial identity in x, proved by exact computation. Finally $t_1 - t_2 = -(x^6+6x^4-52x^2-120)/(64x^2(x^2-2))$, and for $0 < x^2 < 2$ the numerator is below $8+24-120 < 0$, so $t_1 \neq t_2$. At $x = 1$, $\mu = -4t$ gives 13 and $\frac{43}{16}$. □

In plain terms: on every lattice of the family with $\kappa > \frac{1}{2}$ the two graviton polarizations travel at slightly different speeds at wavelengths approaching the lattice spacing, and on the $\kappa = 1$ lattice the speed depends on the direction. Along $(1, 4, 1, 3)$ one polarization is subluminal and the other superluminal at this order. At $\kappa = \frac{1}{3}$ the two travel alike at this order. The guess that the exact branch is the zero set of one edge-class Laplacian is excluded, because such a branch has one value for both polarizations.

27.16 The premises of reading the cost as the graviton's action

Section 27.10 named the premises that turn J's comparison into the graviton's charge: tick-free least postings, the coherent reading, independent axes (the statistical face reading), locality and $\kappa = 1$. None of them follows from the accepted foundation: each is either separated from it by an explicit model of the foundation's facts in which the premise fails, or reduced to one sharper named reading.

Proposition 27.76 (Where the named premises stand)**.** *In classical mathematics:*

(a) Tick-free writing. *No accepted fact makes the ledger write a step by its cheapest record: counting the extra comparisons a longer writing makes orders writings by their number of postings and so restates least writing; every writing of a step leaves the same record for a recognition chain to read, which chooses nothing; and a world that writes the three-counter step with three postings meets the foundation's facts. One structural reading forces the count* $(1, 2, 1)$ *without minimizing: if each step is one comparison event that writes at most one unit on each of its two parties' records, charged per unit, parity and the tick-free lower bound leave exactly one, two and one postings.*

(b) The coherent reading. *With a credit read as lowering its counter (a signed balance, an identification), double entry together with the reading that the charge reads a strain only through what comparison events post forces the charge to read only spatial strains, and so gives it the face-frame parity; neither premise alone does. For such charges the coherent reading is exactly no birefringence at the face wave.*

(c) Locality. *If the derived scalar record is a ledger balance and its updates are double entry, it cannot carry the gap that would force Einstein's trace coefficient; every value of the coefficient, Einstein's included, is reached by a double-entry record, so nothing is selected. Double entry itself is a separate premise.*

(d) $\kappa = 1$. *The readings of the ledger's records into the Kuhn lattice (the sixteen-record cell, whose histories are the Kuhn simplices, and the posting-lattice reading) are positive with both posts in their domain at every* $\kappa \geq 1$*, and a completely positive writing map onto the posts' Kuhn records exists in every record world; so these readings do not give* $\kappa = 1$*. In the reading direction, on the plane of the two posting images, the only linear recovery is positive exactly when* $\kappa = 1$*, which is the purity of each post's lattice record (Theorem 27.42).*

(e) Independent axes. *In the* $\kappa = 1$ *record geometry the Born rule is the coherent carrier's posting law, and reading a strain through the same rule moves each face direction's record only with its own stretch, the sign set by the probing record. Which records probe the strain is not fixed by the accepted results: the unbiased reference state sees no face stretch, single postings couple the face directions, and only the records of the double steps charge the three face directions independently. The statistical face reading is therefore separated, and reading it through the double steps is a named statement that restates face-axis additivity.*

Conditions and scope.

Base and premises
The foundation's accepted facts and the named readings; finite linear algebra; classical mathematics.

Route given
Each separation rests on an explicit model that the proof names and describes but does not print in full: the three-posting world of (a), the double-entry records of (c) that reach every value of the coefficient, the writing maps of (d) with their Choi matrices, and the probes of (e). The reductions are finite linear algebra on the four counters, the six transfers and the fifteen steps, described in the proof.

Proof. Each separation exhibits an explicit model of the accepted facts (for (a), a world of the foundation's interpreter that meets the three facts of Proposition 27.45(a)) in which the premise fails; each reduction is an equivalence between the premise and the named reading, proved by finite linear algebra on the four counters, the six transfers between accounts, or the fifteen steps. (a) A unit posting changes exactly three comparisons by one unit, so a writing with c postings makes $3c$ unit comparison changes, of which a step with k counters keeps $k(4-k)$; the three-posting world writes the triple step forward. (b) Double entry keeps the total, which makes a charge read an event and its reversal alike; with the posting reading this kills the time-space part. (c) A translation-invariant update keeps every total exactly when its zero-wavelength multiplier is one, and a gradient update conserves its total exactly when that multiplier's coefficient vanishes. (d) The writing maps are explicit, with Choi matrices checked positive semidefinite; the recovery on the plane of the two images is a 2×2 problem whose positivity is $\kappa = 1$. (e) The posting law of the strained geometry shifts by $\frac{1}{3} v^{\mathsf{T}} H e_i$ for a probe v, and the cross terms vanish exactly for the double-step probes. □

Two of these readings rest on double entry, the ledger's reversal symmetry, which is itself a premise about writing and not one of the foundation's three facts.

Remark 27.77 (The one-loop graviton)**.** The near-flat one-loop graviton of the $\kappa = 1$ lattice has been computed numerically, and those numbers are not theorems of this book. One tool behind them is: an adaptive integrator over the Brillouin zone with the long-wave corner cut out, built on $\mathbb{R}_\delta$ from interval arithmetic with δ's own π, cosine and sine, proved sound with no omniscience principle and no choice, together with the rule that decides the sign of a zone integral when the enclosure's error plus a bound on the corner is smaller than the enclosure's distance from zero. The enclosure the one-loop question needs has not been certified with it: near the corner the propagator's soft modes turn with the direction of the wave, which defeats every cell-by-cell interval rule of feasible size. The gravity preprint states what is established and what is open at one loop [197].

Questions to work through

1. (Theorem 27.3.) At $K = e_0$ take the strain $h = E_{11} - E_{22}$. Compute $J(1 + \varepsilon h)$ exactly, its long-wave limit and $\mathrm{FP}(h, e_0)$. Then add the gauge mode $E_{03} + E_{30}$ and compute both again.

2. (Theorem 27.5.) For $D = 3$ and $m = (1, -1, 0, 0)$, find two strains that span the TT strains at m.

3. (Theorem 27.24.) Check that k_1 and k_2 are static and null and that Ξ is a gauge mode at $k_1 + k_2$. Using the slot permutation $(0\,9)(1\,8)(2\,6)(4\,7)$ of the central inversion, check on the monomials 000, 444 and 044 of Table 27.2 that both cubic forms are invariant. Finally, explain why the test of part (d) cannot exclude a second-order static field when V_d is replaced by Regge's vertex V_r alone.

4. (Theorem 27.26.) At $\kappa = 1$ compute $\det G$, the four values of Q_t, and check the identity of part (c) for the triangle 012.

5. (Theorem 27.40.) Take $\kappa = \frac{5}{4}$ and a tick-normalized identification. Compute the squared Bloch length of a posting record, the largest probability with which a sharp test can pass it, and the depolarizing strength r.

6. (Theorem 27.44.) Show that the parity law of part (d) is not pair-reading at the site 0, by exhibiting, for each partner, two assignments that agree on the site and the partner and give different posts.

Part VIII

The library, learning and open problems

Part VIII prices the conventions of classical mathematics as it is used in practice, prices the act of learning a law from records, and states what remains open. Chapter 28 shows what the conventions of a classical library cost on $\mathbb{R}_\delta$: a total inverse with $0^{-1} = 0$ costs the LPO function, choosing a representative for every point costs the WLPO function, and a nonnegative derivative gives monotonicity at no more than that price. Chapter 29 treats time, chance and learning: the logic of one recorded history, exchangeable records and de Finetti's theorem, and the exact prices of learning a law in the limit, with finitely many errors and by committing once. Chapter 28 ends with the price table of the mathematics that physics uses, 1467 statements, of which 1166 are free, 279 have an exact price in the table's sense and 22 are open, listed in full in Appendix Q. Chapter 30 collects proved and refuted statements at the frontier and lists the open problems of the whole book exactly.

Chapter 28

The classical library on the line

A standard classical library of algebra, order and analysis divides by zero. Its inverse is a total map with $0^{-1} = 0$, so that $1/0 = 0$, $x/0 = 0$ and $\log 0 = 0$ are values like any other; its linear orders carry stored decisions of $\leq$, $=$ and $<$; its derivative is "the derivative where one exists and 0 elsewhere". These conventions make classical algebra smooth, and classically they cost nothing. What does one of them cost on $\mathbb{R}_\delta$?

Here is the worked case. Suppose i is a map on $\mathbb{R}_\delta$ with $i(0) = 0$ and $x \cdot i(x) = 1$ for every $x \# 0$. Take a binary sequence α and its jump point x_α (Lemma 12.4): $x_\alpha = 2^{-N}$ when N is the first index with $\alpha(N) = 1$, and $x_\alpha = 0$ when there is none. For $\alpha = 0, 0, 0, 1, 0, \ldots$ we get $x_\alpha = \frac{1}{8}$ and $x_\alpha \cdot i(x_\alpha) = \frac{1}{8} \cdot 8 = 1$; for the zero sequence we get $x_\alpha = 0$ and $x_\alpha \cdot i(x_\alpha) = 0$. In general we do not know which case we are in, yet the point $e = x_\alpha \cdot i(x_\alpha)$ is 0 or 1 all the same. The order is cotransitive: since $0 < 1$, either $0 < e$ or $e < 1$. If $0 < e$, then x_α has the inverse $i(x_\alpha)/e$, so $x_\alpha \# 0$ and $e = 1$. If $e < 1$, then $x_\alpha \# 0$ is impossible, because it would give $e = 1$; so $x_\alpha = 0$ and $e = 0$. Stage 7 of any regular sequence naming e lies within $\frac{1}{8}$ of e, so comparing it with $\frac{1}{2}$ reads off the bit, and the bit does not depend on the sequence used. The rule

$$d(\alpha) = \begin{cases} 1, & \text{stage 7 of } x_\alpha \cdot i(x_\alpha) \text{ exceeds } \frac{1}{2}, \\ 0, & \text{otherwise,} \end{cases}$$

decides for every binary sequence whether it ever takes the value 1. It is the LPO function of Definition 21.1: one map that answers the question LPO poses, for all sequences at once. Conversely, the LPO function decides apartness from 0 and so builds the inverse. The convention $0^{-1} = 0$ costs exactly the LPO function.

Not every convention is this expensive. Setting $\sqrt{x} = 0$ for $x \leq 0$ costs nothing, because the extended square root is continuous. The sign function, which one would predict to cost the LPO function as well, costs only the WLPO function: its jump at 0 does not reveal on which side of 0 a point lies. One rule gives a lower bound for every such price (Theorem 28.8), and Table 28.1 lists eighteen conventions with the exact price of each.

The chapter opens Part VIII by reading the rest of the classical library on $\mathbb{R}_\delta$ in the same way. A map that picks a regular sequence for every point, the classical library's choice of representatives, costs exactly the WLPO function (Section 28.3). The classical linear order costs exactly the WLPO function (Section 28.4); the ordered field costs the LPO function and the complete ordered field Markov's principle with a double-negation decision (Section 28.5). The derivative convention costs exactly Markov's principle with a decision of differentiability (Section 28.6), and monotonicity from a nonnegative pointwise derivative costs at most the WLPO function (Section 28.7). Two models show where these principles stop: over intuitionistic second-order arithmetic WLPO does not give Π^0_2 weak excluded middle (Section 28.8), and, in a calculus of streams, WLPO does not collect the signs of the tails of a signed-digit stream (Section 28.9). Section 28.10 proves two theorems that move whole areas of the library at no cost, by density and by algebraic certificates, and reports an audit of the library read on

$\mathbb{R}_\delta$; every count of library theorems or of their uses in this chapter comes from that audit and is not a theorem of the book. Finally, Section 28.11 adds what is new about programs from classical proofs beyond Section 20.4.

Throughout, maps are read as in Section 21.1: a map is a rule given as data, and a proof that every input has exactly one output does not by itself produce a map. "Free", "costs exactly", "at most" and "at least" have the meanings fixed there. Every theorem of this chapter is proved with no choice principle unless its statement names one; the two model constructions of Sections 28.8 and 28.9 reason in classical mathematics with the axiom of choice, and we say so where they begin. A ratio compared with a point stands for its point, as in Chapter 13, and we write 0 and 1 for $\eta(0)$ and $\eta(1)$.

28.1 Tests and decisions as data

Chapter 12 priced the decisions on the line as propositions: deciding $x = 0$ for every point is WLPO, deciding $x > 0$ or $x = 0$ or $x < 0$ is LPO, and a sign for every nonzero point is MP (Corollary 12.18). A classical library stores decisions as data. We record the data forms once and use them in every later section.

Definition 28.1 (Decisions stored as data)**.** Let R be a relation between points of $\mathbb{R}_\delta$. A *decision of R* is a map d from pairs of points to $\{0,1\}$ with $d(x,y) = 1$ exactly when $R(x,y)$. We speak of *decided equality*, a *decided order* $\le$ and a *decided strict order* $<$. A *floor map* is a map $\lfloor\cdot\rfloor$ from $\mathbb{R}_\delta$ to the integers with $\lfloor x\rfloor \le x < \lfloor x\rfloor + 1$ for every x. A map a from $\mathbb{R}_\delta$ to $\{0,1\}$ is a *positivity test* if $a(x) = 1$ exactly when $x > 0$.

A decision procedure for a family of propositions, stored as data, is the same thing as the data form of its principle. For the statements $\exists n\, \alpha(n) = 1$, one for each binary sequence α, it is the LPO function; for $\forall n\, \alpha(n) = 0$ it is the WLPO function; for the propositions $\neg\neg P$ it is the WEM function. A decision used at one fixed proposition inside a proof is different: it costs only excluded middle for that proposition.

Two facts about the jump point carry most reductions in this chapter. For a binary sequence α let x_α be the point of its positive jump presentation (Lemma 12.4, with every sign $+1$). Then

$$x_\alpha = 0 \iff \forall n\, \alpha(n) = 0, \qquad x_\alpha > 0 \iff \exists n\, \alpha(n) = 1, \qquad \neg(x_\alpha < 0). \tag{28.1}$$

The first is Lemma 12.5. For the second, an event at N makes every stage from N on equal to 2^{-N}, which exceeds $2/(n+1)$ at $n = 2^{N+2}$; conversely a positive stage is nonzero, so the bounded search behind it has found an event. The third holds because no stage is negative. The map $\alpha \mapsto x_\alpha$ is a rule: it computes the stages from α.

Lemma 28.2 (Tests descend to points)**.** *For a regular sequence s let $o_s(n) = 1$ when $|s_n| > 2/(n+1)$ and $p_s(n) = 1$ when $s_n > 2/(n+1)$, and 0 otherwise. If s names x, then $x = 0$ exactly when $o_s(n) = 0$ for every n, and $x > 0$ exactly when $p_s(n) = 1$ for some n. Consequently:*

1. *if w is the WLPO function, then $z(x) = w(o_s)$ is a zero test, and $w(p_s)$ is a map whose value is 1 exactly when $x \le 0$;*
2. *if l is the LPO function, then $l(p_s)$ is a positivity test;*

3. *if $x = 0$ or $x = 1$, then the bit $[s_7 > \frac{1}{2}]$ is 1 exactly when $x = 1$.*

In each case the value depends only on x, not on the sequence s that names it.

Proof. The first equivalence is Bishop's zero condition, Lemma 12.15; the second is the definition of $x > 0$, which does not depend on the sequence. In item 1 the bit $w(o_s)$ is 1 exactly when $x = 0$. If s' also names x, the bits $w(o_s)$ and $w(o_{s'})$ are each 1 exactly when $x = 0$, so they are equal: two bits with the same condition for being 1 coincide. So the rule is a map on points in the sense of Section 21.1. The bit $w(p_s)$ is 1 exactly when no stage of s is a positive witness, that is, when $\neg(x > 0)$, which is $x \leq 0$. Item 2 is the same argument with l. For item 3, regularity gives $|s_7 - s_m| \leq \frac{1}{8} + \frac{1}{m+1}$ for every m, so $|x - s_7| \leq \frac{1}{8}$. If $x = 0$ then $s_7 \leq \frac{1}{8} < \frac{1}{2}$, and if $x = 1$ then $s_7 \geq \frac{7}{8} > \frac{1}{2}$; the bit is therefore fixed by which of the two holds. □

Theorem 28.3 (Decisions on the line, as data)**.**

1. *The LPO function exists exactly when the WLPO function exists and MP holds.*
2. *A zero test, decided equality and a decided order $\leq$ each exist exactly when the WLPO function exists.*
3. *An apartness test, a positivity test, a decided strict order $<$ and a floor map each exist exactly when the LPO function exists.*

No choice principle is used in either direction.

Proof. 1. If l is the LPO function, $w(\alpha) = 1 - l(\alpha)$ is the WLPO function, and MP holds: if α is not all zero, $l(\alpha) = 0$ would make every $\alpha(n)$ zero, so $l(\alpha) = 1$. Conversely put $l(\alpha) = 1 - w(\alpha)$. If $l(\alpha) = 1$, then α is not all zero and MP gives an index with $\alpha(n) = 1$; if some $\alpha(n) = 1$, then $w(\alpha) = 0$.

2. From the WLPO function, Lemma 28.2 gives a zero test, and a decided order by $d(x, y) = w(p_s)$ for s naming $x - y$, since $x \leq y$ is $\neg(x - y > 0)$. Decided equality is $d(x, y)\, d(y, x)$, because $x \leq y \leq x$ gives $x = y$ (Proposition 12.19, item 2). Conversely each of the three gives a zero test, $z(x) = d(x, 0)$ or $z(x) = d(x, 0)\, d(0, x)$, and a zero test gives the WLPO function $\alpha \mapsto z(x_\alpha)$ by (28.1).

3. From the LPO function, Lemma 28.2 gives a positivity test a; then $a(x) + a(-x) - a(x)a(-x)$ is an apartness test and $a(y - x)$ decides $x < y$. For a floor map, let x be a point. Search the integers in the order $0, -1, 1, -2, 2, \ldots$ for the first m with $\neg(x < m)$ and $x < m + 1$, each decided by the decided order. The search ends: a stage of a regular sequence naming x gives an integer B with $-B < x < B$, and the largest m between $-B$ and B with $\neg(x < m)$, found by a bounded search, satisfies $x < m + 1$. Any two integers m, m' with this property satisfy $m < m' + 1$ and $m' < m + 1$, so they are equal; the result depends only on x. Conversely, an apartness test a gives $\alpha \mapsto a(x_\alpha)$, which is 1 exactly when $x_\alpha > 0$ by (28.1); a positivity test or a decided $<$ gives the same at once. A floor map gives $\lfloor -x_\alpha \rfloor < 0$ exactly when $x_\alpha > 0$: if $\lfloor -x_\alpha \rfloor = m < 0$ then $-x_\alpha < m + 1 \leq 0$, and if $x_\alpha > 0$ then $m \geq 0$ would give $0 \leq m \leq -x_\alpha < 0$. □

The second item contrasts with Corollary 12.18, which gives the same price for the proposition that every point is 0 or not 0. The difference is real under the reading of this part: by Section 21.1 the data form and the proposition coincide once unique choice is assumed, and the next proposition shows what the data form collects that the proposition does not.

Proposition 28.4 (What a data principle collects)**.**

1. *The LPO function gives* $\mathrm{LPO}_{\mathrm{seq}}$*: for every double sequence of bits A a binary sequence f with $f(i) = 1$ exactly when $A(i, n) = 1$ for some n.*
2. *The WLPO function gives* $\mathrm{WLPO}_{\mathrm{seq}}$ *(Definition 13.8), and countable unique choice into* $\{0, 1\}$ *for* Π^0_1 *relations: if for each i exactly one bit b has $r(i, b, n) = 1$ for every n, then some f has $r(i, f(i), n) = 1$ for all i and n.*
3. *The WEM function gives the WLPO function, and the WEM function with MP gives the LPO function.*

No choice principle is used.

Proof. 1 and 2. Apply the map to each row: $f(i) = l(A(i, \cdot))$, or $f(i) = w(A(i, \cdot))$. For the choice statement put $f(i) = w(\beta_i)$ with $\beta_i(n) = 1 - r(i, 1, n)$, so $f(i) = 1$ exactly when $r(i, 1, n) = 1$ for every n. If $f(i) = 0$, the unique bit is not 1, so it is 0. 3. Put $w(\alpha) = d(\forall n\, \alpha(n) = 0)$; a universal statement about decidable equations is equivalent to its double negation. With MP, Theorem 28.3, item 1, applies. □

In the model of named objects of the computable calculus (Definition 16.20) this is a separation. There LPO holds, as in the proof of Theorem 16.27, but the WLPO function fails: a WLPO function run on the computed codes of the rows of a computable double sequence would compute the sequence f of item 2, and the proof of Theorem 16.27 exhibits a computable double sequence, built from bounded halting, with no computable such f. The same argument refutes the LPO function. So in that model, which has no unique choice, LPO holds and its data form fails; the argument reasons in a classical metatheory.

Remark 28.5 (Under the default reading)**.** Section 21.1 shows that unique choice turns LPO into the LPO function, WLPO into the WLPO function and WEM into the WEM function. Under the default reading of this book, which contains unique choice, every price in this chapter that names a data form therefore becomes the price of the principle: a zero test costs exactly WLPO, a floor map exactly LPO, and so on. We state the theorems in their data form because that is what is proved, and it holds a fortiori under the default reading. Where unique choice changes a statement beyond this translation, the text says so.

28.2 Conventions at excluded points

A convention gives an operation a value where mathematics leaves it undefined: the inverse at 0, the logarithm at 0, the square root of a negative number. On $\mathbb{R}_\delta$ a total map has to produce its value from a regular sequence, without being told whether the point is the excluded one. The conventions we meet fall into three classes, according to how the map behaves near the excluded point.

Definition 28.6 (Jumps)**.** A map $f : \mathbb{R}_\delta \to \mathbb{R}_\delta$ *jumps at* 0 if there are $\varepsilon > 0$ and $r > 0$ with $|f(y) - f(0)| \geq \varepsilon$ for every $y \# 0$ with $|y| < r$. It *jumps on the right* at 0 if this holds for every y with $0 < y < r$. A jump *carries a test* if, in addition, $|f(y) - f(0)| > 0$ implies $y \# 0$ for every y.

The inverse i with $i(0) = 0$ jumps and carries a test. For $y \# 0$ with $|y| < 1$ we have $|i(y)| = 1/|y| > 1$. And $y \cdot i(y)$ is 0 or 1 and is 0 only at $y = 0$, by the worked case at the start of the chapter; so $|i(y)| > 0$ forces $y \cdot i(y) = 1$, hence $y \# 0$. The map with value 1 at 0 and 0 at every $y \neq 0$ jumps but carries no test, since a value can be known to differ from 1 without its argument being known apart from 0. A continuous map does not jump at all. The rule below gives a lower bound for each class with a jump and shows that a continuous convention needs no principle.

Lemma 28.7 (The jump reading is two-valued)**.** *Let $f : \mathbb{R}_\delta \to \mathbb{R}_\delta$, $\varepsilon > 0$ and $r > 0$, and suppose $|f(y) - f(0)| \geq \varepsilon$ whenever $0 < y < r$. For a point y put $y' = \min(|y|, r/2)$ and*

$$e(y) = \min\Big(1,\ \frac{|f(y') - f(0)|}{\varepsilon}\Big).$$

Then e is a map, and for every y: $e(y) = 0$ or $e(y) = 1$, and $e(y) = 0$ exactly when $y = 0$. If moreover $|f(u) - f(0)| > 0$ implies $u \# 0$ for every u, then $e(y) = 1$ exactly when $y \# 0$.

Proof. The point y' satisfies $0 \leq y' \leq r/2 < r$, and $y' > 0$ exactly when $|y| > 0$, that is, when $y \# 0$, since $r/2 > 0$. So $y \# 0$ gives $0 < y' < r$, hence $|f(y') - f(0)| \geq \varepsilon$ and $e(y) = 1$; and $y = 0$ gives $y' = 0$ and $e(y) = 0$.

Now let y be arbitrary. Since $0 < 1$, cotransitivity gives $0 < e(y)$ or $e(y) < 1$. If $e(y) < 1$, then $y \# 0$ is impossible, by the first paragraph; a point that is not apart from 0 equals 0, because every stage of a regular sequence naming it then satisfies $|s_n| \leq 2/(n+1)$ (Lemma 12.15); so $y = 0$ and $e(y) = 0$. If $0 < e(y)$, then $|f(y') - f(0)| > 0$, so $y' \neq 0$ and $y \neq 0$. We show $\varepsilon \leq |f(y') - f(0)|$, which is the negation of $|f(y') - f(0)| < \varepsilon$: under that strict inequality $y \# 0$ is impossible, so $y = 0$, against $y \neq 0$. Hence $e(y) = 1$. No step uses Markov's principle: the conclusion $\varepsilon \leq |f(y') - f(0)|$ is itself a negation.

For the last assertion, $e(y) = 1$ gives $|f(y') - f(0)| > 0$, hence $y' \# 0$ by the hypothesis, hence $y' > 0$ and $y \# 0$. □

Theorem 28.8 (The convention rule)**.** *On $\mathbb{R}_\delta$:*

1. *If some map jumps at* 0*, or jumps on the right at* 0*, the WLPO function exists; conversely, if the WLPO function exists, some map jumps at* 0*.*
2. *If some map jumps at* 0 *and its jump carries a test, the LPO function exists; conversely, if the LPO function exists, some map has such a jump.*
3. *A map continuous at* 0 *(for every k some j has $|f(y) - f(0)| \leq 1/(k+1)$ whenever $|y| \leq 1/(j+1)$) does not jump on the right at* 0*. Every map g of the ratios into the ratios that is uniformly continuous with a modulus extends to a uniformly continuous map of $\mathbb{R}_\delta$, with a modulus, agreeing with g at every ratio.*

No choice principle is used.

Proof. 1. A jump at 0 is in particular a jump on the right. By Lemma 28.7 and Lemma 28.2, item 3, the map $y \mapsto 1 - [\text{ stage 7 of } e(y) > \frac{1}{2}]$ is a zero test, and Theorem 28.3 gives the WLPO function. Conversely, a zero test z gives the map $f(y) = z(y)$, read as a point, which is 1 at 0 and 0 at every $y \# 0$: a jump of size 1.

2. Now $e(y) = 1$ exactly when $y \# 0$, so the bit of $e(y)$ is an apartness test, and Theorem 28.3 gives the LPO function. Conversely the apartness test a, read as a point, is 0 at 0 and 1 at every $y \# 0$, and $|a(y) - a(0)| > 0$ means $a(y) = 1$, that is, $y \# 0$.

3. Suppose f is continuous at 0 and $|f(y) - f(0)| \geq \varepsilon$ for $0 < y < r$. Take k with $1/(k+1) < \varepsilon$, its j, and $y = \min(1/(j+1), r/2)$. Then $0 < y < r$, and $\varepsilon \leq |f(y) - f(0)| \leq 1/(k+1) < \varepsilon$.

For the extension, let ω be a modulus of g: $|q - q'| \leq 1/(\omega(k)+1)$ gives $|g(q) - g(q')| \leq 1/(k+1)$. Put $M(k) = \max_{i \leq 2k+1} \omega(i)$, and for a regular sequence s let $t_k = g(s_{4M(k)+3})$. For $k \leq k'$, $|s_{4M(k)+3} - s_{4M(k')+3}| \leq 1/(2M(k)+2) \leq 1/(\omega(2k+1)+1)$, so $|t_k - t_{k'}| \leq 1/(2k+2)$ and t is regular; the point it names lies within $1/(2k+2)$ of t_k for every k. Two sequences naming the same point have $|s_n - s'_n| \leq 2/(n+1)$ at every stage (Theorem 12.17 and its proof), so their sequences t and t' satisfy $|t_k - t'_k| \leq 1/(2k+2)$ and name the same point. The map $F(x) =$ the point of t is therefore a map on points, and at a ratio q it is $g(q)$. For the modulus, let $|x - y| \leq 1/(2M(2k+1)+2)$ and put $j = 2k+1$. Stage $n = 4M(j)+3$ of sequences s, s' naming x, y satisfies $|s_n - s'_n| \leq 2/(n+1) + |x - y| \leq 1/(M(j)+1) \leq 1/(\omega(2k+1)+1)$, so $|t_j - t'_j| \leq 1/(2k+2)$ and $|F(x) - F(y)| \leq 1/(4k+4) + 1/(2k+2) + 1/(4k+4) = 1/(k+1)$. The modulus is $k \mapsto 2M(2k+1)+1$. □

The second assertion of part 3 is why continuous conventions are free: a convention given by a uniformly continuous formula on the ratios is already a map on the line. Part 3 leaves a gap: a map can be discontinuous at 0 without jumping, and then the rule does not apply.

Theorem 28.9 (The prices of the conventions)**.** *On $\mathbb{R}_\delta$, with no choice principle in either direction:*

1. *A map i with $i(0) = 0$ and $x \cdot i(x) = 1$ for every $x \# 0$ exists exactly when the LPO function exists. The same holds for a map with $i(0) = 0$ and $x \cdot i(x) = 1$ for every $x \neq 0$; for a division map v with $v(a, 0) = 0$ and $v(a, b) \cdot b = a$ for every $b \# 0$; and, for each n, for a map q with $q(0) = 0$ and $x^{n+1} q(x) = 1$ for every $x \# 0$.*

2. *A map L with $L(0) = 0$ and $\exp(L(x)) = |x|$ for every $x \# 0$ exists exactly when the LPO function exists.*

3. *A map P with $P(0) = 1$ and $P(y) = 0$ for every $y \neq 0$, the convention $0^0 = 1$, $0^y = 0$, exists exactly when the WLPO function exists.*

4. *A sign map S with $S(0) = 0$, $S(x) = 1$ for $x > 0$ and $S(x) = -1$ for $x < 0$ exists exactly when the WLPO function exists.*

5. *The following exist with no principle: a map R with $R(x) \geq 0$ for every x, $R(x)^2 = x$ for $x \geq 0$ and $R(x) = 0$ for $x \leq 0$; the natural powers x^n; truncated subtraction on the natural numbers; the truncation of the integers to the natural numbers.*

6. *Every $x \neq 0$ has an inverse exactly when MP holds.*

Proof. 1. Let i be given and put $e(x) = x \cdot i(x)$. Cotransitivity at $0 < 1$ gives $0 < e(x)$ or $e(x) < 1$. In the first case x has the inverse $i(x)/e(x)$, so $x \# 0$ by Proposition 12.19, item 3, and $e(x) = 1$. In the second, $x \# 0$ is impossible, so $x = 0$ and $e(x) = 0$. So e is two-valued and equals 1 exactly at the points apart from 0; its bit (Lemma 28.2, item 3) is an apartness test, and Theorem 28.3 gives the LPO function. Conversely, the LPO function gives an apartness test a; put $i(x) = x^{-1}$ if $a(x) = 1$, which is defined because $a(x) = 1$ supplies $x \# 0$, and $i(x) = 0$ otherwise. A map specified at the points $x \neq 0$ is specified in particular at the points $x \# 0$; conversely the LPO function gives MP (Theorem 28.3, item 1), which turns $x \neq 0$ into $x \# 0$ (Corollary 12.18), so the map just built serves. For division, $x \mapsto v(1, x)$ is an inverse of the first kind and $v(a, b) = a \cdot i(b)$ is a division map. For negative powers, $x \mapsto x^n q(x)$ is an inverse of the first kind, and $q(x) = i(x)^{n+1}$ is a map of the required kind.

2. Let L be given and put $g(y) = |y| \exp(-L(y))$. At $y \# 0$, $g(y) = \exp(L(y)) \exp(-L(y)) = 1$; at $y = 0$, $g(y) = 0$. As in part 1, $0 < g(y)$ gives $|y| > 0$, because $\exp(-L(y)) > 0$, hence $y \# 0$ and $g(y) = 1$, while $g(y) < 1$ excludes $y \# 0$, so $y = 0$ and $g(y) = 0$. So the bit of g is an apartness test. Conversely, with an apartness test a put $L(x) = \log |x|$ when $a(x) = 1$, using the logarithm of a positive point (Definition 21.4), and $L(x) = 0$ otherwise; Section 21.2 proves $\exp(\log |x|) = |x|$.

3. Every $y \# 0$ is $\neq 0$, so $|P(y) - P(0)| = 1$ there: P jumps at 0, and Theorem 28.8, part 1, gives the WLPO function. Conversely, a zero test, read as a point, is such a map.

4. For $y \# 0$, $|S(y) - S(0)| = 1$, so S jumps at 0 and part 1 of Theorem 28.8 applies. Conversely, let w be the WLPO function and $u(x) = w(p_s)$ for s naming x, so that $u(x) = 1$ exactly when $\neg(x > 0)$ (Lemma 28.2). Put $S(x) = 1$ if $u(x) = 0$; otherwise $S(x) = -1$ if $u(-x) = 0$; otherwise $S(x) = 0$. If $x > 0$ then $u(x) = 0$ and $S(x) = 1$. If $x < 0$ then $\neg(x > 0)$ and $-x > 0$, so $S(x) = -1$. If $x = 0$ both tests return 1 and $S(x) = 0$.

5. Put $R(x) = \sqrt{\max(x, 0)}$. The square root of a nonnegative point (Proposition 12.19, item 5) is computed stage by stage from a regular sequence naming the point, by bisection on ratios, and the bound $|\sqrt{a} - \sqrt{b}| \leq \sqrt{|a - b|}$ for $a, b \geq 0$ makes the result independent of the sequence; so R is a map, uniformly continuous, with no jump. Then $R(x)^2 = \max(x, 0)$, which is x for $x \geq 0$ and 0 for $x \leq 0$. Natural powers are defined by recursion, and the two truncations are decided by comparisons of integers.

6. By Proposition 12.19, item 3, a point has an inverse exactly when it is apart from 0, and Corollary 12.18 prices $x \neq 0 \to x \# 0$ at MP. □

The sign is the instructive case. Its jump at 0 looks like the jump of the inverse, and a first guess prices it at the LPO function. But the specification of the sign says nothing at a point that is merely not 0: the map built in part 4 returns 1 at every point that is not nonpositive, a condition weaker than positivity unless MP holds. Its jump carries no test, and part 1 of the rule gives the WLPO function, which part 4 shows is the exact price.

Table 28.1 collects eighteen conventions of a classical library. Rows 13 to 16 are decisions stored as data, priced by Theorem 28.3; a ceiling map is $x \mapsto -\lfloor -x \rfloor$ and costs what a floor map costs. Row 10, the derivative convention, is an operator on all maps, and its exact price

Table 28.1. Conventions of a classical library at excluded points, and their exact prices on $\mathbb{R}_\delta$. "Jump, test" is part 2 of Theorem 28.8, "jump" part 1, "continuous" part 3; a decision is a map to $\{0, 1\}$. Every price is an equivalence proved with no choice principle.

	Convention	Kind	Price	Result
1	inverse, $0^{-1} = 0$, specified at $x \# 0$	jump, test	LPO function	28.9.1
2	inverse, $0^{-1} = 0$, specified at $x \neq 0$	jump, test	LPO function	28.9.1
3	division, $a/0 = 0$	jump, test	LPO function	28.9.1
4	$x^{-(n+1)}$ with value 0 at 0, each n	jump, test	LPO function	28.9.1
5	$\log 0 = 0$ and $\log x = \log \lvert x \rvert$	jump, test	LPO function	28.9.2
6	$0^0 = 1$ and $0^y = 0$ for $y \neq 0$	jump	WLPO function	28.9.3
7	natural powers x^n	none	free	28.9.5
8	$\sqrt{x} = 0$ for $x \leq 0$	continuous	free	28.9.5
9	sign, with sign of 0 equal to 0	jump	WLPO function	28.9.4
10	derivative where one exists, 0 elsewhere	operator	MP and the differentiability decision	28.24
11	truncated subtraction on $\mathbb{N}$	none	free	28.9.5
12	truncation of $\mathbb{Z}$ to $\mathbb{N}$	none	free	28.9.5
13	floor and ceiling	decision	LPO function	28.3.3
14	decided equality	decision	WLPO function	28.3.2
15	decided $\leq$	decision	WLPO function	28.3.2
16	decided $<$	decision	LPO function	28.3.3
17	a hypothesis $x \neq 0$ read as $x \# 0$	reading	MP	28.9.6
18	$\lvert x \rvert$, max, min	none	free	12.19

is the subject of Section 28.6: the rule gives the WLPO function as a lower bound, and the operator costs more. Row 17 is not a convention at all; it is the reading of a hypothesis $x \neq 0$ as apartness, and its price is Markov's principle.

The rule gives the lower bound of every row it covers, and Theorem 28.9 supplies the matching construction. Rows 1 to 5 are jumps whose size is positive only away from the excluded point, so their price is at least the LPO function, and exactly that by Theorem 28.9; rows 6 and 9 are jumps without that test, at least and exactly at the WLPO function; rows 7, 8, 11, 12 and 18 do not jump. The decisions of rows 13 to 16 are indicators of jumps: equality and $\leq$ give zero tests, and $<$ and the floor give apartness tests. Real powers of negative numbers with non-integer exponents are left unpriced; no row of the audit reported in Section 28.10 uses them. Among the uses of the classical library that the audit counted for Recognition Science's forcing chain and its gravity sector, 584 uses of 72 library theorems concern inverse or division, where the value at 0 can enter; 27 uses of 4 theorems concern integer powers, 9 uses of 6 theorems the logarithm, 12 uses of 7 theorems real powers, 21 uses of 9 theorems the square root, 4 uses of 3 theorems the derivative, 2 uses of one theorem truncated subtraction, and 27 uses of 6 theorems stored decisions. No use involves the sign, the integer truncation or the floor.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ with its free ordered-ring structure; maps read as in Section 21.1.

Conclusion

A convention that jumps at the excluded point costs at least the WLPO function, and at least the LPO function when its jump reveals apartness; a map that jumps exists exactly when the WLPO function does, and one whose jump carries a test exactly when the LPO function does; a continuous convention is free. For the eighteen conventions of Table 28.1 the price is exact (Theorems 28.9, 28.3 and 28.24, and Proposition 12.19 for row 18); under unique choice each price is the corresponding principle (Remark 28.5).

Not claimed

That the rule decides every discontinuous convention: a map can be discontinuous at a point without jumping there. Nor that a jump fixes the price: row 10 costs more than the lower bound its jump gives.

28.3 Choosing representatives

A point of $\mathbb{R}_\delta$ is a class of regular sequences. Every point has a regular sequence naming it, and for one given point we may use one, because an assertion about a single point is a proposition. A classical library goes further: with the axiom of choice it fixes one representative of every class at once, and many of its constructions read a point through that representative. On $\mathbb{R}_\delta$ such a choice would be a map s from points to regular sequences with $s(x)$ naming x, a *section* of the passage from sequences to points. Chapter 12 showed that countable choice supplies representatives for one sequence of points at a time and decides nothing (Theorem 12.22). A section is a different object, and it has a price.

The price comes from one observation. A section lets us look at a stage of the chosen sequence: the bit "stage 2 of $s(x)$ is at most $\frac{1}{2}$" is a map from points to $\{0,1\}$, and it is 1 at 0 and 0 at 1. A two-valued map on the line is already strong.

For a binary sequence β write $\nu_n(\beta) = \sum_{k<n} \beta(k)2^{n-1-k}$ for the numeral of its first n digits and $[\beta]$ for the point $\sum_k \beta(k)2^{-(k+1)}$, named by the regular sequence of the ratios $\nu_n(\beta)/2^n$; so β is a binary expansion of $[\beta]$ in the sense of Section 12.9. If $\beta(k) = 1$ for every $k \geq N$, then $[\beta] = (\nu_N(\beta) + 1)/2^N$, and if $\beta(k) = 0$ for every $k \geq N$, then $[\beta] = \nu_N(\beta)/2^N$.

Theorem 28.10 (Two values give the WLPO function)**.** *Let g be a map from $\mathbb{R}_\delta$ to $\{0,1\}$, and let a and b be points with $g(a) \neq g(b)$. Then the WLPO function exists. No choice principle is used.*

Proof. Put $G(t) = g(a + t(b-a))$ if $g(a) = 0$ and $G(t) = 1 - g(a + t(b-a))$ if $g(a) = 1$. Then G is a map to $\{0,1\}$ with $G(0) = 0$ and $G(1) = 1$.

Bisection. Define digits $\beta(n)$ by recursion. Let $\ell_n = \nu_n(\beta)$, so $\ell_0 = 0$, and look at the midpoint $m_n = (2\ell_n+1)/2^{n+1}$ of $[\ell_n/2^n, (\ell_n+1)/2^n]$: put $\beta(n) = 1$ if $G(m_n) = 0$ and $\beta(n) = 0$ if $G(m_n) = 1$. By induction on n,

$$G\big(\ell_n/2^n\big) = 0 \qquad \text{and} \qquad G\big((\ell_n+1)/2^n\big) = 1, \tag{28.2}$$

since a midpoint with value 0 becomes the new left end and one with value 1 the new right end. Each step is a case distinction on a bit. Let $c = [\beta]$ and $v = G(c)$.

Modified names. For a binary sequence α let $\sigma_\alpha(k) = 1$ when $\alpha(i) = 1$ for some $i \le k$, a bounded search. If $v = 0$, let $\mu(\alpha)$ be the sequence $\max(\beta(k), \sigma_\alpha(k))$; if $v = 1$, the sequence $\min(\beta(k), 1 - \sigma_\alpha(k))$. If α is all zero, then $\mu(\alpha) = \beta$. If α has a first 1 at N, then $\mu(\alpha)$ agrees with β below N and is constant from N on: all ones when $v = 0$, all zeros when $v = 1$. So $[\mu(\alpha)]$ is the right end $(\ell_N + 1)/2^N$ in the first case and the left end $\ell_N/2^N$ in the second, and by (28.2) $G([\mu(\alpha)]) = 1 - v$ in both.

The function. Put $d(\alpha) = 1$ if $G([\mu(\alpha)]) = v$ and $d(\alpha) = 0$ otherwise; d is a composite of maps. If α is all zero, then $[\mu(\alpha)] = c$ and $d(\alpha) = 1$. If $d(\alpha) = 1$ and $\alpha(n) = 1$ for some n, the first 1 of α lies at some $N \le n$, and then $G([\mu(\alpha)]) = 1 - v \neq v$; so every $\alpha(n)$ is 0. Hence $d(\alpha) = 1$ exactly when α is all zero. □

The bisection is the familiar proof that a two-valued function on an interval has no continuous version; here it returns a map rather than a proposition. Three consequences follow at once. A map from $\mathbb{R}_\delta$ into any set with decidable equality, such as the integers, that takes two different values gives the WLPO function: compose with the decided equality to one of the values. A map assigning to every point of $[0, 1]$ a binary expansion gives it: the first digit of an expansion of 0 is 0, since $\eta(e_0/2) \le 0$, and of 1 is 1, since $1 \le \eta(e_0/2 + \frac{1}{2})$; compose with the clamp $x \mapsto \min(\max(x, 0), 1)$. A map assigning to every point of $[-1, 1]$ a signed-digit expansion gives it in the same way, since the first digit of an expansion of 1 is 1 and of -1 is -1. Every point of $[-1, 1]$ has a signed-digit expansion with no principle (Proposition 12.62); what costs the WLPO function is a map that writes one out for every point.

Theorem 28.11 (Choosing representatives costs exactly the WLPO function)**.** *Each of the following exists exactly when the WLPO function exists, with no choice principle in either direction:*

1. *a map from $\mathbb{R}_\delta$ to $\{0, 1\}$ taking two different values;*
2. *a map from $\mathbb{R}_\delta$ to the integers taking two different values;*
3. *a map assigning to every point of $[0, 1]$ a binary expansion of it;*
4. *a map assigning to every point of $[-1, 1]$ a signed-digit expansion of it;*
5. *a section: a map s from points to regular sequences with $s(x)$ naming x for every point x;*
6. *a section over $[0, 1]$;*
7. *a map s from points to regular sequences with $s(0)$ naming 0 and $s(1)$ naming 1;*
8. *a map q from points to ratios with $|x - q(x)| \le 1$ for every x;*
9. *a map assigning to every point x a sequence of ratios that converges to x: for every k some M has $|x - q_n| \le 1/(k + 1)$ for all $n \ge M$.*

Proof. Each object gives two values. Items 1 to 4 were treated above. For item 7, the bit $g(x) = [\, s(x)_2 \le \frac{1}{2} \,]$ compares two ratios, so it is a map; stage 2 of a sequence naming x lies

within $\frac{1}{3}$ of x, so $g(0) = 1$ and $g(1) = 0$. Items 5 and 6 give item 7, composing with the clamp for item 6. For item 8, $|q(0)| \le 1$ and $q(3) \ge 2$, so $[\, q(x) \le 1 \,]$ separates 0 from 3. For item 9, the sequences for 0 and for 3 come within 1 of their points from some indices on; at one index n beyond both, the bit $[\, q_n \le \frac{3}{2} \,]$ separates 0 from 3. Theorem 28.10 gives the WLPO function in every case.

Conversely, let w be the WLPO function. Theorem 28.3 gives a zero test, which is 1 at 0 and 0 at 1: items 1 and 2. It also gives a decided order $\le$. For item 3 run the bisection of the proof of Theorem 12.61 with the decided comparisons $B(n, j) = [\, j/2^n \le x \,]$ in place of the table chosen there: if $B(n, j) = 0$ then $\neg(j/2^n \le x)$, which gives $x \le j/2^n$ because $j/2^n \le x$ is $\neg(x < j/2^n)$; nothing is chosen. For item 4, a binary expansion (e_i) of $(x + 1)/2$ gives the signed digits $2e_i - 1$ of x: their partial sums are $2c_n - 1 + 2^{-n}$, and $2c_n - 1 \le x \le 2c_n - 1 + 2^{1-n}$.

For item 8, search the integers in a fixed order for the first m with $m - 1 \le x$ and $x \le m + 1$, both decided. The search ends, because stage 1 of a sequence naming x lies within $\frac{1}{2}$ of x and the integer nearest to it qualifies; the result depends only on x. For item 5 we turn q into a section. Put $s(x)_n = q\big(2(n + 1)x\big)/\big(2(n + 1)\big)$. Then $|s(x)_n - x| \le 1/(2n + 2)$, so $|s(x)_m - s(x)_n| \le 1/(2m + 2) + 1/(2n + 2)$ and $s(x)$ is regular; and a regular sequence t naming x has $|t_n - x| \le 1/(n + 1)$, so $|s(x)_n - t_n| \le 2/(n + 1)$ for every n and $s(x)$ names x, as in the proof of Lemma 12.15. Items 6, 7 and 9 follow from item 5. □

A section gives representatives to every family of points, indexed by any set, by composition. With representatives the limit of a Cauchy sequence can be written down, and so the WLPO function buys completeness without countable choice.

Corollary 28.12 (Completeness at the WLPO function)**.** *Assume the WLPO function. Then every family of points $(F_i)_{i \in I}$ has a family of regular sequences naming it, and every sequence of points with $|F_m - F_n| \le 1/(k + 1)$ for all $m, n \ge k$ has a limit L with $|F_m - L| \le 1/(k + 1)$ for all $m \ge k$. No choice principle is used.*

Proof. Let s be a section and $f(i) = s(F_i)$. For the limit, put $t_n = s(F_{4n+3})_{4n+3}$. Then $|t_n - F_{4n+3}| \le 1/(4n + 4)$, and for $m \ge n$ the modulus gives $|F_{4n+3} - F_{4m+3}| \le 1/(4n + 4)$, so $|t_n - t_m| \le 3/(4n + 4) < 1/(n + 1)$ and t is regular. Let L be its point. For $m \ge k$ and every $n \ge k$, $|F_m - L| \le |F_m - F_{4n+3}| + |F_{4n+3} - t_n| + |t_n - L| \le 1/(k + 1) + 2/(n + 1)$, and since n is arbitrary, $|F_m - L| \le 1/(k + 1)$. □

Chapter 12 reached the same limit with countable choice, which selects representatives sequence by sequence and decides nothing. A section selects them point by point, uniformly, and that costs exactly the WLPO function. In classical mathematics the choice operator that picks a member of each equivalence class is a section of $\mathbb{R}_\delta$; so the object behind every representative choice of a classical library, read on $\mathbb{R}_\delta$, costs exactly the WLPO function. Under unique choice (Remark 28.5) Theorem 28.11 says that each of the nine objects exists exactly when WLPO holds.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ as a set of classes of regular sequences; maps read as in Section 21.1.

Conclusion

A two-valued map on the line, a map writing out a name or a representative for every point, or a rational approximation within 1 of every point, each costs exactly the WLPO function; with it the line is complete for Cauchy sequences with a modulus, with no countable choice.

Not claimed

That countable choice of representatives, one sequence of points at a time, gives the WLPO function; it decides none of LPO, WLPO, LLPO and MP (Theorem 12.22).

28.4 The linear order and the ordered field

On $\mathbb{R}_\delta$ the strict order comes first: $x < y$ when $y - x$ has a positive stage, and $x \le y$ is defined as $\neg(y < x)$. A classical library goes the other way. Its basic notion is a total order $\le$, and it defines the strict order from it. We read its structures by their content.

Definition 28.13 (The classical structures, by content)**.** A *linear-order structure* on a set consists of a relation $\le$ that is reflexive, transitive, antisymmetric and total; a relation $<$ required to satisfy $x < y$ exactly when $x \le y$ and not $y \le x$; maps max and min with $\max(a,b) = b$ if $a \le b$ and $\max(a,b) = a$ otherwise, and dually; and stored decisions of $\le$, $=$ and $<$. A *field structure* on the ring $\mathbb{R}_\delta$ is a map $x \mapsto x^{-1}$ with $0^{-1} = 0$ and $x \cdot x^{-1} = 1$ for every $x \neq 0$. An *ordered field* is a field structure with a linear-order structure satisfying the strict-ordered-ring laws: $a < b$ gives $a + c < b + c$, $0 < c$ and $a < b$ give $ac < bc$, and $0 < 1$, together with the corresponding laws for $\le$ (addition preserves and cancels $\le$, and $0 \le 1$), which hold on $\mathbb{R}_\delta$ with no principle. A *floor structure* is a linear-order structure together with maps $\lfloor\cdot\rfloor$ and $\lceil\cdot\rceil$ to the integers with $z \le \lfloor a \rfloor$ exactly when $z \le a$, and $\lceil a \rceil \le z$ exactly when $a \le z$, for all integers z. The *Archimedean property* states that for every x and every $y > 0$ some natural number n has $x \le ny$.

Read on $\mathbb{R}_\delta$ with δ's own $\le$, the definition forces the strict order: $x \le y$ and $\neg(y \le x)$ is $\neg(y < x) \wedge \neg\neg(x < y)$, which is $\neg\neg(x < y)$, since $x < y$ already excludes $y < x$. So there are two ways to put a classical linear order on the line: with δ's $\le$ and the strict order $\neg\neg <$ that the definition forces, or with δ's own $<$, which agrees with $\neg\neg <$ exactly when MP holds. They have different prices.

Theorem 28.14 (The classical linear order costs exactly the WLPO function)**.**

1. *If a linear-order structure on $\mathbb{R}_\delta$ has δ's $\le$ as its $\le$, the WLPO function exists, and the structure's $<$ is $\neg\neg(x < y)$.*
2. *Conversely, the WLPO function gives a linear-order structure whose $\le$ is δ's $\le$ and whose $<$ is $\neg\neg(x < y)$; with δ's sum and product it satisfies the strict-ordered-ring laws.*

No choice principle is used.

Proof. 1. The structure stores a decision of δ's $\le$; Theorem 28.3, item 2, gives the WLPO function. The form of $<$ was computed above.

2. Theorem 28.3 gives a decided order d. Totality: if $d(x,y) = 1$ then $x \le y$; if $d(x,y) = 0$ then $\neg(x \le y)$, that is, $\neg\neg(y < x)$, and then $x < y$ is impossible, so $y \le x$. Decided equality is $d(x,y)d(y,x)$, by antisymmetry (Proposition 12.19, item 2), and the decided strict order is $d(x,y)(1 - d(y,x))$. For max take δ's own max (Proposition 12.19, item 5): if $a \le b$ it equals b, and if not, then $b \le a$ by totality and it equals a; so it is the case split the definition asks for, and min likewise. Reflexivity, transitivity and antisymmetry of $\le$ are Proposition 12.19, item 2. The structure's $<$ is $\neg\neg(x < y)$, and the strict-ordered-ring laws for it follow from the laws for δ's $<$ in Proposition 12.19, item 1, applied under the double negation: from $\neg\neg(a < b)$ we get $\neg\neg(a + c < b + c)$, and from $\neg\neg(0 < c)$ and $\neg\neg(a < b)$ we get $\neg\neg(ac < bc)$. □

Theorem 28.15 (The classical ordered field costs exactly the LPO function)**.** *Each of the following exists on $\mathbb{R}_\delta$, with δ's sum and product and, where an order is part of the structure, with δ's $\le$ and δ's $<$, exactly when the LPO function exists: a field structure; a linear-order structure; an ordered field; a floor structure. The strict-ordered-ring laws for δ's $\le$ and the strict order it forces are free. The Archimedean property for δ's $\le$ and the strict order it forces holds exactly when MP holds. No choice principle is used.*

Proof. A field structure is row 2 of Table 28.1 (Theorem 28.9, item 1). A linear-order structure with δ's $<$ stores a decided $<$, hence gives the LPO function (Theorem 28.3, item 3); an ordered field and a floor structure contain one. Conversely, the LPO function gives decided $\le$ and $<$, and MP (Theorem 28.3). Build the structure of Theorem 28.14, item 2, but with δ's $<$: the required identity of $x < y$ with $x \le y \wedge \neg(y \le x)$, which is $\neg\neg(x < y)$, is MP for the points $y - x$ (Corollary 12.18). The field structure is Theorem 28.9, item 1, and the strict-ordered-ring laws for δ's $<$ are Proposition 12.19, item 1. For the floor structure take the floor map of Theorem 28.3 and $\lceil a \rceil = -\lfloor -a \rfloor$. If $z \le \lfloor a \rfloor$ then $z \le a$; if $z \le a$ and $\lfloor a \rfloor < z$, then $\lfloor a \rfloor + 1 \le z \le a$, against $a < \lfloor a \rfloor + 1$.

The strict-ordered-ring laws for $\le$ and $\neg\neg <$ are the last step of the proof of Theorem 28.14 and use no decision. For the Archimedean property, MP turns $\neg\neg(0 < y)$ into $0 < y$, and then Proposition 12.19, item 4, gives n with $x/y < n$, so $x \le ny$. Conversely, let α be a binary sequence that is not all zero. Then $\neg\neg(0 < x_\alpha)$ by (28.1), and the property gives n with $1 \le nx_\alpha$. Cotransitivity at $0 < 1$ gives $0 < nx_\alpha$ or $nx_\alpha < 1$; the second is excluded, so $nx_\alpha > 0$, hence $x_\alpha > 0$ and $\alpha(k) = 1$ for some k. □

The two theorems separate what a lemma about a linear order asks of the line. Its hypotheses may be stated with δ's $<$ at no cost, and its conclusions transfer at no cost when they are stable under double negation. Only a conclusion that has to produce δ's $<$ from the library's $<$ costs more, and the extra price is exactly Markov's principle.

Proposition 28.16 (Where the strict order costs Markov's principle)**.**

1. *For all points, $x < y$ gives $x \le y$ and $\neg(y \le x)$. No principle is used.*
2. *The converse, for all points x and y, holds exactly when MP holds.*
3. *The statement "for every positive a, $1 < \max(a, a^{-1})$ exactly when $a \neq 1$" holds exactly when MP holds.*

Proof. 1. $x < y$ excludes $y < x$, so $x \leq y$, and $y \leq x$, which is $\neg(x < y)$, is refuted. 2. The hypothesis $x \leq y \wedge \neg(y \leq x)$ is $\neg\neg(x < y)$, and $\neg\neg(z > 0) \to z > 0$ for all points is MP (Corollary 12.18). 3. Under MP, $a \neq 1$ gives $a \# 1$, so $a > 1$ or $a^{-1} > 1$; and $1 < \max(a, a^{-1})$ excludes $a = 1$. Conversely, let $z \neq 0$ and $a = 1 + z^2$. Then $a \neq 1$, since $z^2 = 0$ would give $z = 0$, so $1 < \max(a, a^{-1}) = a$, hence $z^2 > 0$ and $z \# 0$. That every $z \neq 0$ is apart from 0 is MP (Corollary 12.18). □

With the linear order of Theorem 28.14 in place, a classical lemma about ordered groups, rings and fields can be read on $\mathbb{R}_\delta$ in one of three ways: at the price of the order alone, the WLPO function, when its statement only assumes strict inequalities and concludes something stable under double negation; at Markov's principle on top of the WLPO function, which together make the LPO function, when it produces a strict inequality; or at the price of a convention it states, such as $0^{-1} = 0$. The audit reported in Section 28.10 applied this criterion to 102 lemmas of the classical theory of ordered groups, rings and fields: those that its later routes through the ordered field of Theorem 28.15 price at the LPO function, among the rows its first transfer does not move. For each row it recorded a proof of an implication from the price to the δ statement, or of the δ statement outright, with no choice principle except in the two rows noted below. We report its counts; the row-by-row arguments are not reproduced. Fifty-six rows become free: 14 are class statements whose structure has a free instance, 3 are free classes on $\mathbb{R}_\delta$, 5 hold by definition, 6 are strict conclusions about positive points proved directly, 16 are proved free on the line although the transfer through the linear order prices them at the WLPO function, and 12 more, eight about fields and four about parity, are proved free on the line directly. A typical row of the sixteen is $f(\max(x, y)) = \max(f(x), f(y))$ for monotone f: an equation, so the case split on $x \leq y$, which holds up to double negation, costs nothing. Twenty-seven rows are proved at the WLPO function, as an upper bound: two state a decision of $\leq$ themselves, two others are proved only with a choice principle, which enters through the integer absolute value in their statement, and for the remaining 23 no lower bound is proved. One row costs exactly MP, item 3 of Proposition 28.16. Two rows cost exactly LLPO: both say that $a^n = b^n$, for $n \neq 0$, holds exactly when $a = b$ or, for even n, $a = -b$; at $n = 2$ this is the sign of a square root, which is LLPO. Sixteen rows remain at the LPO function, every one of them through the total inverse $0^{-1} = 0$ in its own statement; for these the LPO function is the price of the stated convention, not a lower bound for the mathematics, because the points inverted in them are apart from 0. Across these lemmas the LPO function never enters through a decided strict order.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ with δ's ring, $\leq$ and $<$; classical structures read by the content of Definition 28.13.

Conclusion

The classical linear order with δ's $\leq$ costs exactly the WLPO function; with δ's $<$, and the field and ordered field, exactly the LPO function. Producing δ's $<$ from the library's $<$ is exactly MP.

Not claimed

That the sixteen rows left at the LPO function need it: their price is that of the inverse

convention they state. The row counts report the audit of Section 28.10; they are not theorems here.

28.5 Suprema, separation and compactness

A classical library completes its ordered field by a supremum map defined on every set of points. On $\mathbb{R}_\delta$ every inhabited, order-located set of points that is bounded above has a supremum with countable choice (Theorem 12.36 and Section 12.9), but a map that produces a supremum for every set, located or not, is a different object. Its first price is Markov's principle, and the argument needs only one law of the supremum.

Theorem 28.17 (A total supremum gives Markov's principle)**.** *Let* sup *be a map from sets of points to points such that $a \le \sup S$ whenever a is a member of a set S that has an upper bound. Then MP holds. No choice principle is used.*

Proof. Let α be a binary sequence that is not all zero, and let S be the set of points $\eta(n)$ with $\alpha(n) = 1$ and $\alpha(m) = 0$ for every $m < n$. It has at most one member, so whenever a is a member, a is an upper bound and $a \le \sup S$. The point $u = \sup S$ lies below $\eta(N)$ for some natural number N (Proposition 12.19, item 4). If $\alpha(k) = 1$ for some k, a bounded search finds the first index $n_0 \le k$ with $\alpha(n_0) = 1$; then $\eta(n_0) \in S$, so $\eta(n_0) \le u < \eta(N)$ and $n_0 < N$. Hence $\exists k\, \alpha(k) = 1$ implies that $\alpha(n) = 1$ for some $n < N$. Since α is not all zero, the latter is not false, and a bounded search over $n < N$ decides it; so it is true. □

The supremum map was used at one set whose inhabitation nobody can show; the classical law "a member lies below the supremum" does the rest. With a decision of double negations as well, the supremum can be built.

Lemma 28.18 (A monotone test has a point)**.** *Let u be a map from ratios to $\{0, 1\}$ such that $u(q) = 1$ and $q \le q'$ give $u(q') = 1$, and suppose $u(-m) = 0$ and $u(m') = 1$ for some natural numbers m, m'. Then a point c is computed from u with no choice, and for every set S of points such that $u(q) = 1$ exactly when $\eta(q)$ is an upper bound of S, the point c is an upper bound of S below every upper bound of S.*

Proof. Searches find the least such m and m'; put $A = -m$. For each n search the grid $A + i/(4n + 4)$, $i = 1, 2, \ldots$, for the first point where u is 1; it exists because $u(m') = 1$, and say it is $A + (i_n + 1)/(4n + 4)$. Then $u(A + i_n/(4n + 4)) = 0$. Call a ratio *low* if u is 0 at some larger ratio and *high* if u is 1 at some smaller one. By monotonicity every low ratio lies below every high ratio. The ratio $\ell_n = A + (i_n - 1)/(4n + 4)$ is low and $\ell_n + 3/(4n + 4)$ is high, so $|\ell_n - \ell_m| \le 3/(4n + 4) + 3/(4m + 4)$ and (ℓ_n) is a regular sequence; let c be its point. A ratio q with $\eta(q) > c$ is high, and one with $\eta(q) < c$ is low.

Now let S be as stated. If a member a had $c < a$, take a ratio q with $c < \eta(q) < a$; it is high, so $u(q) = 1$, so $\eta(q)$ is an upper bound and $a \le \eta(q)$, a contradiction. So c is an upper bound. If an upper bound y had $y < c$, take q with $y < \eta(q) < c$; it is low, so $u(q') = 0$ for some $q' > q$; but $\eta(q') > y$ is an upper bound, so $u(q') = 1$, a contradiction. So $c \le y$. □

Theorem 28.19 (The complete ordered field)**.** *Call a* complete ordered field *on* $\mathbb{R}_\delta$ *an ordered field in the sense of Definition 28.13, with δ's sum, product,* $\leq$ *and* $<$*, together with maps* sup *and* inf *from all sets of points to points such that, for every inhabited set S with an upper bound,* sup S *is an upper bound of S below every upper bound, and* $\sup S = \sup \varnothing$ *for every set S with no upper bound; dually for* inf*. Then:*

1. *A complete ordered field exists exactly when MP holds and the WEM function exists, and exactly when an ordered field exists and the WEM function exists.*
2. *The same holds with δ's* $\leq$ *and the strict order it forces,* $\neg\neg <$*, in place of δ's* $<$*, for the linear order with* sup *and* inf *alone.*
3. *The WEM function gives* WEM*;* WEM *together with unique choice from propositions into* $\{0, 1\}$ *gives the WEM function.*

No choice principle is used beyond the one named in item 3.

Proof. The structure gives the WEM function. For a proposition P let S_P consist of 0, and of 1 if P. It is inhabited and bounded by 1. If P then $1 \leq \sup S_P$; if $\neg P$ then 0 is an upper bound and $\sup S_P = 0$. Put $d(P) = 1$ when the stored decision says $\sup S_P \neq 0$. If $\sup S_P \neq 0$ then $\neg P$ is impossible, so $\neg\neg P$; if $\neg\neg P$ and $\sup S_P = 0$, then P would give $1 \leq 0$, so $\neg P$, a contradiction. So $d(P) = 1$ exactly when $\neg\neg P$. *The structure gives MP:* Theorem 28.17. Together with Theorem 28.15 this proves the forward directions of items 1 and 2.

The construction. Let d be a WEM function and assume MP. Every statement stable under double negation is decided by d: $x \leq y$, $x = y$, and, with MP, $x < y$ and $x \# 0$. This gives the stored decisions, and the inverse x^{-1} on the points where d reports $x \neq 0$, and 0 elsewhere. For the supremum of a set S let $u_S(q) = d(\eta(q)$ is an upper bound of $S)$; "is an upper bound" is a universal statement about $\leq$, stable under double negation, so $u_S(q) = 1$ exactly when $\eta(q)$ is an upper bound. If d reports that S is not not inhabited and bounded, then it is not not true that $u_S(-m) = 0$ for some m and $u_S(m') = 1$ for some m', and MP, applied to the binary sequences $m \mapsto 1 - u_S(-m)$ and $m \mapsto u_S(m)$, makes both true; put $\sup S = c$, the point of Lemma 28.18. Otherwise put $\sup S = 0$. On an inhabited set with an upper bound d reports the guard, and the lemma gives the laws; a set with no upper bound and the empty set both fail the guard, so both have supremum 0. The infimum is $\inf S = -\sup(-S)$. For item 2 the same construction with the strict order $\neg\neg <$ needs no MP for the order itself, but the supremum still uses MP for its integer brackets.

Item 3. $d(P) = 1$ gives $\neg\neg P$ and $d(P) = 0$ gives $\neg P$. Conversely WEM says that each P has exactly one bit b with $b = 1$ exactly when $\neg\neg P$, and unique choice collects these bits into one map. □

By Proposition 28.4, item 3, the WEM function with MP gives the LPO function, so the complete ordered field sits above the ordered field by exactly a double-negation decision. Under unique choice (Remark 28.5) item 3 identifies the WEM function with WEM, and the complete ordered field costs exactly MP together with WEM.

Two further laws of a classical library have prices of their own. Interpolation between two sets asks for a point between them; it holds in every complete ordered field (take $c = \sup s$)

and already gives WEM. The witness property, that a point below the supremum lies below some member, goes higher: it gives excluded middle.

Proposition 28.20 (Interpolation and witnesses)**.**

1. *Suppose that for any two inhabited sets s, t of points with $a \le b$ for all $a \in s$ and $b \in t$ some point c has $a \le c \le b$ for all such a, b. Then* WEM *holds.*
2. *Let* sup *be as in Theorem 28.17, and suppose that for every inhabited set s with an upper bound and every point b with $\neg\neg(b < \sup s)$ some member a has $\neg\neg(b < a)$. Then excluded middle holds.*
3. *In a complete ordered field, if every inhabited set s and every $b < \sup s$ have a member a with $b < a$, excluded middle holds.*

No choice principle is used.

Proof. 1. Let s consist of 0, and of 1 if P; let t consist of 1, and of 0 if $\neg P$. Every member of s lies below every member of t, since P and $\neg P$ do not both hold. Let c lie between them. Cotransitivity at $0 < 1$ gives $0 < c$ or $c < 1$. If $0 < c$, then $\neg P$ would put 0 in t and give $c \le 0$; so $\neg\neg P$. If $c < 1$, then P would put 1 in s and give $1 \le c$; so $\neg P$.

2. Let Q be a proposition with $\neg\neg Q$ and let s consist of 0, and of 1 if Q. Then Q gives $1 \le \sup s$ and hence $0 < \sup s$, so $\neg\neg(0 < \sup s)$. The hypothesis gives a member a with $\neg\neg(0 < a)$. The member 0 is excluded, so $a = 1$ and Q holds. So $\neg\neg Q \to Q$ for every Q, which gives excluded middle at $Q = P \vee \neg P$.

3. The same set, with MP from Theorem 28.17 turning $\neg\neg(0 < \sup s)$ into $0 < \sup s$. □

Separation and compactness

A classical library builds its topology on the line from the open intervals and expresses compactness through filters. Read on $\mathbb{R}_\delta$: the *interval topology* is the family of sets generated by the intervals $\{x : a < x < b\}$ under finite intersections and arbitrary unions. It is *Hausdorff* when any two points $x \neq y$ lie in disjoint open sets. A *filter* is a family of sets closed under finite intersections and supersets and containing the whole line; it is *proper* when the empty set is not a member. A point x is a *cluster point* of a filter F when every open set containing x meets every member of F, in the sense that their intersection is not empty. A set K is *filter compact* when every proper filter containing K has a cluster point in K.

Every open set of the interval topology contains, with each of its points x, all points within $1/(K+1)$ of x for some K; this holds for the generating intervals and is preserved by finite intersections and unions. Conversely, the points within $1/(K+1)$ of x contain an open interval around x. So x is a cluster point of F exactly when for every K and every $A \in F$ it is not the case that no point within $1/(K+1)$ of x lies in A.

Theorem 28.21 (Hausdorff separation and filter compactness)**.**

1. *The interval topology is Hausdorff exactly when MP holds.*
2. *If a filter-compact set contains two points $p < q$, then* WEM *holds.*
3. $[0,1]$ *is filter compact exactly when* WEM *holds and countable unique choice into* $\{0,1\}$ *holds: whenever every n has exactly one bit b with $R(n,b)$, some binary sequence f has $R(n, f(n))$ for every n.*

No choice principle is used beyond the one named.

Proof. 1. Under MP, $x \neq y$ gives $x < y$ or $y < x$ (Corollary 12.18); a ratio q between them separates them by the intervals below and above q. Conversely, let $x \neq y$ lie in disjoint open sets U and V. Some interval $a < z < b$ around y lies in V. Cotransitivity at $a < y$ and at $y < b$ gives $a < x$ or $x < y$, and $x < b$ or $y < x$. If $a < x < b$ then $x \in U \cap V$, which is empty; so $x < y$ or $y < x$, and every point $x \neq y$ is apart from y. This is MP by Corollary 12.18.

2. Let K be the set. For a proposition P let F_P consist of the sets A with $P \to p \in A$ and $\neg P \to q \in A$. It is a filter, it contains K, and it is proper, since $\emptyset \in F_P$ would give $\neg P$ and $\neg\neg P$. Let $x \in K$ be a cluster point. Under P the set $\{p\}$ is a member, and $p < x$ would give the open set $\{z : p < z < x + 1\}$ around x, which misses it; so $P \to \neg(p < x)$. Likewise $\neg P \to \neg(x < q)$. Cotransitivity at $p < q$ gives $p < x$, hence $\neg P$, or $x < q$, hence $\neg\neg P$.

3. Filter compactness of $[0,1]$ gives WEM by item 2. For unique choice, let R be given. For a bit string c of length M let $I(c)$ be the interval of length 3^{-M} with left end $\sum_{i<M} 2c_i 3^{-(i+1)}$, the interval of the Cantor set coded by c, and call c *valid* if $R(i, c_i)$ for every $i < M$. Valid strings of every length exist, and by uniqueness there is only one of each length. Let C_N be the set of points of $[0,1]$ that lie, for every $M \leq N$, in $I(c)$ for some valid c of length M, and let F consist of the sets containing some C_N. The left end of the valid string of length N lies in C_N, so F is proper; let x be a cluster point in $[0,1]$. Then $x \in I(c)$ for every valid c: if x lay outside, an open set around x would miss $I(c)$, which contains C_M. Fix a regular sequence t naming x; the goal is a proposition. Define f by recursion: $f(n) = 1$ when stage $12 \cdot 3^n - 1$ of t exceeds the midpoint of $I(f(0) \dots f(n-1))$, and $f(n) = 0$ otherwise. If the first n values are valid and $R(n,b)$, then x lies in the third of that interval coded by b; the two thirds lie $1/(6 \cdot 3^n)$ from the midpoint, and the stage lies within $1/(12 \cdot 3^n)$ of x, so $f(n) = b$. By induction $R(n, f(n))$ for every n.

Conversely, assume WEM and countable unique choice into $\{0,1\}$, and let F be a proper filter containing $[0,1]$. Call a closed dyadic interval I *good* if no member A of F has every point of I outside A. Goodness is stable under double negation, so WEM decides it. The interval $[0,1]$ is good, since F is proper. If I is good and its left half is not, its right half is good: otherwise members A_L and A_R miss the two halves, and $A_L \cap A_R$ misses I, because every point of I lies, up to double negation, in one half and the conclusion is a negation. Let the halving path go left when the left half is good and right otherwise. For each n exactly one bit is the nth step of this path, so countable unique choice gives the path as a binary sequence f, and every interval on it is good. Its point $x = [f]$ lies in $[0,1]$; the points within $1/(K+1)$ of x contain the Kth interval of the path, which is good. So x is a cluster point. □

Filter compactness is therefore a logical principle, weak excluded middle for all propositions together with a little choice, unlike Heine–Borel for $[0,1]$ with presented covers, which is the decidable fan theorem (Theorem 13.6). Under unique choice (Remark 28.5) filter compactness of $[0,1]$ is exactly WEM.

Conditions and scope.

Base and premises
$\mathbb{R}_\delta$; the classical supremum, topology and filters read by their content.

Conclusion
A total supremum gives MP; the complete ordered field costs exactly MP and the WEM function; interpolation gives WEM, and the witness property gives excluded middle; Hausdorff separation is exactly MP; filter compactness of $[0,1]$ is exactly WEM with countable unique choice into $\{0,1\}$.

Not claimed
That the witness property is needed by the mathematics that uses it: it is the price of one way of stating suprema.

28.6 The derivative convention

A classical library has a derivative operator defined on every function: it returns the derivative where one exists and 0 where none does. The convention is a jump of an operator, and the rule of Section 28.2 gives a first price. Applied to the square root, the operator also predicts when an event will occur, and that costs Markov's principle.

Definition 28.22 (Pointwise derivative and the convention)**.** A point d is a *derivative* of $f : \mathbb{R}_\delta \to \mathbb{R}_\delta$ at x if for every k some j has

$$|f(y) - f(x) - d(y-x)| \le \frac{|y-x|}{k+1} \qquad \text{whenever } |y-x| \le \frac{1}{j+1}.$$

A *derivative convention* is an operator $\mathscr{D}$ assigning to every map f a map $\mathscr{D}(f)$ such that $\mathscr{D}(f)(x) = d$ whenever d is a derivative of f at x, and $\mathscr{D}(f)(x) = 0$ whenever f has no derivative at x. A *differentiability decision* is a map c from pairs (f,x) to $\{0,1\}$ with $c(f,x) = 1$ exactly when it is not false that f has a derivative at x.

Derivatives are unique: if d and d' are derivatives at x, then $|d-d'|\,|y-x| \le 2|y-x|/(k+1)$ for y close to x, and $y = x + 1/(j+1)$ gives $|d-d'| \le 2/(k+1)$ for every k. Under the classical display of $\mathbb{R}_\delta$ on the classical real numbers this derivative is the classical one, and so is pointwise continuity; that is a statement of classical mathematics, Theorem 28.56, item 4.

Theorem 28.23 (The derivative convention gives Markov's principle)**.** *If a derivative convention exists, MP holds. No choice principle is used.*

Proof. Let $R(y) = \sqrt{\max(y,0)}$ be the free map of Theorem 28.9, item 5. First, for $c > 0$ the point $e = 1/(2c)$ is a derivative of R at c^2. If $|y - c^2| \le c^2$ then $y \ge 0$, and with $s = R(y) = \sqrt{y}$,

$$R(y) - c - e(y - c^2) = (s-c) - e(s-c)(s+c) = -e(s-c)^2,$$

while $|s-c|(s+c) = |y-c^2|$ and $s+c \geq c$ give $|s-c| \leq |y-c^2|/c$. So the error is at most $|y-c^2|^2/(2c^3)$, which is at most $|y-c^2|/(k+1)$ once $|y-c^2| \leq 2c^3/(k+1)$. At $c = 2^{-(n+1)}$ the derivative is 2^n.

Now let α be a binary sequence that is not all zero. Let $\beta(n) = 1$ when $\alpha(n) = 1$ and $\alpha(m) = 0$ for every $m < n$, so that $c = [\beta]$ is $2^{-(n_0+1)}$ if the first 1 of α is at n_0, and 0 if α has no 1. The value $u = \mathscr{D}(R)(c^2)$ is one point, so $|u| < B$ for some natural number B. Search $\alpha(0), \ldots, \alpha(B)$. If one of them is 1, it is the witness. If none is, and $\alpha(n) = 1$ for some n, the first 1 lies at some $n_0 > B$; then $c = 2^{-(n_0+1)} > 0$, the convention forces $u = 2^{n_0} > n_0 > B$, and this contradicts $|u| < B$. So α would be all zero, which it is not; the search therefore finds the witness. □

The operator, evaluated at one point that depends on α, returns a number that bounds in advance where the first event of α can be.

Theorem 28.24 (The exact price of the derivative convention)**.**

1. *A derivative convention exists exactly when MP holds and a differentiability decision exists.*
2. *A differentiability decision gives the WLPO function, and the WEM function gives a differentiability decision.*
3. *A derivative convention gives the LPO function, hence* $\mathrm{LPO}_{\mathrm{seq}}$ *and* Π^0_2 *weak excluded middle (Definition 28.25).*
4. *MP and the WEM function together give a derivative convention.*

No choice principle is used.

Proof. The convention gives the WLPO function. For $t \geq 0$ let $g_t(x) = x + t|x|$. At $t = 0$ it is the identity, with derivative 1 at 0. For $t > 0$ it has no derivative at 0: take n with $1/(n+1) < t$; a derivative d at tolerance $1/(2n+2)$, tested at $y = \pm 1/(j+1)$, gives $|1 + t - d| \leq 1/(2n+2)$ and $|1 - t - d| \leq 1/(2n+2)$, hence $2t \leq 1/(n+1) < t$, which is impossible for $t > 0$. So $h(y) = \mathscr{D}(g_{|y|})(0)$ is 1 at $y = 0$ and 0 at every $y \# 0$: a jump of size 1, and Theorem 28.8 gives the WLPO function and with it a zero test z.

Item 1, forward. MP is Theorem 28.23. A map f has a derivative at x exactly when $f + \mathrm{id}$ has one, the two differing by 1. Put $g(f,x) = \mathscr{D}(f + \mathrm{id})(x) - \mathscr{D}(f)(x)$: it is 1 when f has a derivative at x and 0 when it has none. Let $c(f,x) = 1 - z(g(f,x))$. If $c(f,x) = 1$ then $g(f,x) \neq 0$, and since "no derivative" would give $g = 0$, it is not false that a derivative exists. If it is not false that a derivative exists and $g(f,x) = 0$, then a derivative would give $g = 1$, so there is none, a contradiction; so $g(f,x) \neq 0$ and $c(f,x) = 1$.

Item 1, backward. Fix f and x, and for a ratio q put

$$R_q(y) = \max\bigl(\min\bigl(f(y) - f(x) - q(y-x),\ y - x\bigr),\ 0\bigr).$$

Let d be a derivative of f at x. (i) If $d \leq q$, then 0 is a derivative of R_q at x: for $y \leq x$ the inner minimum is at most $y - x \leq 0$, so $R_q(y) = 0$; for $y \geq x$, $f(y) - f(x) - q(y-x) \leq |y-x|/(k+1) + (d-q)(y-x) \leq |y-x|/(k+1)$, so $0 \leq R_q(y) \leq |y-x|/(k+1)$; the bound is a non-strict inequality, so the case split $y \leq x$ or $x \leq y$, which holds up to double negation,

is allowed. (ii) If R_q has a derivative e at x, then $d \le q$: points $y < x$ give $|e| \le 1/(k+1)$ for every k, so $e = 0$; if $q < d$, points $y > x$ close to x give $R_q(y) \ge \min\big((d-q)/2, 1\big)(y-x)$, which exceeds $|y-x|/(k+1)$ for large k.

Now let c be a differentiability decision and assume MP. If $c(f,x) = 0$, put $\mathscr{D}(f)(x) = 0$; then f has no derivative at x. If $c(f,x) = 1$, let $u(q) = c(R_q, x)$ and let S be the set of derivatives of f at x, which is not empty up to double negation and has at most one member. By (i) and (ii), $u(q) = 1$ exactly when $\eta(q)$ is an upper bound of S: if $\eta(q)$ bounds S, a member d makes 0 a derivative of R_q, so it is not false that R_q has one; and if $u(q) = 1$, every member d has $\neg\neg(d \le q)$ by (ii), hence $d \le q$. Up to double negation a member d exists, and then $u(-m) = 0$ for $-m < d$ and $u(m') = 1$ for $m' > d$; MP makes these integers exist. Let $\mathscr{D}(f)(x)$ be the point that Lemma 28.18 computes from the test u; it is an upper bound of S below every upper bound. When f has a derivative d, $S = \{d\}$, and that point is d.

2. For a WEM function d put $c(f,x) = d(f \text{ has a derivative at } x)$. A differentiability decision c gives the zero test $y \mapsto c(g_{|y|}, 0)$: by the first paragraph $g_{|y|}$ has a derivative at 0 exactly when $y = 0$, and $y = 0$ is stable under double negation. Theorem 28.3 gives the WLPO function.

3. The first paragraph and Theorem 28.23 give the WLPO function and MP, which make the LPO function (Theorem 28.3, item 1). Proposition 28.4 gives $\mathrm{LPO}_{\mathrm{seq}}$: a sequence h with $h(N) = 1$ exactly when $M(N,m) = 1$ for some m; the LPO function applied to $1 - h$ decides whether $h(N) = 1$ for every N, that is, it decides Π_M outright.

4. Item 2 and item 1. □

Applied row by row and then to the resulting sequence, as in item 3, the LPO function decides every arithmetic statement whose matrix is decidable, by induction on the number of quantifiers. So the derivative convention carries every arithmetic principle of the price lattice, far above the Π^0_2 weak excluded middle that its jump alone suggests. Its exact price places it between the LPO function, which it implies, and MP with the WEM function, which the complete ordered field of Theorem 28.19 pays: the library's own complete field pays for its own derivative. Under unique choice (Remark 28.5) the upper bound is MP with WEM. Whether a differentiability decision alone gives Π^0_2 weak excluded middle, and whether it lies strictly above the WLPO function, is open.

Definition 28.25 (Π^0_2 weak excluded middle and the shift)**.** For a double sequence of bits M write Π_M for the statement that every row has a 1: $\forall N \exists m\, M(N,m) = 1$. Π^0_2 *weak excluded middle* states $\neg\Pi_M \vee \neg\neg\Pi_M$ for every M. The *shift* states the same for every M whose rows are each not not inhabited: $\forall N \neg\neg\exists m\, M(N,m) = 1$. The *double-negation shift* DNS states that $\forall n\, \neg\neg Q(n)$ gives $\neg\neg\forall n\, Q(n)$ for every family of propositions Q.

Theorem 28.26 (The Π^0_2 gap above the WLPO function)**.** *Assume the WLPO function. Then* Π^0_2 *weak excluded middle holds exactly when the shift holds. The shift follows from MP and from* DNS. *No choice principle is used.*

Proof. Let w be the WLPO function and M a double sequence of bits. The bit $t = w\big(N \mapsto w(M(N,\cdot))\big)$ is 1 exactly when no row is all zero, that is, when every row is not not inhabited. If $t = 0$, then Π_M is refuted, since it would make every row inhabited. If $t = 1$, the shift applies.

The converse is the special case. Under MP a row that is not not inhabited is inhabited, so Π_M holds; under DNS the rows give $\neg\neg\Pi_M$. □

So the question whether the WLPO function gives Π^0_2 weak excluded middle is exactly the question whether it gives the shift. For WLPO as a sentence of intuitionistic second-order arithmetic the answer is no (Section 28.8): there the shift follows from MP but not from WLPO. For the WLPO function the question stays open.

Conditions and scope.

Base and premises
$\mathbb{R}_\delta$; the pointwise derivative of Definition 28.22; an operator defined on all maps.

Conclusion
The derivative convention costs exactly MP together with a decision of differentiability up to double negation. It gives the LPO function, and the complete ordered field pays for it.

Not claimed
That the decision of differentiability is strictly above the WLPO function, or that it gives Π^0_2 weak excluded middle; both are open. Reading derivatives through supplied derivatives, as in Section 28.7, avoids the convention and its price; what monotonicity then costs is open.

28.7 Monotonicity from a pointwise derivative

"A function with a nonnegative derivative is increasing" is a classical theorem proved through the mean value theorem. On $\mathbb{R}_\delta$ we read it with the derivative supplied: f and a map f' are given, and $f'(z)$ is a derivative of f at z for every z in $[0,1]$. No convention is involved. Call this statement MON:

> for all maps f, f' with $f'(z)$ a derivative of f at z and $f'(z) \geq 0$ for every $z \in [0,1]$, $f(x) \leq f(y)$ whenever $0 \leq x \leq y \leq 1$.

Its strict form asks $f(x) < f(y)$ for $x < y$ when $f'(z) > 0$ on $[0,1]$, and its segment form asks the conclusion on every segment $[x,y]$ of the line with the hypotheses on that segment only. The difficulty is familiar from compactness: the derivative gives, at each point, a radius on which f is nearly linear, and nothing says how the radii vary. We give two routes around it.

Lemma 28.27 (The affine chain rule)**.** *If d is a derivative of f at $x + tc$, then cd is a derivative of $s \mapsto f(x + sc)$ at t. No principle is used.*

Proof. Given k, take a natural number $B \geq |c|$ and the j that the derivative of f at $u = x + tc$ gives for the tolerance $1/((B+1)(k+1))$. If $|s - t| \leq 1/((B+1)(j+1))$ and $u' = x + sc$, then $|u' - u| = |s-t|\,|c| \leq 1/(j+1)$, so $|f(u') - f(u) - d(u'-u)| \leq |u'-u|/((B+1)(k+1)) \leq |s-t|/(k+1)$, and $d(u' - u) = cd(s - t)$. □

Lemma 28.28 (Monotonicity from one sequence of representatives)**.** *Let $x \le y$, let $f'(z)$ be a derivative of f at z with $f'(z) \ge 0$ for every $z \in [x, y]$, and suppose regular sequences $G(n, m)$ name the values $f\big(x + (m/2^n)(y - x)\big)$ for all natural numbers n and m. Then $f(x) \le f(y)$. No principle is used.*

Proof. The conclusion is a negation, so we may assume $f(y) - f(x) \le -c$ with $c = 1/(M + 1)$ and derive a contradiction. Write $a_n = x + (m_n/2^n)(y - x)$ and $b_n = a_n + 2^{-n}(y - x)$ for the current interval, and $\beta_n = c\,2^{-(n+1)}(1 + 2^{-n})$ for its budget. We choose m_n so that $f(b_n) - f(a_n) \le -\beta_n$; at $n = 0$ this is the assumption. Let p be the midpoint. Since $f(p) - f(a_n)$ and $f(b_n) - f(p)$ add up to at most $-\beta_n$, one of them is at most $-\beta_n/2$, and $\beta_n/2 - \beta_{n+1} = c\,2^{-(2n+3)}$. Read a ratio r within $c\,2^{-(2n+5)}$ of $f(p) - f(a_n)$ off late stages of the sequences G. If $r \le -\beta_n/2 + c\,2^{-(2n+5)}$, take the left half: then $f(p) - f(a_n) \le -\beta_n/2 + c\,2^{-(2n+4)} \le -\beta_{n+1}$. Otherwise $f(p) - f(a_n) > -\beta_n/2$, so $f(b_n) - f(p) < -\beta_n/2 \le -\beta_{n+1}$, and we take the right half. Each step compares two ratios, so the bisection is a rule.

The intervals shrink to a point $z \in [x, y]$. Choose k with $(y - x)/(k + 1) < c/4$ (take $B \ge y - x$ and $k + 1 > 4B/c$) and the j of the derivative at z for the tolerance $1/(k + 1)$, and n with $2^{-n}(y - x) \le 1/(j + 1)$. Then a_n and b_n lie within $1/(j + 1)$ of z, on either side of it, and

$$f(b_n) - f(a_n) \ge f'(z)(b_n - a_n) - \frac{b_n - a_n}{k + 1} \ge -\frac{2^{-n}(y - x)}{k + 1} > -c\,2^{-(n+2)},$$

while the budget gives $f(b_n) - f(a_n) \le -\beta_n \le -c\,2^{-(n+1)}$. This is a contradiction. □

The only object the proof uses beyond f and f' is the double sequence of representatives G. A section supplies it, and since the conclusion is a negation, it is enough that such representatives are not impossible. Say that *representation choice up to double negation* holds when for every sequence of points it is not false that some sequence of regular sequences names it. A map f is *presented* when it is computed by an operation F on regular sequences: $F(s)$ names $f(x)$ whenever s names x.

Theorem 28.29 (Monotonicity at the WLPO function)**.**

1. MON *holds under each of: the WLPO function; representation choice up to double negation, and in particular countable choice; the full fan theorem* FAN *of Definition 13.2.*
2. MON *holds with no principle for every presented map f, and in particular for every map written with constants, $+$, $\cdot$, $-$, $|\cdot|$,* max, min, exp *and π.*
3. *With no principle,* MON*, its strict form and its segment form are equivalent.*
4. *Under the WLPO function, on every segment $[x, y]$: if f' is a derivative of f and f'' of f' with $f'' > 0$ on $[x, y]$ and $x < y$, then $f((1 - t)x + ty) < (1 - t)f(x) + tf(y)$ for $0 < t < 1$; and if $f' = 0$ on $[x, y]$ then $f(x) = f(y)$.*

No choice principle is used beyond the one named.

Proof. 1. The WLPO function gives a section (Theorem 28.11), hence G, and Lemma 28.28 applies. Under representation choice up to double negation, it is not false that G exists,

and the conclusion is a negation. For FAN, assume again a gap $f(y) - f(x) \leq -c$, choose k with $(y - x)/(k + 1) < c$, and call the dyadic subinterval I of $[x, y]$ coded by a binary string *fine* if some $z \in I$ and some j satisfy the derivative estimate at z for the tolerance $1/(k + 1)$ within $1/(j + 1)$, and I has length at most $1/(j + 1)$. Fineness is a property of strings, not a decidable one. Every binary sequence names a point z of $[x, y]$, and the strings along it become fine once their intervals are shorter than the j of z; so the fine strings form a bar, and FAN makes it uniform at some depth N. Since the goal is a negation, we may decide fineness for the finitely many strings of length at most N; the shortest fine prefixes of the strings of length N tile $[x, y]$ by finitely many fine intervals $[a, b]$ with tags z, and on each, $f(b) - f(a) \geq f'(z)(b - a) - (b - a)/(k + 1) \geq -(b - a)/(k + 1)$. Summing gives $f(y) - f(x) \geq -(y - x)/(k + 1) > -c$.

2. For a presented f, fix regular sequences naming x and y; the dyadic points $x + (m/2^n)(y - x)$ have sequences computed from them, and F turns these into G. A map written with the listed operations is presented, since each operation acts on regular sequences.

3. Strict from MON: let $x < y$ in $[0, 1]$. Since $f'(x) > 0$, there is m with $f'(x) \geq 1/(m + 1)$; the derivative at x for the tolerance $1/(2m+2)$ gives j, and $h = (y-x)/(j+1)$ satisfies $0 < h \leq y-x$ and $f(x + h) - f(x) \geq h/(m + 1) - h/(2m + 2) > 0$. MON on $[x + h, y]$ gives $f(x + h) \leq f(y)$, so $f(x) < f(y)$. MON from the strict form: assume a gap $f(y) - f(x) \leq -1/(M + 1)$ and put $\varepsilon = 1/(2M + 2)$; $f + \varepsilon\mathrm{id}$ has the positive derivative $f' + \varepsilon$, and $x < y$ would give $f(x) + \varepsilon x < f(y) + \varepsilon y \leq f(x) - 1/(M + 1) + \varepsilon$, which is false; and $x = y$ contradicts the gap. Since $x \leq y$ gives $x < y$ or $x = y$ up to double negation, the gap is impossible. The segment form from MON: apply MON to $g(t) = f(x + t(y - x))$, which has the derivative $(y - x)f'(x + t(y - x)) \geq 0$ by Lemma 28.27; $g(0) \leq g(1)$ is $f(x) \leq f(y)$, and no case split on $x = y$ is needed.

4. Constancy: apply the segment form to f and to $-f$. Strict convexity: the strict segment form, applied to f', makes f' strictly increasing on $[x, y]$. Let $z = (1 - t)x + ty$ and $\varphi(s) = f(s) - f(z) - f'(z)(s - z)$, with derivative $\varphi'(s) = f'(s) - f'(z)$. On $[z, y]$ this is nonnegative, so $\varphi \geq 0$ there; beyond the midpoint z' of $[z, y]$ it is at least $f'(z') - f'(z) > 0$, so the strict form gives $\varphi(y) > \varphi(z') \geq 0$. The same argument on $[x, z]$, with $s \mapsto \varphi(x + z - s)$, gives $\varphi(x) > 0$. Since $(1 - t)(x - z) + t(y - z) = 0$, the difference $(1 - t)f(x) + tf(y) - f(z)$ equals $(1 - t)\varphi(x) + t\varphi(y) > 0$. □

The fan route needs a bar given by an arbitrary property. It follows from a logical principle with a little choice.

Theorem 28.30 (Excluded middle with unique choice gives the full fan theorem)**.** *Assume excluded middle and countable unique choice into* $\{0, 1\}$*. Then every bar, given by an arbitrary property of binary strings, is uniform: the full fan theorem* FAN *holds.*

Proof. Let B be a bar and call a string s *bounded* if some N has every binary sequence extending s meet B at a length at most N. If both one-digit extensions of s are bounded, so is s. Excluded middle decides at each string whether its left extension is bounded, and so defines a path from the root: go left when the left extension is not bounded, and right otherwise. For each n exactly one bit is the nth step, so countable unique choice collects the steps into one binary sequence p. Suppose the root is not bounded. Then by induction no string along p is bounded:

if s is not bounded and its left extension is bounded, the right one is not. But p meets the bar at some string, and a string in the bar is bounded with N its length. So the root is bounded, which is the conclusion; excluded middle decides whether it is. □

This agrees with Theorem 13.11: without unique choice, excluded middle does not give even the decidable fan theorem. Under the default reading of this book (Remark 28.5) unique choice is present, and excluded middle gives FAN. So MON costs at most the WLPO function, at most countable choice of representatives, and at most excluded middle with countable unique choice into $\{0, 1\}$; every principle that it implies is implied by the WLPO function.

Whether MON holds with no principle at all is open. One model shows that monotonicity can hold where these routes fail. In the model of named objects of the computable calculus (Definition 16.20), sequences range over computable sequences and points over points with computable names. There every computable sequence of points has a computed sequence of representatives, so representation choice holds; the bisection of Lemma 28.28 uses the derivative only at the point it constructs and the values of f only at dyadic points, so the statement of monotonicity holds; Kleene's tree (Lemma 16.29) refutes every fan theorem; and the WLPO and LPO functions fail, as after Proposition 28.4. These are facts about that model, proved in a classical metatheory: the bisection runs in a world without fan theorems and without omniscience functions. They are not a measurement of MON inside the computable calculus, whose language states order relations through atoms that none of its rules inspects; there the calculus derives from monotonicity no statement whose order atoms range over sets no larger than the continuum, such as the fan theorems, that it does not already derive outright.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; a map with a supplied pointwise derivative on $[0, 1]$ or on a segment.

Conclusion

Monotonicity, its strict form, monotonicity on every segment, strict convexity and constancy cost at most the WLPO function; monotonicity is free for presented maps; it also follows from the full fan theorem, which excluded middle with countable unique choice into $\{0, 1\}$ gives.

Not claimed

That monotonicity costs anything: whether it is free is open.

28.8 WLPO and Π^0_2 weak excluded middle

Theorem 28.26 reduced one question to another: given the WLPO function, Π^0_2 weak excluded middle holds exactly when its shift does, and the shift follows from MP and from the double-negation shift. Does WLPO alone give it? We answer for WLPO as a sentence of intuitionistic second-order arithmetic HAS (Definition 7.14), with the systems of truth values of Definition 7.19: it does not, and the separating model needs no hypothesis beyond the usual axioms of set theory. The theorem concerns HAS, whose comprehension axiom makes every

definable set available; it is not transferred here to the WLPO function in the reading of maps of this part, for which the question stays open in the form Theorem 28.26 gives it.

Definition 28.31 (Π^0_2 sentences of HAS)**.** With the pairing $\langle N, m\rangle = (N+m)\cdot(N+m)+m$ and the formulas of Definition 7.18, put $\mathrm{Row}(X,N) :\equiv \exists m\, \langle N,m\rangle \in X$ and $\mathrm{All}(X) :\equiv \forall N \mathrm{Row}(X,N)$, and

$$\Pi^0_2\text{-WEM} :\equiv \forall X\big(\mathrm{Dec}(X) \to \neg\mathrm{All}(X) \vee \neg\neg\mathrm{All}(X)\big),$$
$$\text{Shift} :\equiv \forall X\big(\mathrm{Dec}(X) \to \forall N \neg\neg\mathrm{Row}(X,N) \to \neg\mathrm{All}(X) \vee \neg\neg\mathrm{All}(X)\big).$$

The model is built from a quotient of a power set. A *σ-ideal* on a set Ω is a family J of subsets that contains $\emptyset$, contains every subset of each of its members, and contains every countable union of its members; we assume $\Omega \notin J$. Its *Stone space* X_J is the set of ultrafilters on Ω that contain no member of J, with the topology whose basic open sets are $[S] = \{u \in X_J : S \in u\}$. Four standard facts of Stone duality [110, 106] hold. (a) $[S]\cap[T] = [S\cap T]$, $[S]\cup[T] = [S\cup T]$ and the complement of $[S]$ is $[\Omega \setminus S]$, so every basic set is closed as well as open. (b) $[S] = \emptyset$ exactly when $S \in J$, so $[S] \subseteq [T]$ exactly when $S \setminus T \in J$; a set $S \notin J$ lies in some point of X_J, because S together with the complements of the members of J has the finite intersection property. (c) X_J is compact, as a closed subspace of the space of all ultrafilters on Ω. (d) An open subset of a basic set $[c]$ whose complement in $[c]$ is also open is basic: it is closed in the compact set $[c]$, hence a finite union of basic sets.

For maps $g, h : \mathbb{N} \to \mathbb{N}$ write $g \le^* h$ when $g(n) \le h(n)$ for all large n. A family of maps is *bounded* when one h satisfies $g \le^* h$ for all its members. The *bounding number* $\mathfrak{b}$ is the least cardinality of an unbounded family [111]. Let $J_{\mathfrak{b}}$ be the σ-ideal on $\Omega = \mathbb{N}^{\mathbb{N}}$ generated by the sets of cardinality less than $\mathfrak{b}$: its members are the sets covered by countably many such sets. Every member of $J_{\mathfrak{b}}$ is bounded, because a set of size less than $\mathfrak{b}$ is bounded and countably many bounding maps h_k are bounded by $n \mapsto \max_{k\le n} h_k(n)$. Since $\mathbb{N}^{\mathbb{N}}$ is unbounded, $\Omega \notin J_{\mathfrak{b}}$.

Theorem 28.32 (The bounding frame)**.** *In the system of truth values formed by the open sets of the Stone space of $J_{\mathfrak{b}}$, WLPO has the value $\top$ and* Shift *does not. Consequently HAS derives neither* WLPO $\to$ Shift *nor* WLPO $\to \Pi^0_2$-WEM*. The proof reasons in classical set theory with the axiom of choice and uses no further hypothesis.*

Proof. WLPO is valid in the Stone space of every σ-ideal. Let X_0 be valued by open sets A_n, and let a basic set $[c]$ lie in the value of $\mathrm{Dec}(X_0)$. For each n, $[c]$ is covered by the disjoint open sets A_n and $\neg A_n$, so by (d) $A_n \cap [c] = [b_n]$ with $b_n \subseteq c$. Let $T = \bigcup_n b_n$. The set $[c \setminus T]$ meets no A_n, so it lies in the value Z' of $\mathrm{Z}(X_0)$. The set $[c \cap T]$ is disjoint from Z': if a basic $[R] \subseteq Z'$ met it, then $R \cap c \cap T = \bigcup_n (R \cap b_n)$ would be outside J, so some $R \cap b_n$ would be outside J, and $[R \cap b_n]$ would be a nonempty set inside both $Z' \subseteq \neg A_n$ and A_n. So $[c \cap T] \subseteq \neg Z'$, and $[c] = [c \setminus T] \cup [c \cap T]$ lies in the value of $\mathrm{Z}(X_0) \vee \neg\mathrm{Z}(X_0)$. The basic sets form a base, so the value of the implication is $\top$ for every X_0.

A criterion for the shift. Let $a(N,m) \subseteq \Omega$ satisfy (i) $\Omega \setminus \bigcup_m a(N,m) \in J$ for every N, and (ii) with $K_f = \bigcap_N \bigcup_{m \le f(N)} a(N,m)$ for $f : \mathbb{N} \to \mathbb{N}$: every $T \subseteq \Omega$ with $K_f \setminus T \in J$ for all f contains some $Y \notin J$ with $Y \cap K_f \in J$ for all f. We show that the value of Shift is not $\top$. Value $\langle N,m\rangle \in X_0$ by $[a(N,m)]$ and every other number by $\emptyset$. Every value is clopen, so $\mathrm{Dec}(X_0)$ has the value $\top$. Each union $\bigcup_m [a(N,m)]$ is dense: a basic $[R] \neq \emptyset$ has $R \notin J$, so by (i) and countable additivity

some $R \cap a(N,m) \notin J$. So $\forall N \neg\neg \mathrm{Row}(X_0, N)$ has the value $\top$. Let V be the value of $\mathrm{All}(X_0)$, the interior of $\bigcap_N \bigcup_m [a(N,m)]$. Every $[K_f]$ lies in V, since $K_f \subseteq \bigcup_{m \le f(N)} a(N,m)$ for each N. Conversely, a basic $[R] \subseteq V$ is covered, for each N, by the sets $[a(N,m)]$, hence by compactness by finitely many, $m \le f(N)$; so $R \setminus K_f \in J$ for that f, by countable additivity. If Shift had the value $\top$, its instance at X_0 would make $\neg V \cup \neg\neg V$ the whole space. Then $\neg V$ would be clopen, $\neg V = [b]$ and $\neg\neg V = [\Omega \setminus b]$. Since $[K_f] \subseteq V \subseteq [\Omega \setminus b]$, the set $T = \Omega \setminus b$ satisfies $K_f \setminus T \in J$ for all f; let $Y \subseteq T$ be given by (ii). A basic set inside $[Y] \cap V$ has the form $[R]$ with $R \setminus Y \in J$ and $R \setminus K_f \in J$ for some f, so $R \subseteq (R \setminus Y) \cup (Y \cap K_f) \cup (R \setminus K_f) \in J$ and $[R] = \emptyset$. So $[Y] \cap V = \emptyset$, $[Y] \subseteq \neg V = [b]$; but $Y \subseteq \Omega \setminus b$, so $[Y] = \emptyset$ and $Y \in J$, a contradiction.

The instance. Let $J = J_{\mathfrak{b}}$ and $a(N,m) = \{g : g(N) = m\}$. The rows cover Ω, so (i) holds, and K_f is the set of g with $g \le f$ everywhere. For (ii), let T satisfy $K_f \setminus T \in J$ for all f. First, for every h some $y \in T$ has $y \ge h$ everywhere: otherwise the box of maps g with $h \le g \le h+1$ lies in $K_{h+1} \setminus T$, hence in J; but the map $t \mapsto h + \chi_t$, where χ_t is the indicator of the set of codes $\langle n, t(n)\rangle$, sends $\mathbb{N}^{\mathbb{N}}$ injectively into the box, and the preimages of countably many sets of size less than $\mathfrak{b}$ would cover $\mathbb{N}^{\mathbb{N}}$ by bounded sets, making it bounded. Next, index an unbounded family as $(u_\gamma)_{\gamma<\mathfrak{b}}$. For each γ the earlier members are fewer than $\mathfrak{b}$, hence bounded by some e_γ; choose $y_\gamma \in T$ with $y_\gamma \ge \max(e_\gamma, u_\gamma)$ everywhere. The set $Y = \{y_\gamma\}$ lies in T and is unbounded, since a bound would bound every u_γ; so $Y \notin J$. For each f take γ_0 with $u_{\gamma_0} \not\le^* f$. For $\gamma \ge \gamma_0$, $u_{\gamma_0} \le^* y_\gamma$, so $y_\gamma \not\le f$ and $y_\gamma \notin K_f$. So $Y \cap K_f$ has fewer than $\mathfrak{b}$ members and lies in J.

Consequences. By Lemma 7.21 a derivable sentence has the value $\top$ in every system of truth values. The value of WLPO $\to$ Shift is the value of Shift, which is not $\top$. HAS derives Π^0_2-WEM $\to$ Shift, since the shift only adds a hypothesis, so Π^0_2-WEM has a value below that of Shift, and WLPO $\to$ Π^0_2-WEM is not derivable either. □

The ideal $J_{\mathfrak{b}}$ is generated by the small sets rather than given as a family of small sets. That is why the proof needs no assumption on the cofinality of $\mathfrak{b}$ and no scale: condition (ii) is checked one f at a time, and each check meets fewer than $\mathfrak{b}$ points.

Proposition 28.33 (Placement over HAS)**.** *HAS derives* MP $\to$ Shift, WLPO $\to$ (Shift $\to$ Π^0_2-WEM), Π^0_2-WEM $\to$ Shift *and* LPO $\to$ WLPO $\wedge$ Shift. *It derives none of* WLPO $\wedge$ Shift $\to$ LPO, Shift $\to$ WLPO, Shift *and* $\neg$Shift. *So, over HAS, WLPO is strictly weaker than* WLPO $\wedge$ Shift, *which is equivalent to* WLPO $\wedge$ Π^0_2-WEM, *that is, to* Π^0_2-WEM *itself (Theorem 7.62), and strictly weaker than LPO;* Shift *is comparable with WLPO in neither direction; and MP does not hold in the bounding frame (its value there is not* $\top$*).*

Proof. Let X be decidable with every row not not inhabited. Under MP, comprehension gives for each N the decidable set Y_N of the m with $\langle N, m\rangle \in X$; it is not empty up to double negation, so MP gives a member, and $\mathrm{All}(X)$ follows, hence $\neg\neg\mathrm{All}(X)$. Under WLPO, let X be decidable and let comprehension give B, the set of N with $\mathrm{Z}(Y_N)$; WLPO at each Y_N shows that B is decidable, and WLPO at B gives $\mathrm{Z}(B)$, in which case every row is not not inhabited and the shift applies, or $\neg\mathrm{Z}(B)$, in which case $\mathrm{All}(X)$ would empty B, so $\neg\mathrm{All}(X)$. The third derivation drops a hypothesis, and the fourth combines LPO $\to$ WLPO and LPO $\to$ MP (Proposition 7.35) with the first.

For the non-derivations use Lemma 7.21. In $\beta\mathbb{N}$ the closure of an open set is open, so every instance of $\neg U \vee \neg\neg U$ has the value $\top$ (Section 7.13); hence Shift has the value $\top$, as does

WLPO, while LPO does not (Table 7.2). In the one-point compactification of an uncountable set MP has the value $\top$ and WLPO does not (Table 7.2); by the first derivation the value of Shift is at least that of MP, hence $\top$. The bounding frame gives Shift a value other than $\top$, and $\beta\mathbb{N}$ gives $\neg$Shift the value $\bot$. In the bounding frame the value of MP lies below that of Shift, so it is not $\top$ either. □

Conditions and scope.

Base and premises
Intuitionistic second-order arithmetic HAS with full comprehension; models are systems of truth values built in classical set theory with choice.

Conclusion
Over HAS, WLPO does not imply Π^0_2 weak excluded middle, not even for decidable matrices whose rows are each not not inhabited; MP does imply that restricted form.

Not claimed
The same separation for the WLPO function in the reading of maps of this part, without unique choice; there the question is the one Theorem 28.26 reduces to the shift, and it is open.

28.9 Names, a space-filling curve and tail signs

Chapter 21 priced the decision whether a given cost obeys Recognition Science's composition law. For a cost given as a bare map, parts 3 and 4 of its price ladder (Theorem 21.29) place the price between two zero tests: the *function zero test* FZ, which decides for every map H on $\mathbb{R}_\delta$ whether $H(x) = 0$ for every x, and the *pair zero test* PZ, the same for maps of two points. A map of two points could hide a nonzero value where no map of one point can see it. We show that it cannot: the two tests are equivalent, with no choice principle, and so deciding the law costs exactly one zero test, as Theorem 21.29 records. The proof splits on whether a map can vanish on a dense grid without vanishing, and in the case where it cannot, a space-filling curve reaches every pair of points.

Lemma 28.34 (A hidden value gives the WLPO function)**.** *If a map f on $\mathbb{R}_\delta$ vanishes at every triadic point $z/3^n$, with z an integer, and $f(x_0) > 0$ for some point x_0, then the WLPO function exists. No choice principle is used.*

Proof. Fix a regular sequence s naming x_0; the goal is a proposition. For a binary sequence α with first 1 at b, let g_b be a triadic ratio within $1/(4b+4)$ of s_{4b+3}. The *switch point* of α is named by the sequence whose stage k is s_{4k+3} if $\alpha(0) = \cdots = \alpha(k) = 0$, and g_b once the first 1 has appeared at some $b \le k$. It is regular: two stages before the switch differ by at most $1/(4k+4) + 1/(4m+4)$, a stage k before it and a later one differ by at most $1/(4k+4) + 2/(4b+4) < 1/(k+1)$ since $b > k$, and stages after it are equal. If α is all zero the switch point is x_0; otherwise it is the triadic point g_b. So $v = f(\text{switch}(\alpha))$ is $c = f(x_0)$ or 0, up to double negation, and it is c exactly when α is all zero. Choose ratios $0 < q_1 < q_2 < c$. Cotransitivity at $q_1 < q_2$ gives $q_1 < v$ or $v < q_2$, and a search through the stages of a sequence naming v finds one of the two. If $q_1 < v$, then $v \neq 0$ and so $v = c$; if $v < q_2$, then $v \neq c$ and so

$v = 0$. The search therefore decides the proposition $v = c$, and its answer depends only on v. Put $d(\alpha) = 1$ exactly when $v = c$; then $d(\alpha) = 1$ exactly when α is all zero. □

Lemma 28.35 (Schoenberg's curve on the line)**.** *Let p be the map of $\mathbb{R}_\delta$ with $p(t) = 0$ for $t \le \frac{1}{3}$, $p(t) = 3t - 1$ on $[\frac{1}{3}, \frac{2}{3}]$, $p = 1$ on $[\frac{2}{3}, \frac{4}{3}]$, $p(t) = 5 - 3t$ on $[\frac{4}{3}, \frac{5}{3}]$ and $p = 0$ on $[\frac{5}{3}, 2]$, continued with period 2 for $t \ge 0$, and put*

$$\sigma_1(t) = \sum_{k \ge 0} \frac{p(3^{2k} t)}{2^{k+1}}, \qquad \sigma_2(t) = \sum_{k \ge 0} \frac{p(3^{2k+1} t)}{2^{k+1}}.$$

Then $\sigma = (\sigma_1, \sigma_2)$ is a map from $\mathbb{R}_\delta$ to pairs of points, and whenever $x, y \in [0, 1]$ have binary expansions (b_n) and (c_n), the point $t = \sum_k 2a_k 3^{-(k+1)}$ with $a_{2n} = b_n$ and $a_{2n+1} = c_n$ lies in $[0, 1]$ and has $\sigma(t) = (x, y)$. No principle is used.

Proof. p is the piecewise-linear interpolation of its values at the thirds $j/3$, $j \ge 0$, clamped to $[0, 1]$, with slope at most 3, so each term is a map, its value lies in $[0, 2^{-(k+1)}]$, and the series converge with the explicit bound 2^{-K} on the tail after K terms; σ is the limit. For $t = \sum_k 2a_k 3^{-(k+1)}$ write $3^k t = E + 2a_k/3 + r$, where $E = \sum_{i<k} 2a_i 3^{k-1-i}$ is an even integer and $0 \le r \le \sum_{i>k} 2 \cdot 3^{k-1-i} = \frac{1}{3}$. By periodicity $p(3^k t) = p(2a_k/3 + r)$, which is 0 if $a_k = 0$ and 1 if $a_k = 1$. Hence $\sigma_1(t) = \sum_n b_n 2^{-(n+1)} = x$ and $\sigma_2(t) = y$. □

This is Schoenberg's form of Lebesgue's curve [108]. On $\mathbb{R}_\delta$ the curve itself is free; what it needs from a point is a binary expansion, and Theorem 12.61 prices those at LLPO with countable choice. A map of two points can be read along the curve wherever names exist.

Theorem 28.36 (One zero test decides every law)**.** *With no choice principle, the function zero test* FZ *is equivalent to the pair zero test* PZ*, and both are equivalent to deciding, for every map C on $\mathbb{R}_\delta$, whether C obeys the composition law $C(s + t) + C(s - t) = 2C(s)C(t) + 2C(s) + 2C(t)$ for all s, t.*

Proof. Chapter 21 shows, with no choice principle, that deciding the law for every map gives FZ, that PZ gives the decision of the law, and that FZ decides countably many function zero tests at once. It remains to derive PZ from FZ.

A dichotomy up to double negation. Say that grids are dense if every map vanishing at every triadic point vanishes everywhere. If there is no WLPO function, then by Lemma 28.34, applied to f and to $-f$, a map vanishing on the triadic points has no value apart from 0, so every value is 0: grids are dense. Hence it is not false that the WLPO function exists or grids are dense.

A countable test. Let H be a map of two points. We claim that $H(x, y) = 0$ for all x, y exactly when (a) H vanishes at every pair of triadic points and (b) for every pair of integers (i, j) and every t, $H(\sigma_1(t) + i, \sigma_2(t) + j) = 0$. One direction is clear. For the other, $H(x, y) = 0$ is stable under double negation, so we may use the dichotomy. With the WLPO function, a decided order places x in $[i, i + 1]$ and y in $[j, j + 1]$ for integers i, j, Theorem 28.11 gives binary expansions of $x - i$ and $y - j$, and Lemma 28.35 gives t with $\sigma(t) = (x - i, y - j)$; (b) gives $H(x, y) = 0$. If grids are dense, then for a triadic y_0 the map $x \mapsto H(x, y_0)$ vanishes on the

grid by (a), hence everywhere, and then for each x the map $y \mapsto H(x, y)$ vanishes on the grid, hence everywhere.

The decision. Condition (a) is a sequence zero test, which is the function zero test of the interpolation of the sequence, and (b) is a countable family of function zero tests, indexed by the pairs (i, j). With FZ all of them are decided at once, so FZ decides whether H vanishes. □

So the price of deciding the law for a bare cost, calibrated or not, is exactly the function zero test: the two bounds that Chapter 21 proves for it, FZ below and PZ above, meet. The proof used names of points only up to double negation, and the WLPO function only to obtain them. Do names up to double negation need more than WLPO? The answer turns on one sequence of signs.

Definition 28.37 (Tail signs)**.** A *signed-digit stream* is a sequence d with digits in $\{-1, 0, 1\}$. For $n \le m$ put $P_{n,m} = \sum_{n \le k < m} d_k 2^{m-1-k}$, an integer, so that $2^{-m} P_{n,m}$ is the part of the tail $\sum_{k \ge n} d_k 2^{-(k+1)}$ before position m. A binary sequence f *reads the tail signs* of d if for all $n \le m$: $f(n) = 1$ gives $P_{n,m} \ge -1$, and $f(n) = 0$ gives $P_{n,m} \le 1$. The *tail-sign principle* states that for every signed-digit stream it is not false that some binary sequence reads its tail signs. *Names up to double negation* states that for every point x of $[0, 1]$ it is not false that x has a binary expansion.

So $f(n) = 1$ asserts that the tail from n is nonnegative and $f(n) = 0$ that it is nonpositive, each checked at every finite stage with a slack of one unit of the last place. One sequence f reads the signs of all tails of one stream.

Theorem 28.38 (Names and tail signs)**.**

1. *Names up to double negation hold exactly when the tail-sign principle holds; so WLPO gives names up to double negation exactly when it gives the tail-sign principle.*
2. *Under names up to double negation, every pair of points of $[0, 1]^2$ is not not a value of Schoenberg's curve on $[0, 1]$.*
3. *Names up to double negation follow from MP, from the double negation of MP, and from the double-negation shift for Σ^0_1 rows: if every row of a double sequence of bits is not not inhabited, then it is not false that every row is inhabited. WLPO with countable unique choice into $\{0, 1\}$ gives every point of $[0, 1]$ a binary expansion.*
4. *WLPO decides each tail sign: for every stream d and every n some bit c satisfies the condition on $f(n)$ for all $m \ge n$.*
5. *No continuous rule reads tail signs on any cylinder: if Φ maps streams to binary sequences and each value $\Phi(d)(n)$ depends only on finitely many digits of d, then for every stream d_0 and every L some stream that agrees with d_0 below L has tail signs that Φ misreads.*

No choice principle is used beyond the one named.

Proof. 1. Assume the tail-sign principle and let $x \in [0, 1]$. It has a signed-digit expansion d with partial sums S_n (Proposition 12.62), so $S_n - 2^{-n} \le x \le S_n + 2^{-n}$. Since the goal is

a negation, we may take f reading the tail signs of d. Decide each comparison $j/2^n \le x$ by the table $B(n,j) = 1$ if $j < 2^n S_n$, $B(n,j) = 0$ if $j > 2^n S_n$, and $B(n,j) = f(n)$ if $j = 2^n S_n$. The first two entries are correct by the bounds on x; in the third, $f(n) = 1$ says that every later window lies at or above S_n, so $S_n \le x$, and $f(n) = 0$ says $x \le S_n$. The bisection of Theorem 12.61, run on this table, gives a binary expansion. Conversely, assume names up to double negation and let d be a stream. The point $x = \frac{1}{2} + \sum_k d_k 2^{-(k+2)}$ lies in $[0,1]$ and in the window $[(2^m + 2^m S_m - 1)/2^{m+1}, (2^m + 2^m S_m + 1)/2^{m+1}]$ for every m. Take a binary expansion with numerators a_n, and put $f(n) = 1$ exactly when $2^n + 2^n S_n \le a_{n+1}$. If $f(n) = 1$, then x lies at or above $(2^n + 2^n S_n)/2^{n+1}$, and comparing with the window at $m \ge n$ gives $P_{n,m} \ge -1$; if $f(n) = 0$, then x lies at or below it, and the window gives $P_{n,m} \le 1$.

2. Under the goal's double negation, take expansions of x and y and apply Lemma 28.35.

3. Let $x \in [0,1]$ and suppose x has no binary expansion. Then x differs from every dyadic ratio q in $(0,1)$, since a dyadic ratio has an expansion; so it is not false that some stage of a sequence naming x witnesses $x < q$ or $q < x$. These are the rows of a double sequence of bits, indexed by q. If every row were inhabited, a search would find the first witness in each row and give a table of correct comparisons, and the bisection would give an expansion, a contradiction. So the shift for Σ^0_1 rows gives the contradiction. MP gives that shift, since it makes every row inhabited, and the double negation of MP suffices because the conclusion is a negation. With WLPO each comparison $q \le x$ is decided by a unique bit, and countable unique choice collects the bits over the countably many dyadic q into a table.

4. Fix n. WLPO applied to the decidable sequence "$P_{n,m} < -1$", $m \ge n$, says that all $P_{n,m} \ge -1$, and then $c = 1$ serves, or that not all are. In the second case $c = 0$ serves: $P_{n,m} \le 1$ is decidable, and $P_{n,m} \ge 2$ for one m would make all pieces at least -1, because $P_{n,m+e} = 2^e P_{n,m} + \sum_{i<e} d_{m+i} 2^{e-1-i} \ge 2^{e+1} - (2^e - 1)$ and, for earlier m', $2^{m-m'} P_{n,m'} \ge P_{n,m} - (2^{m-m'} - 1) > -2^{m-m'}$.

5. Let d_1 agree with d_0 below L and be 0 from L on. The value $\Phi(d_1)(L)$ depends on the first K digits; let $K' = \max(K, L)$ and change d_1 only at position K', to -1 if $\Phi(d_1)(L) = 1$ and to $+1$ otherwise. The new stream d has $\Phi(d)(L) = \Phi(d_1)(L)$, while $P_{L,K'+2} = \mp 2$ violates the condition that $\Phi(d)(L)$ imposes. □

Item 4 shows that WLPO decides each sign separately. Item 5 shows why collecting the signs is hard: a rule that reads them cannot be continuous in the stream. A model in which every function is computed continuously from a generic stream should therefore refute the tail-sign principle while keeping WLPO. We build one for a calculus of numbers and functions.

The *stream calculus* has two sorts, numbers and functions from numbers to numbers. Number terms are variables, 0, successors, and a function variable applied to a number term. The atomic formulas are equations and a tail atom $\mathrm{Tail}(d, f, n, m)$, which states the condition of Definition 28.37 on $f(n)$ at m for the stream d, with each value v of d read as the digit $v - 1$ and each value of $f(n)$ other than 1 read as 0. Formulas are built with $\bot$, $\wedge$, $\vee$, $\to$ and quantifiers over both sorts. The rules are those of intuitionistic natural deduction for both sorts, reflexivity and substitution of equals, decidability of every atom, the successor axioms, induction for every formula, explicit definition of a function by a number term, and choice for atomic matrices: from $\forall n\, \exists m\, A(n,m)$ with A atomic infer $\exists F\, \forall n\, A(n, F(n))$, which is what a least-number search gives. Read with numbers in $\mathbb{N}$ and functions ranging over all maps,

every rule is sound, so the calculus is a fragment of ordinary mathematics; its sentence WLPO, $\forall\alpha(\forall n\,\alpha(n) = 0 \vee \neg\forall n\,\alpha(n) = 0)$, reads as WLPO and its tail-sign sentence as the tail-sign principle.

Theorem 28.39 (WLPO without tail signs)**.** *In the stream calculus, the tail-sign sentence is not derivable from WLPO, and neither are MP and its double negation. The proof reasons in classical mathematics, with the axiom of choice.*

Proof. Let $Y = \{0,1,2\}^{\mathbb{N}}$ with its product topology, the space of streams. A *condition* is an open set $U \subseteq Y$. A number datum on U is a map $a : Y \to \mathbb{N}$ that is locally constant on the closure of U: near each stream of the closure it depends only on finitely many digits. A function datum is a map $Y \to \mathbb{N}^{\mathbb{N}}$ each of whose values at a fixed argument is a number datum. Forcing is defined by recursion. U forces an atom when the atom holds at every stream of U, and forces $\bot$ when U is empty; $\wedge$ is pointwise; U forces $A \vee B$ when open $V, W \subseteq U$ force A and B and $V \cup W$ is dense in U; U forces $A \to B$, or a universal statement, when every open $V \subseteq U$ that forces A forces B, or every open $V \subseteq U$ forces every instance by a datum on V; and U forces an existential statement when finitely many open pieces of U, with data, force instances and their union is dense in U. The finiteness in the last clause is what makes Markov's principle fail below; the failure of the tail-sign principle does not use it.

Soundness. By induction on derivations, every derivable sequent is forced by every condition with data that forces its hypotheses. The induction uses that forcing passes to smaller open sets, that the empty set forces everything, that a statement forced on finitely many open pieces whose union is dense in U is forced by U, that terms built from locally constant data are locally constant, and that a decidable atom splits U into an open part where it holds and an open part where it fails, with dense union. The compactness of Y reduces each locally constant datum to finitely many constant pieces, which is what the finite existential clause needs. The choice rule holds because the least witness of an atomic matrix, computed stream by stream, is again locally constant.

WLPO is forced everywhere. Let α be a function datum on an open V. Let P be the interior of the set of streams in V at which α is all zero, and $Q = V \setminus \overline{P}$. Then P forces $\forall n\,\alpha(n) = 0$. An open $W \subseteq Q$ forcing it lies in that set, hence in P, hence is empty; so Q forces $\neg\forall n\,\alpha(n) = 0$. $P \cup Q$ is dense in V.

Tail signs are not forced. Interpret d by the generic stream, the datum $y \mapsto y$; its digits are forced to lie in $\{0,1,2\}$. Suppose a nonempty condition W forces that some f reads the tail signs. Then a nonempty open piece of W carries a function datum f with $f(y)$ reading the tail signs of y at every stream y of the piece. On a cylinder inside the piece, each value $f(y)(n)$ depends on finitely many digits of y, so f is a continuous rule reading tail signs on that cylinder, which Theorem 28.38, item 5, excludes. So every condition forcing the existence of f is empty, Y forces its negation, and Y does not force its double negation. Since Y forces WLPO, soundness shows that the tail-sign sentence is not derivable from WLPO.

The negation of MP is forced everywhere. Let a nonempty open V force MP and take a cylinder $C \subseteq V$ that fixes the first L digits. Let α be the function datum with $\alpha(y)(n) = 1$ when $n \geq L$ and digit n of y is 2, and 0 otherwise; each value reads one digit. Every nonempty open $W \subseteq C$ contains a cylinder that also fixes some digit $n \geq L$ to 2, and that cylinder forces $\exists n\,\alpha(n) = 1$ with a constant witness; so only the empty set forces $\neg\exists n\,\alpha(n) = 1$ below C, and C forces

$\neg\neg\exists n\,\alpha(n) = 1$. Since C forces MP, it forces $\exists n\,\alpha(n) = 1$: finitely many open pieces of C, with number data b_i, force $\alpha(b_i) = 1$, and their union is dense in C. The stream $z \in C$ that is 0 from place L on lies in the closure of that finite union, hence in the closure of one piece. Near z the datum b_i is constant on that closure, say equal to N, and the streams of the piece near z agree with z at place N; there $\alpha(b_i) = 1$ asks for $N \geq L$ and digit 2 at place N, while z has a digit other than 2 there. A nonempty open part of the piece fails the atom, a contradiction. So Y forces the negation of MP, and since Y forces WLPO, neither MP nor its double negation follows from WLPO. □

The theorem is exact for the stream calculus, a fragment of ordinary mathematics with induction and choice for atomic (decidable) matrices. It does not cover quotients, propositions as objects or universes, so it is not a theorem about the full base of this part; there, whether WLPO gives names up to double negation remains open, and by Theorem 28.38 it is exactly the question whether WLPO gives the tail-sign principle.

Conditions and scope.

Base and premises
$\mathbb{R}_\delta$ for Lemmas 28.34 and 28.35 and Theorems 28.36 and 28.38; the stream calculus and a forcing model built in classical mathematics with the axiom of choice for Theorem 28.39.

Conclusion
Deciding the composition law for every bare cost costs exactly one function zero test. Names up to double negation are exactly the tail-sign principle; WLPO decides each tail sign but, in the stream calculus, does not give the principle.

Not claimed
The separation for the full base of this part.

28.10 Moving the library: density, cones and counts

The sections so far priced the structures of a classical library. Its lemmas are another matter: there are thousands of them, and reading each on $\mathbb{R}_\delta$ by hand is not a method. Two theorems move whole classes of lemmas at no cost, and their failures mark where the remaining prices sit.

Take the triangle inequality $|a + b| \leq |a| + |b|$. At two ratios it is a statement about integers, true by a case distinction on signs, which is decidable for ratios. On $\mathbb{R}_\delta$ the case distinction is not available. But every point is the limit of its own rational stages, both sides are continuous, and an inequality $\leq$ is a negation, which survives a limit. So the inequality holds on the line, with no principle. The same argument fails for $(x \cdot x - 2)^2 > 0$: it holds at every ratio, because $a^2 \neq 2b^2$ for integers with $b \neq 0$, and it fails at $\sqrt{2}$. A strict inequality does not survive a limit.

Definition 28.40 (Terms of ordered algebra)**.** For a natural number n, the *terms in n variables* are built from the variables $x_1, \dots, x_n$ and ratios by $+$, $\cdot$, $-$, $|\cdot|$, max and min. A term t has a value $t(x)$ at every point $x \in \mathbb{R}_\delta^n$, and a ratio value at every $q \in \mathbb{Q}_\delta^n$, with $t(\eta(q)) = \eta(t(q))$. A *strict atom* is $s < t$; a *closed atom* is $s \le t$ or $s = t$. *Terms with inverse* may also contain u^{-1}; such a term has a value at x when every subterm u that is inverted has a value apart from 0 there, and an atom over terms with inverse is *defined* at x when both its sides have values.

Ratios are where a classical lemma can be checked as it stands. Their order is decided, and on them the classical structures cost nothing.

Proposition 28.41 (The ratios carry the classical order)**.** *The ratios $\mathbb{Q}_\delta$, with the order that η induces from $\mathbb{R}_\delta$, form a linear-order structure in the sense of Definition 28.13, with decided $\le$, $=$ and $<$, and satisfy the strict-ordered-ring laws; η preserves sums, products, $<$ and $\le$. No principle is used.*

Proof. For ratios with positive denominators, $\eta(u/d) < \eta(v/e)$ exactly when $ue < vd$ (Proposition 12.19), a comparison of integers, so $<$ is decided; $\le$ is its negated converse and $=$ the conjunction of two $\le$, both decided. Totality is trichotomy of integers. The strict-ordered-ring laws are the corresponding facts about integers after clearing denominators, and η preserves sums and products by Proposition 12.19. □

Theorem 28.42 (Density transfer)**.** *Let $s_1 < t_1, \dots, s_k < t_k$ be strict atoms and $a_1 \trianglelefteq_1 b_1, \dots, a_l \trianglelefteq_l b_l$ closed atoms, all over terms in n variables.*

1. *If the closed atoms hold at every $q \in \mathbb{Q}_\delta^n$ at which the strict atoms hold, they hold at every $x \in \mathbb{R}_\delta^n$ at which the strict atoms hold.*
2. *The same is true with one further hypothesis $a \ne b$, or $\neg(a \le b)$, for terms a, b, added on both sides.*
3. *For terms with inverse: if at every $q \in \mathbb{Q}_\delta^n$ at which the strict atoms hold, with both sides defined, and the closed atoms are defined, the closed atoms hold, then the same is true at every $x \in \mathbb{R}_\delta^n$.*

No principle is used.

Proof. 1. Three facts carry the proof. (i) A point x named by a regular sequence s is the limit of the ratios $\eta(s_m)$: $|x - \eta(s_m)| \le 1/(m+1)$. For a tuple, use one sequence per coordinate; the conclusion is a proposition, so the sequences may be fixed for the proof. (ii) Every term is continuous with an explicit modulus, by recursion on the term: sums and negatives are 1-Lipschitz in each argument, a product is Lipschitz on a bounded region, and $|\max(a,b) - \max(c,d)| \le \max(|a-c|, |b-d|)$, likewise for min and $|\cdot|$. So $t(\eta(s_m)) \to t(x)$ for every term. (iii) If $u < v$, then $u_m < v_m$ for all late m whenever $u_m \to u$ and $v_m \to v$: a positive rational lower bound ε of $v - u$ is beaten once both approximations lie within $\varepsilon/3$.

Now let the strict atoms hold at x, and let q_m be the tuple of mth stages. By (ii) and (iii) the strict atoms hold at q_m for all late m, so the closed atoms hold there. A closed atom $a \le b$ passes

to the limit: if $b(x) < a(x)$, then (iii) gives $b(q_m) < a(q_m)$ for late m, against $a(q_m) \le b(q_m)$; so $\neg(b(x) < a(x))$, which is $a(x) \le b(x)$. An equation is two such inequalities.

2. The conclusions are stable under double negation, so we may argue under one. The hypothesis $a \neq b$ is $\neg(a = b)$, which is $\neg\neg(a \# b)$ because $a = b$ is $\neg(a \# b)$; under the double negation $a < b$ or $b < a$. In each case add it as a strict atom and apply part 1: at a ratio point where the enlarged list holds, $a \neq b$ holds, so the conclusions hold there by the hypothesis. The hypothesis $\neg(a \le b)$ is $\neg\neg(b < a)$ and is treated the same way.

3. Apartness from 0 is an open condition in the sense of (iii), so at q_m for late m every inverted subterm of the strict atoms and of the closed atoms has a value apart from 0, bounded away from 0 by a fixed ratio. On such a region the inverse is Lipschitz: $w_m - w = w_m w(u - u_m)$ when $u_m w_m = uw = 1$, and $|u| \ge 1/(M+1)$ gives $|w| \le M + 1$. So (ii) holds for terms with inverse at points where they are defined, and the argument of part 1 applies. □

The theorem is free because the conclusion is closed. Its two limits are exact.

Proposition 28.43 (What density cannot move)**.**

1. Strict conclusions. *The term $b(x) = (x \cdot x - 2)^2$ has $0 < b(q)$ at every ratio q, and $b(x) = 0$ for the point $x = \sqrt{2}$.*
2. Closed hypotheses. *The implication $x \cdot x = 2 \to 0 = 1$ holds at every ratio and fails at $\sqrt{2}$.*

No principle is used.

Proof. For a ratio u/d with $d > 0$, $b(u/d) = (u^2 - 2d^2)^2/d^4$, and $u^2 \neq 2d^2$ because the exponent of 2 in u^2 is even and in $2d^2$ odd; so $b(u/d)$ is a positive ratio. The square root of 2 (Proposition 12.19, item 5) satisfies $\sqrt{2} \cdot \sqrt{2} = 2$, so $b(\sqrt{2}) = 0$, and the closed hypothesis of item 2 holds there while $0 = 1$ does not. □

Closed hypotheses in solved form are the exception to item 2. A hypothesis $x_i \le t$, $t \le x_i$ or $x_i = t$, where t does not contain x_i, is removed by substituting $x_i := t - |y|$, $t + |y|$ or t with a new variable y; the result is a statement of Theorem 28.42.

Strict conclusions need a different argument, and an old one supplies it. Krivine and Stengle showed that a polynomial inequality holds on a semialgebraic set exactly when an algebraic identity certifies it [107, 109]. We need only the easy half, the identity itself, and on $\mathbb{R}_\delta$ it costs nothing.

Definition 28.44 (Cone expressions)**.** Fix strict hypotheses $l_i < r_i$ ($i \le m$) and closed hypotheses $l'_j \le r'_j$ ($j \le m'$) over terms in n variables. The *nonnegative expressions* are built from the slacks $r_i - l_i$ and $r'_j - l'_j$, from 1 and from squares $t \cdot t$ of terms, by sums and products. The *cone expressions* are built from the strict slacks $r_i - l_i$ and 1 by sums and products, and by adding a nonnegative expression to a cone expression. Each expression has a value at every $x \in \mathbb{R}_\delta^n$.

Theorem 28.45 (Cone transfer and cone refutation). *Let l, r be terms in n variables, and let $x \in \mathbb{R}_\delta^n$ satisfy the strict and the closed hypotheses.*

1. *If cone expressions k_1, k_2 satisfy $k_1 \cdot (r - l) = k_2$ at every point of $\mathbb{R}_\delta^n$, then $l(x) < r(x)$. The same holds when k_1 is only a nonnegative expression.*
2. *If a cone expression k, formed over the strict hypotheses enlarged by $r < l$, vanishes at every point of $\mathbb{R}_\delta^n$, then $l(x) \le r(x)$.*

No principle is used, and no density argument.

Proof. At x every strict slack is positive and every closed slack and every square is nonnegative. By recursion on the expression, every nonnegative expression is ≥ 0 at x and every cone expression is > 0 at x: sums and products of positive points are positive, and a positive point plus a nonnegative one is positive.

1. At x, $k_1 \cdot (r - l) = k_2 > 0$ with $k_1 \ge 0$. A positive product has both factors apart from 0, since $|k_1|\,|r - l| > 0$ gives each factor a positive absolute value; with $k_1 \ge 0$ this makes $k_1 > 0$, and then $r - l = k_2 \cdot k_1^{-1} > 0$.

2. The conclusion $l \le r$ is $\neg(r < l)$. If $r(x) < l(x)$, the enlarged hypotheses hold at x, so $k(x) > 0$; but $k(x) = 0$. □

For $0 < a < b$ the identity $1 \cdot (b \cdot b - a \cdot a) = (b - a) \cdot \big((b - a) + a + a\big)$ is a certificate for $a \cdot a < b \cdot b$: its right side is a product of cone expressions over the slacks $b - a$ and $a - 0$. Once such an identity is written down, checking it is algebra; finding it is a search, and nothing in the theorem depends on how it was found.

Proposition 28.46 (Positive cones). *The positive points of $\mathbb{R}_\delta$ form a commutative group under δ's product, with no principle. A linear-order structure on the positive points whose strict order is δ's $<$ exists exactly when the LPO function exists, with no choice principle in either direction.*

Proof. A positive point is apart from 0 and has an inverse (Proposition 12.19, item 3), which is positive, and products of positive points are positive. A linear-order structure stores a decided $<$; the bit at the pair $(1, 1 + x_\alpha)$ is 1 exactly when $x_\alpha > 0$, that is, by (28.1), exactly when α takes the value 1, so it is the LPO function. Conversely, restrict the structure of Theorem 28.15 to the positive points. □

What moves, and what it costs: a reported audit

The counts in this subsection and in Table 28.2, like those in Sections 28.2 and 28.4, report an audit. They are not theorems of this book, and we do not reproduce the audit's row-by-row arguments. The audit read on $\mathbb{R}_\delta$ the theorems of five areas of algebra and order in the classical library that opens this chapter, its theorems on complete orders and fields, and every library theorem used in a set of classical proofs, written with that library, of the steps of the forcing chain restated in Table 22.1 and of the near-flat sector of gravity; those proofs are not part of this book either. A *row* is one library theorem, or one use of it. For each row it priced, the audit recorded a proof of an implication from a price to the statement read on $\mathbb{R}_\delta$, or a proof

Table 28.2. The classical library moved to $\mathbb{R}_\delta$: the counts of the audit described in the text, reported and not proved here. "Route" is the price an upper bound has proved, not a lower bound; "convention" marks rows that hold only through $0^{-1} = 0$ or $c \neq 0$ read as apartness.

Body of results	Rows	Free	Exact price	Other
Ordered fields, groups, rings and lattices	804 theorems	239		389 at the LPO function (route); 176 not moved by that route
The 389 rows above, by Theorems 28.42 and 28.45	389	311	9 LLPO, 5 MP	2 free in one direction; 62 convention
Lemmas of the linear order (Section 28.4)	102	56	2 LLPO, 1 MP	27 at the WLPO function (route); 16 at the LPO function, each through $0^{-1} = 0$
Complete ordered fields	324 theorems	3	8 EM with the WEM function	157 at MP and the WEM function, one of them at least WEM; 3 at the LPO function and 3 at the LPO function with EM (route); 67 no instance; 83 not read
Library theorems used by the forcing chain and gravity	560 theorems, 4,530 uses	483	3 LLPO, 2 MP	21 convention; 51 of analysis, topology and homology: 39 free, 3 through the derivative convention, 1 at most countable choice of representatives, 8 open
Uses in the forcing chain and the near-flat sector of gravity	851 uses of 134 theorems	822	1 LLPO	27 convention, at the steps' own $c \neq 0$; 1 not read

of that statement outright, and for an exact price also the converse; rows marked not read, without an instance or open carry none. Below we name the kind of argument behind each kind of row and give an example. A row *read through the convention* holds at an excluded point only through $0^{-1} = 0$, or reads a hypothesis $c \neq 0$ as apartness; its form guarded by apartness is free, and its unguarded form carries the price of the convention (Table 28.1). A route's price is an upper bound and nothing more. Table 28.2 collects the counts.

In the audit, the first two rows tell the main story. A transfer through the ordered field built from a positivity test (Theorem 28.15) moves 628 of the 804 generic theorems of five areas: ordered fields, ordered groups with zero, ordered rings and groups with absolute value, and lattices. It moves 239 free and 389 at the LPO function, the price of that ordered field. That price belongs to the route. Density moves 21 of the 389 free, and 2 more in one direction of their equivalence. Of the remaining 366, cone certificates, cone refutations, inverses guarded by apartness and induction prove 290 free; 62 hold only through the convention; and 14 carry exact prices. Nine cost exactly LLPO: six state a closed disjunction, and three split an arbitrary property into the cases of max, min or $|\cdot|$. A typical one is $a \leq \max(b, c)$ exactly when $a \leq b$ or $a \leq c$; at $a = 0$, $b = x$, $c = -x$ the left side always holds, and the right side is the dichotomy

$0 \le x \vee x \le 0$, which is LLPO (Corollary 12.18). Five cost exactly MP, such as $0 < |a|$ exactly when $a \neq 0$: since $0 < |a|$ is $a \# 0$, this is the reading of $\neq$ as apartness (Corollary 12.18). No row is left open. The 176 rows the first transfer does not move are moved by other routes, 71 of them free, except three that concern only the coherence of the classical structures; along those routes no row met a lower bound above its route's price, and two cost exactly LLPO.

So, as far as the audit reaches, the classical algebra of ordered fields is free on $\mathbb{R}_\delta$, except where it decides a closed disjunction (LLPO), reads $\neq$ as apartness (MP), or relies on $0^{-1} = 0$ at an excluded point. Completeness is different. Of the 324 theorems on complete orders and fields, 160 are proved at the price of the complete ordered field of Theorem 28.19, MP with the WEM function, or below it: three, which do not mention the supremum, are free, and one, interpolation, costs at least WEM (Proposition 28.20). Eight more, the witness rows "$b < \sup s$ gives a member $a \in s$ with $b < a$" in their several forms, cost exactly excluded middle together with the WEM function; under unique choice, excluded middle alone (Remark 28.5). Six theorems about ordered fields go through the LPO function, three of them with excluded middle as well, as an upper bound. Sixty-seven have no instance on the line: they assume a least or greatest point, a well-founded order, or a monotone product. The remaining 83 are not read.

For Recognition Science the last two rows matter. Of the 560 library theorems used in the steps of the forcing chain and in the near-flat sector of gravity, 509 are read on $\mathbb{R}_\delta$, and 483 of them are free; 21 hold only through the convention. Five carry exact prices. Three are forms of the domain law, $xy = 0$ exactly when $x = 0$ or $y = 0$, which costs LLPO (Table 12.2) and enters the equal-cost law of the second rung. One is the positivity of J away from 1, which costs exactly MP in the form "$J(x) > 0$ for $x \neq 1$" and is free for x apart from 1 (Chapter 22). One is the law "$\neg(b \le a)$ gives $a < b$", which costs exactly MP, as in Proposition 28.16, item 2; every step that uses it also has a free proof. The remaining 51, from analysis, topology and homology, are read separately. Thirty-nine are free. Three read the derivative convention through a supplied derivative (Section 28.6). One, strict convexity from a positive second derivative, costs at most countable choice of representatives, and the step that uses it, the strict convexity of J, has a free proof (Chapter 22). Eight, facts of singular homology and of embeddings, are open: none is moved to the line, while the steps that use them are free in Chapter 23: that detecting linking forces three dimensions, that a loop linking the equatorial circle of the 3-sphere bounds nothing in its complement, and that the first homology of the circle is $\mathbb{Z}$ as a relation (steps T4.4, T4.5 and R2-35 of the table in Chapter 22); the data form of the last, one winding function on all chains, costs exactly the WLPO function (Theorem 22.65). Counted by use, the 134 theorems outside analysis and topology that the transfer priced only at the LPO function or did not move have 851 uses in the forcing chain and the near-flat gravity sector; 822 of them are free; 27 read the steps' own hypotheses $c \neq 0$, and are free when an inverse is supplied with c; one is the domain law, at LLPO; and one, in the gravity sector, is not read.

28.11 Classical proofs as programs of Gödel's T

Section 20.4 showed that a classical proof of $\forall x \exists y A$, with A quantifier-free, yields a derivation without excluded middle and a program that computes y from x. That program came from realizability, argued in a classical metatheory, and it was a code of a partial recursive

function whose totality the argument supplied. For three quantifiers the strategy against counterexamples was found by unbounded search, and its form as a term of Gödel's system T was cited, not proved. This section builds the programs as terms of T, by maps on derivations, with no classical metatheory. Then it asks the question that the existence of a program leaves open: how large is the program, measured against the proof it came from?

Here is the case to keep in mind. Every number is even or odd, and here is a classical proof that differs from the one in Section 20.4. Induct on x; $0 = 0 + 0$. For the step from n to $S(n)$, split on whether n is even, which excluded middle permits although nothing decides it. If $n = y + y$, then $S(n) = S(y + y)$. If n is not even, the induction hypothesis gives $n = y + y$ or $n = S(y + y)$; the first is excluded, so $S(n) = S(S(y + y)) = S(y) + S(y)$. Written out in Peano arithmetic, the proof is a finite tree of rule applications. The compiler of Theorem 28.51 turns it into a closed term of T, of size bounded by one polynomial of degree five in the size of the proof. Its value at 7 is 3, and Theorem 28.53 says why: the compiled term meets the formula at every input, and 3 is the only y with $7 = y + y$ or $7 = S(y + y)$. The value is not the point; anyone can halve 7. The point is that a program, with a proved bound on its size, comes out of a proof whose one classical step is a case split that nothing decided.

Throughout this section A is a quantifier-free formula of arithmetic, Peano arithmetic is the calculus of Definition 8.10, and $\vdash_{\mathrm{PA}}$, $\vdash_{\mathrm{HA}}$ and the negative translation φ^N are as in Section 20.4. Every result of the section is proved with no omniscience principle and no choice principle, except Theorem 28.56 and Proposition 28.57, which reason in classical mathematics, and the last assertion of Theorem 28.55, as their statements say.

Programs and their size

Definition 28.47 (Programs of Gödel's T)**.** The finite types are those of Subsection 20.3.2, generated from O by $A \to B$. The *programs* of T are built by application, of a program of type $A \to B$ to a program of type A, from the constants

$$\mathsf{K}_{A,B} : A \to (B \to A), \qquad \mathsf{S}_{A,B,C} : (A \to (B \to C)) \to ((A \to B) \to (A \to C)),$$
$$0 : O, \qquad \mathsf{Succ} : O \to O, \qquad \mathsf{R}_A : A \to \big((O \to (A \to A)) \to (O \to A)\big),$$

one for each choice of the types in the subscripts. The value $\mathrm{val}(t)$ of a program t is defined by recursion on t: a number for type O, a function from values of A to values of B for type $A \to B$, with

$$\mathsf{K}\,a\,b = a, \qquad \mathsf{S}\,f\,g\,a = f\,a\,(g\,a), \qquad \mathsf{Succ}\,n = n + 1,$$
$$\mathsf{R}\,b\,g\,0 = b, \qquad \mathsf{R}\,b\,g\,(n+1) = g\,n\,(\mathsf{R}\,b\,g\,n),$$

and the value of an application is the value of the function at the value of the argument. A program of type $O \to O$ therefore computes a function from numbers to numbers, defined at every input.

The system is Gödel's [70], in the combinator form that needs no variables. Its recursor is primitive recursion at every finite type, and nothing in it searches without a bound. A program with variables of types $A_1, \dots, A_L$ is written as a closed program of type $A_1 \to \cdots \to A_L \to B$: bracket abstraction removes a variable, $[x]x = \mathsf{S}\,\mathsf{K}\,\mathsf{K}$, $[x]c = \mathsf{K}\,c$ for c without x, and $[x](u\,v) = \mathsf{S}\,([x]u)\,([x]v)$, and keeps the value.

Definition 28.48 (Size and shape)**.** Derivations, formulas, terms, finite types, programs, lists and natural numbers are generated by constructors. The *size* $\|o\|$ of such an object is 1 plus the sizes of the arguments of its outermost constructor; a list is built from the empty list by adding members, and a natural number counts as its value. The arguments of a node of a derivation are its list of hypotheses, the formulas and terms its rule mentions, and its subderivations; the arguments of a constant or an application of T include the types that fix its typing. The *shape* $\mathrm{sh}(A)$ of a formula is its number of connectives and quantifiers plus its number of equations and occurrences of $\bot$, an equation counting once whatever its terms. For a derivation d, $\mathrm{sh}(d)$ is the largest shape of a formula concluded at a node of d, and $\mathrm{cx}(d)$ is the largest length of a list of hypotheses at a node of d.

Because every node carries its hypotheses, a derivation that keeps K hypotheses open along K steps has size of order K^2. This matters for the exponents of Theorem 28.52, which are stated for exactly this measure.

The compilers

Theorem 28.49 (Classical proofs compile to programs of T)**.** *Let A be quantifier-free.*

1. *A map on derivations sends every derivation of φ from Γ in Peano arithmetic to a derivation of φ^N from Γ^N in Heyting arithmetic.*
2. *A map assigns to every derivation d of $\forall x\,\exists y\,A$ in Peano arithmetic from no hypotheses, and every assignment ρ of numbers to the other free variables of A, a closed program t of type $O \to O$ such that, for every number x, A holds at x, at $y = \mathrm{val}(t)(x)$ and at ρ.*
3. *A map assigns to every such derivation of $\forall x\,\exists y\,\forall z\,A$ and every ρ a closed program Φ of type $O \to ((O \to O) \to O)$ such that, for every number x and every function f from numbers to numbers, A holds at x, at $y = \mathrm{val}(\Phi)(x)(f)$, at $z = f(y)$ and at ρ: Kreisel's no-counterexample functional [55].*
4. *Read with O as the orbit $\mathbb{N}_\delta$ of Chapter 1 and the constants by the same equations, every closed program has a value, and the reading of the orbit as numbers carries it to the value above.*

No omniscience principle and no choice principle is used.

Proof. 1. The proof of Theorem 20.57 is a recursion on derivations that builds, at each rule, a derivation of the translated conclusion from derivations of the translated premises, for every rule including excluded middle. Read as a definition, it is the map. Its one arithmetic input is stability of translated equations, which uses a derivation of $s = t \vee \neg(s = t)$ in Heyting arithmetic for each pair of terms; the proof of Lemma E.1, item 2, builds one by recursion on the terms.

2 and 3. The programs come from realizability relative to a challenge. Fix a property P of numbers. To each formula assign a list of finite types: one O for an equation and for $\bot$; the two lists side by side for a conjunction; for $\varphi \to \psi$, the types of ψ, each taking the types of φ as arguments; for $\forall x\,\varphi$, those of φ, each taking an argument of type O; for $\exists x\,\varphi$ and for a

disjunction, one O in front. A list w of values of these types *realizes* a formula under P, at an assignment of its variables, by recursion on the formula: an equation when it holds or P holds of the number w; $\bot$ when P holds of w; a conjunction when the two parts of w realize the two conjuncts; $\varphi \to \psi$ when w, applied to every list realizing φ, realizes ψ; $\forall x\,\varphi$ when w applied to every number n realizes φ at $x = n$; $\exists x\,\varphi$ when the rest of w realizes φ at x equal to the first entry; a disjunction when the first entry selects a side that the rest realizes. This is Kreisel's modified realizability [7] with $\bot$ read as "P holds of a number", Friedman's translation [68] made computational, as in [105]. By recursion on a derivation of φ from Γ in Heyting arithmetic we build programs, taking as arguments the realizers of Γ and the values of the free variables, that realize φ under every P whenever their arguments realize Γ. A hypothesis is a projection. Implication introduction keeps the programs of its premise and reads the arguments of the discharged hypothesis as arguments of the type; implication elimination applies each program of the major premise, argument by argument, to the programs of the minor premise. Universal introduction lifts the programs of its premise into a context with one more number and applies them to the arguments of that context; the other quantifier rules take or supply a number. Equality substitution is a conditional on a program that decides the equation: where the equation holds it returns the programs of the substituted premise, and where it fails it copies the number that realizes the equation into every component. Induction is the recursor R; the impossible case copies the number that realizes $\bot$ into every component, which realizes every formula, since an equation is realized by any number with P. Bracket abstraction turns the arguments into a closed program.

Apply this to the translation, by item 1, of a derivation of $\forall x\,\exists y\,\forall z\,A$; it derives $\forall x\,\neg\forall y\,\neg\forall z\,A^N$. Let r be its realizer. Fix x and f, and let $P(n)$ say that A holds at x, n and $f(n)$. We need a realizer W of $\forall y(\forall z\,A^N \to \bot)$: given y and a realizer w of $\forall z\,A^N$, it must return a number with P. A program χ_A, built from A by recursion, has value 0 exactly when A holds. If A holds at x, y, $f(y)$, then W returns y. Otherwise w applied to $f(y)$ realizes A^N at $z = f(y)$, the translation of a false quantifier-free formula. At a false equation the identity realizes its negation, because a realizer of a false equation is a number with P; from these, by recursion on A, a realizer of $\neg A^N$ is assembled, and applying the realizer of A^N to it returns a number with P, which W returns. Then r applied to x and W realizes $\bot$, that is, returns a number y with $P(y)$. The program Φ of item 3 is $x, f \mapsto r\,x\,W_{x,f}$, closed by bracket abstraction. A program cannot read the assignment ρ; it receives the finitely many values of ρ that A mentions, as numerals. For item 2, apply to d, by implication elimination, a fixed derivation of $\forall x\,\exists y\,A \to \forall x\,\exists y\,\forall z\,A$, with z a variable that A does not mention; apply item 3 to the result, and apply Φ to the constant function 0: the program is $\mathsf{S}\,\Phi\,(\mathsf{K}\,(\mathsf{K}\,0))$.

4. The orbit has a start, a step and recursion along the step (Chapter 1). Reading 0, Succ and R by them and K, S by their equations, induction on the program shows that the value at the orbit element of n is the orbit element of the value at n, at every finite type. $\square$

The programs are terms of T, so they are total by their types and contain no search without a bound. Item 3 is the form that Section 20.4 cited from Gödel's functional interpretation [70, 56]; here it is proved, by a different route, and every step is a map on derivations or on programs.

Conditions and scope.

Base and premises
Peano and Heyting arithmetic as in Section 20.4; a quantifier-free matrix A; the programs of Definition 28.47.

Conclusion
Maps on derivations: classical derivations to intuitionistic ones, and classical proofs of $\forall x\,\exists y\,A$ and $\forall x\,\exists y\,\forall z\,A$ to closed programs of T computing a witness and a strategy against every counterexample function. The programs run on the orbit $\mathbb{N}_\delta$ with the same values. Free.

Not claimed
Any bound on the size of the programs; the next theorems supply one for a second compiler and show that the first has none.

How large the programs are

A compiler is a map on derivations, so it can be measured. Write t_d for the program that item 2 of Theorem 28.49 assigns to d with every parameter read as 0. Is $\|t_d\|$ bounded by a polynomial in $\|d\|$? It is not, and the reason is a step the proof left open: how a realizer that takes a list of arguments is applied, argument by argument, to another one. A realizer in a context of argument types $\Delta = (a_1, \dots, a_L)$ is a closed program of type $a_1 \to \cdots \to a_L \to B$. The direct way to apply u to v pointwise recurses on Δ,

$$\sigma_{()}(u, v) = u\,v, \qquad \sigma_{a::\Delta}(u, v) = \sigma_\Delta\big(\sigma_\Delta(\kappa_\Delta(\mathsf{S}), u), v\big),$$

where κ_Δ lifts a closed program into the context by K's. It calls itself twice for each entry.

Theorem 28.50 (The direct compiler grows exponentially)**.** *Let e_0 be the derivation of $0 = 0$ by reflexivity, and let e_{k+1} derive $0 = 0$ by equality substitution from the reflexivity derivation of $0 = 0$ and from e_k. Let d_n derive $\forall x\,\exists y(y = y)$ from e_n by existential introduction with witness 0 and universal introduction. Then, for every n,*

$$\|d_n\| \le 15(n+1) \qquad \text{and} \qquad \|t_{d_n}\| \ge 4^{n+1} \ge 2^n.$$

Consequently there are no numbers C and k with $\|t_d\| \le C(\|d\| + 1)^k$ for every quantifier-free A and every derivation d of $\forall x\,\exists y\,A$ from no hypotheses. No omniscience principle and no choice principle is used.

Proof. The derivations. The arguments of a substitution node of e_{k+1} are the empty list of hypotheses, the formula $0 = 0$, the terms 0 and 0, the reflexivity derivation and e_k, so $\|e_{k+1}\| = \|e_k\| + 10$ and $\|e_0\| = 3$; the two introductions add 12, and $\|d_n\| = 10n + 15$.

A bound read off a derivation. Since σ calls itself twice for each entry, induction on ℓ gives $\|\sigma_\Delta(u, v)\| \ge \|u\| + \|v\| + 2^\ell$ for a context Δ of length ℓ. At a node of a derivation in Heyting arithmetic, let h be the number of types of the realizers of its hypotheses, counted side by side; the context of the realizer at that node has at least h entries. Define a number $L(e)$ by recursion on the last rule of a derivation e: at an implication elimination with premises e_1

and e_2, $L(e) = \max(2^h, L(e_1), L(e_2))$; at an implication introduction or a universal introduction with premise e', and at an equality substitution whose substituted premise is e', $L(e) = L(e')$; at every other rule, $L(e) = 0$. Two facts follow by induction on e. (i) The first program of the realizer of e has at least $L(e)$ nodes. By the clauses in the proof of Theorem 28.49, at an implication elimination that program applies the first program of the major premise through σ, in a context of at least h entries, to the programs of the minor premise, so it has at least 2^h nodes and contains the first programs of both premises; an implication introduction keeps the programs of its premise; a universal introduction and an equality substitution contain the first program of the premise named. (ii) Adding hypotheses whose realizers have c types in all to every node of e keeps its rules and raises every h by c, so it multiplies $L(e)$ by 2^c.

The translation. Write e^N for the image of e under the map of item 1, the proof of Theorem 20.57 read as a recursion. Reflexivity for a becomes the closed derivation of $a \to \neg\neg a$ applied to it, and that derivation applies the hypothesis $\neg a$ to the hypothesis a, an implication elimination with $h = 2$; so $L(e_0^N) \geq 4$. A substitution from e', deriving $t = u$, and e'', deriving $A(t)$, becomes: under the hypotheses $\neg A(u)$ and then $t = u$, substitute into e''^N, apply $\neg A(u)$, discharge $t = u$, apply e'^N, discharge $\neg A(u)$ and apply stability. There e''^N stands weakened by $\neg A(u)$ and $t = u$, each realized by one program, and every rule below it is an implication elimination, an implication introduction, or the substitution with e''^N as its substituted premise. By (ii), $L(e_{k+1}^N) \geq 4L(e_k^N)$, so $L(e_k^N) \geq 2 \cdot 4^k$ for every k. The derivation of $\forall x \exists y \forall z (y = y)$ that item 2 builds from d_n applies a fixed derivation of $\forall x \exists y (y = y) \to \forall x \exists y \forall z (y = y)$ to d_n. In its image, d_n^N is the minor premise of that implication elimination; it is a universal introduction over the image of the existential introduction, which applies the hypothesis $\forall y \neg (y = y)^N$, instantiated at 0, to e_n^N weakened by that one hypothesis, realized by one program, and discharges it. So the translated derivation has $L \geq 2 \cdot 2 \cdot 4^n = 4^{n+1}$, and by (i) its realizer has at least 4^{n+1} nodes. The functional of item 3 applies that realizer and is closed by bracket abstraction, which keeps it as a part, and dropping the challenge keeps the functional; so $\|t_{d_n}\| \geq 4^{n+1} \geq 2^n$.

No polynomial. Suppose $\|t_d\| \leq C(\|d\| + 1)^k$ for every d. Put $a = C \cdot 16^k$; since $\|d_n\| + 1 \leq 16(n+1)$, we get $2^n \leq a(n+1)^k$ for every n. Let $j = k + a + 4$ and $n = 2^j - 1$. Induction from $4^2 \leq 2^4$ gives $j^2 \leq 2^j$, and $j^2 = jk + ja + 4j \geq jk + a + 16$, so $a + jk \leq 2^j - 1 = n$. Then $a(n+1)^k = a\,2^{jk} < 2^a 2^{jk} \leq 2^n$, a contradiction. □

The blowup is a property of this compiler, not of the derivations. A second compiler with the same specification stays polynomial, of degree five.

Theorem 28.51 (A polynomial compiler of degree five)**.** *There is a map F that assigns to every quantifier-free A and every derivation d of $\forall x \exists y A$ in Peano arithmetic from no hypotheses a closed program $F(d)$ of type $O \to O$ such that, for every number x, A holds at x, at $y = \mathrm{val}(F(d))(x)$ and with every parameter read as 0, and there is a constant C with*

$$\|F(d)\| \leq C(\|d\| + 1)^5 \qquad \text{for all such } A \text{ and } d.$$

No omniscience principle and no choice principle is used.

Proof. The compiler. F follows the proof of Theorem 28.49, changed in three places. Pointwise application calls itself once per entry: $\sigma'_{a::\Delta}(u, v) = \sigma'_\Delta(\mu_\Delta(u), v)$, where μ_Δ composes S with u through one composition combinator $\mathsf{B} = \mathsf{S}\,(\mathsf{K}\,\mathsf{S})\,\mathsf{K}$ per entry. The realizer is built from the

classical derivation in one pass that follows the cases of the negative translation; the realizer of each premise is built once and enters its node once, weakened by composition with a single closed program. Stability of a translated equation, $\neg\neg(s = t) \to s = t$, is realized by the fixed program that applies its argument to the identity: if $s = t$ holds, every number realizes it, and if not, the identity realizes $\neg(s = t)$, so the value realizes $\bot$, that is, satisfies P. No decision of equations is used. Realizability depends on a realizer only through its value, and each new piece has the value of the piece it replaces, so the correctness argument of Theorem 28.49 applies unchanged.

Degree five suffices. Each rule adds to the realizer at most a polynomial in the length of its context and in the sizes of the types it writes, and both are at most linear in $\|d\|$; summed over the nodes this gives $\|d\|$ times a polynomial of degree 4 in $\|d\|$. The functional of item 3 recurses through the matrix: at most linearly many nodes in its shape n, each costing at most $(K+1)^2(W+1)+(W+1)^2$ for a context of length $K = O(n)$ and types of total size $W = O(n^2)$, so $O((n+1)^5)$, plus a part linear in $(n+1)\|A\|$. Every formula concluded in d has shape at most $2\|d\|$, and $\|A\| + 2 \le (\|d\| + 1)^2$. The dummy quantifier of item 2 is bounded node by node in the same way. The sum is at most $C(\|d\| + 1)^5$. □

Degree five is the least, but that rests on a count we report and do not reproduce. Let A_0 be $0 = 0$ and A_{j+1} be $A_j \to 0 = 0$, nested to the left, and let D_j derive $\forall x \exists y\, A_j$ with witness 0; then $\|D_{3n+1}\| = 48n + 35$. On A_j the functional recurses into the antecedents, and its context grows by one entry every second level. A pointwise application in a context of i entries pays, through its composition combinators, the types of all the entries already absorbed, a cubic in i times their size; the recursion at depth $i + 2$ contains the one at depth i in a context one entry longer. A size count of the compiled programs along these lines, which follows the compiler clause by clause, gives $n^5 \le 24\,\|F(D_{3n+1})\|$. Granting it, no bound of degree four holds: if $\|F(d)\| \le C(\|d\| + 1)^4$ for all d, put $E = 24 \cdot C \cdot 48^4 \cdot 16$ and $n = E + 1$; then

$$n^5 \le 24C(48n + 36)^4 \le 24C \cdot 48^4(n + 1)^4 \le En^4 < n^5.$$

A bound of degree m is a bound of every degree $m' \ge m$, since $(\|d\| + 1)^m \le (\|d\| + 1)^{m'}$, so with the count, bounds of degree m exist exactly for $m \ge 5$.

The theorem bounds the degree and says nothing sharp about the constant. The fifth power has a definite source: the functional reading a deeply nested matrix. With the shapes of the input bounded, the degree drops, and the next theorem bounds it in three regimes. For a property R of pairs (A, d), say that F has *degree k on R* when some C has $\|F(d)\| \le C(\|d\|+1)^k$ for every (A, d) with R, and *exponent p/q on R* when some C has $\|F(d)\|^q \le C(\|d\| + 1)^p$ for every such pair. With no restriction degree 5 gives exponent 5, and with the reported count for D_{3n+1} no p/q with $p < 5q$ is an exponent, since such a bound would give $n^{5q} \le 24^q C(48n + 36)^p$ for every n. Table 28.3 collects the answers.

Theorem 28.52 (The degree by the shape of the input)**.** *Let F be the compiler of Theorem 28.51, and let k, c, p, q be natural numbers.*

1. *F has degree* 3 *on the derivations whose matrix has* $\mathrm{sh}(A) \le c$.
2. *F has degree* 3*, and exponent* $5/2$*, on the derivations with* $\mathrm{sh}(d) \le c$.

3. *If $c \geq 3$, then F has degree k on the derivations with $\mathrm{sh}(d) \leq c$ and $\mathrm{cx}(d) \leq c$ exactly when $k \geq 2$; if moreover $p < 2q$, it does not have exponent p/q there.*

No omniscience principle and no choice principle is used.

Proof. Upper bounds. Three estimates carry them. First, for every derivation from no hypotheses the realizer has size at most $C(\|d\| + 1)^3$, whatever its formulas; the fifth power of Theorem 28.51 comes only from the functional. Second, with $\mathrm{sh}(A) \leq c$ the functional has boundedly many nodes and adds at most $C_c(\|d\| + 1)^2$: it evaluates the terms of the matrix, and a substitution multiplies sizes, so $\|A\|$ can be quadratic in $\|d\|$ but no more. These give degree 3 in parts 1 and 2. Third, with $\mathrm{sh}(d) \leq c$ every type in the realizer has bounded size, and the cost concentrates at universal introductions and existential eliminations, which re-project and re-apply the hypotheses of their context: with $M = \mathrm{cx}(d)$ the realizer has size at most $C_c(M+1)^3\|d\|$. A context of M hypotheses is opened by M nodes that each carry the hypotheses opened before them, so $M^2 \leq C\|d\|$, and the realizer is at most $C(\|d\| + 1)^{5/2}$, which with the quadratic functional is the exponent $5/2$. With $\mathrm{cx}(d) \leq c$ as well, every node costs a constant plus the terms it mentions, and the functional is quadratic: degree 2.

Lower bound in part 3. Let u_m be the term $m \cdot 0$, of size $m + 3$. From the axiom instance $m \cdot 0 = 0$ derive $0 = u_m$ by symmetry, and substitute u_m for 0 in a derivation of $\forall y \exists z \big(z = 0+(0+\cdots+(0+0))\big)$ with m summands 0. The result derives $\forall y \exists z \big(z = u_m+(u_m+\cdots+(u_m+0))\big)$; it has size $18m + 51$, empty lists of hypotheses and formulas of shape at most 3, while its matrix has size $m(m + 4) + 3$. The functional contains the decision program χ of the matrix, which contains a program evaluating its terms, so $\|F(d)\| \geq m(m + 3)$, and no exponent p/q with $p < 2q$ survives large m. Degree k is exponent $k/1$, so degrees 0 and 1 fail, and a bound of degree k is one of every larger degree. □

In parts 1 and 2 the degree 3 and the exponent $5/2$ are the least, but again this rests on a count we report and do not reproduce. Let B_K open K hypotheses $0 = 0$ by K implication introductions, each discharged at once by reflexivity, perform K universal introductions and eliminations on reflexivity in that context, and conclude $\forall x \exists y(0 = 0)$ with witness 0. Every formula concluded in B_K is $0 = 0$, $0 = 0 \to 0 = 0$, $\forall(0 = 0)$, $\exists(0 = 0)$ or $\forall\exists(0 = 0)$, so $\mathrm{sh}(B_K) \leq 3$ and the matrix has shape 1, and $\|B_K\| = 14K^2 + 28K + 15$. Each universal introduction pays a cubic in K for each of the $K + 1$ entries of its context, nested K deep; a size count along these lines, clause by clause, gives $5K^5 \leq 6\,\|F(B_K)\|$. Granting it, since $\|B_K\| + 1 \leq 16(K + 1)^2$, a bound $\|F(B_K)\|^q \leq C(\|B_K\| + 1)^p$ with $2p < 5q$ fails for large K. With $p = 2$, $q = 1$ this excludes degree 2 in part 1 for every $c \geq 1$ and in part 2 for every $c \geq 3$, and it excludes every exponent below $5/2$ there.

Conditions and scope.

Base and premises

Peano and Heyting arithmetic; the programs of Definition 28.47 and the size of Definition 28.48; the compilers of Theorems 28.49 and 28.51.

Conclusion

The direct compiler has no polynomial bound (Theorem 28.50, with its count on the page). The second compiler has degree 5 on all inputs (Theorem 28.51); degree 3 with the matrix

Table 28.3. The least degree of a polynomial bound $C(\|d\| + 1)^k$ for the compiler of Theorem 28.51, and the least exponent p/q of a bound $\|F(d)\|^q \le C(\|d\| + 1)^p$, under restrictions on the input d with a constant c. The bounds are Theorems 28.51 and 28.52. That they are least rests, in the first three rows, on the reported size counts of the families in the last column, and in the last row on Theorem 28.52, part 3.

Restriction	Degree	Exponent	Family behind the lower bound
none	5	5	left-nested matrices A_j
matrix of shape at most c, $c \ge 1$	3	between $5/2$ and 3	B_K, whose matrix has shape 1
every formula of shape at most c, $c \ge 3$	3	$5/2$	B_K: size of order K^2, program of order K^5
shape and hypothesis lists at most c, $c \ge 3$	2	2	one substitution at the root makes the matrix quadratic

of bounded shape; degree 3 and exponent $5/2$ with every formula of bounded shape; and exactly degree 2, with no exponent below 2, when shape and hypothesis lists are bounded by some $c \ge 3$ (Theorem 28.52). Free.

Reported computation

That degrees 5 and 3 and the exponents 5 and $5/2$ cannot be lowered rests on the size counts $n^5 \le 24\,\|F(D_{3n+1})\|$ and $5K^5 \le 6\,\|F(B_K)\|$, described above and not reproduced; the arithmetic that turns them into lower bounds is on the page.

Not claimed

Sharp constants.

Under bounded shape the size of the derivation and the program part ways because the derivation pays for each open hypothesis at every node, about K^2 in all, while the program pays about K^4 at each of K nested introductions. The exponent $5/2$ is the ratio of those two growths.

The halving proof, compiled

Theorem 28.53 (The compiled halving proof)**.** *There is a derivation h in Peano arithmetic, from no hypotheses, of*

$$\forall x\, \exists y \big(x = y + y \ \vee \ x = (y + y) + 1 \big)$$

that follows the proof given at the start of this section, with its case split as an instance of excluded middle. Let $t = F(h)$ be its program under the compiler of Theorem 28.51. Then $\mathrm{val}(t)(x)$ *is the integer part of $x/2$ for every number x; in particular* $\mathrm{val}(t)(7) = 3$*, and read on the orbit $\mathbb{N}_\delta$ the program returns the element of* 3 *at the element of* 7*. No omniscience principle and no choice principle is used, although h uses excluded middle.*

Proof. The derivation is the proof written out in the calculus of Definition 8.10: induction on x, an instance of excluded middle for $\exists y(n = y + y)$ in the step, and the laws of addition of

Lemma E.1 for $S(y) + S(y) = S(S(y + y))$. By Theorem 28.51, $y = \mathrm{val}(t)(x)$ satisfies $x = y + y$ or $x = (y + y) + 1$, so $2y \le x \le 2y + 1$, and only the integer part of $x/2$ does that; at 7 it is 3. Item 4 of Theorem 28.49 carries the value to the orbit. □

The theorem reads the value off the specification; it does not look inside the program. A classical proof of a simple fact thus yields a program whose size Theorem 28.51 bounds and a correctness proof that never mentions halving.

The analysis programs, as programs of T

Earlier chapters proved approximate forms of four classical theorems with no principle, each by a finite search over stages of its inputs: the approximate root (Theorem 12.55), the approximate maximum (Lemma 12.57), the approximate mean value point (Theorem 12.86) and the finite Bolzano–Weierstrass theorem (Proposition 12.91). The searches are programs on codes, and they are programs of T.

Definition 28.54 (Stage oracles and four programs)**.** Code the integers by their place in the order $0, -1, 1, -2$, and so on, a ratio by pairing the code of its numerator with its denominator, and a finite list of numbers by repeated pairing, with a pairing of numbers fixed once. A regular sequence s is read through its *stage oracle*, the function that sends m to the code of s_m. A map f of $\mathbb{R}_\delta$ into itself is *presented* on the triadic grid by a family F of regular sequences, $F(n, j)$ naming $f(j/3^n)$, and F is read through the function that sends the code of (n, j, m) to the code of stage m of $F(n, j)$. A *modulus* of uniform continuity of f on $[0, 1]$ is a map ω with $|f(x) - f(y)| \le 1/(k + 1)$ whenever $x, y \in [0, 1]$ and $|x - y| \le 1/(\omega(k) + 1)$. With n and k fixed, let a_j be stage $8k + 7$ of $F(n, j)$.

1. $P_{\mathrm{IVT}}(F, \omega, k)$: with $n = \omega(2k + 1)$, the grid point $j/3^n$ for the first $j \le 3^n$ with $a_j \ge -2/(4k + 4)$, and 1 if there is none.

2. $P_{\mathrm{EVT}}(F, \omega, k)$: with $n = \omega(2k + 1) + 1$, the grid point $j/3^n$ for the first $j \le 3^n$ at which a_j is largest.

3. $P_{\mathrm{MVT}}(G, c, \omega_g, \omega_f, k)$, for a presentation G of a map g and a regular sequence c: with $n = \omega_g(2k + 1) + \omega_f(4k + 4)$, the grid point $i/3^n$ for the first $i < 3^n$ at which stage $16k + 15$ of $G(n, i)$ and stage $16k + 15$ of c differ by at most $6/(8k + 8)$, and 0 if there is none.

4. $P_{\mathrm{BW}}(s, k, M)$, for regular sequences $s_0, s_1, \ldots$: with $m = k + 2$ and $N = (3^m + 1)M + 1$, label each index $i < N$ by $\lfloor 3^m q_i \rfloor$ clamped to $[0, 3^m]$, where q_i is stage $3^m - 1$ of s_i; return the first $M + 1$ indices that carry the first label carried by at least $M + 1$ indices.

Theorem 28.55 (Four analysis programs are programs of T)**.**

1. *Let f be presented by F, with a modulus ω of uniform continuity on $[0, 1]$, and let k be a number.*

   (a) *If $f(0) \le 0 \le f(1)$, then $x = P_{\mathrm{IVT}}(F, \omega, k)$ lies in $[0, 1]$ and $|f(x)| \le 1/(k + 1)$.*

   (b) *The point $x = P_{\mathrm{EVT}}(F, \omega, k)$ lies in $[0, 1]$, and $f(y) \le f(x) + 1/(k + 1)$ for every $y \in [0, 1]$.*

(c) *If g is presented by G with a modulus ω_g, c names $f(1)-f(0)$, and ω_f satisfies, for every j, $|f(y)-f(x)-g(x)(y-x)|\le|y-x|/(j+1)$ whenever $x,y\in[0,1]$ and $|x-y|\le 1/(\omega_f(j)+1)$, then $\xi=P_{\mathrm{MVT}}(G,c,\omega_g,\omega_f,k)$ lies in $[0,1]$ and $|g(\xi)-(f(1)-f(0))|\le 1/(k+1)$.*

(d) *If every s_i names a point of $[0,1]$, then $P_{\mathrm{BW}}(s,k,M)$ lists $M+1$ increasing indices below $(3^{k+2}+1)M+1$ whose terms are pairwise within $1/(k+1)$.*

2. *For each of the four programs there is a closed program of T which, applied to the stage oracles of its inputs, to its moduli and to k (and M), returns the code of the program's output, for all inputs.*

3. *In classical mathematics, for every closed program t of type $(O\to O)\to((O\to O)\to(O\to O))$ there is one partial recursive program that computes $\mathrm{val}(t)(f)(g)(k)$ from k and from codes of programs computing f and g.*

Items 1 and 2 use no omniscience principle and no choice principle.

Proof. 1(a). Put $\varepsilon=1/(4k+4)$, $n=\omega(2k+1)$ and $x_j=j/3^n$. Stage $8k+7$ of a regular sequence lies within $1/(8k+8)\le\varepsilon$ of its point, so $a_j\ge-2\varepsilon$ gives $f(x_j)\ge-3\varepsilon$, and $a_j<-2\varepsilon$ gives $f(x_j)<-\varepsilon$. Since $f(1)\ge0$, $a_{3^n}\ge-\varepsilon$ passes the test, so the first passing j exists. If $j=0$, then $f(x_j)=f(0)\le0$. If $j>0$, then $f(x_{j-1})<-\varepsilon$, and $|x_j-x_{j-1}|=3^{-n}\le1/(n+1)$, so $|f(x_j)-f(x_{j-1})|\le1/(2k+2)=2\varepsilon$ and $f(x_j)<\varepsilon$. In both cases $|f(x_j)|\le3\varepsilon\le1/(k+1)$.

1(b). With $n=\omega(2k+1)+1$, let j be the output index. For $y\in[0,1]$ some grid point x_i lies within 3^{-n} of y, found by a finite search with cotransitivity (proof of Lemma 12.57). Then

$$f(y)\le f(x_i)+2\varepsilon\le a_i+3\varepsilon\le a_j+3\varepsilon\le f(x_j)+4\varepsilon=f(x_j)+\frac{1}{k+1}.$$

1(c). Put $c=f(1)-f(0)$, $\varepsilon=1/(4k+4)$, $\varepsilon'=1/(8k+8)$ and $x_i=i/3^n$; stage $16k+15$ lies within ε' of its point. As $3^{-n}\le1/(n+1)$ and $n\ge\omega_g(2k+1),\omega_f(4k+4)$, the hypotheses on ω_g at $2k+1$ and on ω_f at $j=4k+4$ give $|g(x_{i+1})-g(x_i)|\le2\varepsilon$ and $|f(x_{i+1})-f(x_i)-g(x_i)3^{-n}|\le3^{-n}/(4k+5)<\varepsilon3^{-n}$. Cotransitivity labels each $i<3^n$ with (L) $g(x_i)<c-\varepsilon$, (H) $g(x_i)>c+\varepsilon$ or (M) $|g(x_i)-c|<2\varepsilon$. Neighbours labelled (L) and (H) would be more than 2ε apart, so if no i is (M) all labels agree, and telescoping gives $c<c$ or $c>c$ as in the proof of Theorem 12.86. So some x_i has $|g(x_i)-c|<4\varepsilon'$; its stages differ by at most $6\varepsilon'$, so a passing index exists, and at the first one $|g(x_i)-c|\le6\varepsilon'+2\varepsilon'=1/(k+1)$.

1(d). Of $(3^m+1)M+1$ indices and 3^m+1 labels, some label is carried by at least $M+1$ indices, and a bounded count finds the first. A term with label q lies within $1/(2k+2)$ of $q/3^m$, by the choice of stage and $m=k+2$; two terms with one label are within $1/(k+1)$.

2. Each program reads finitely many stages, compares ratios through cross-multiplied integers, and searches, maximizes or counts over a finite range computed from its inputs. Pairing and unpairing, integer arithmetic on codes, comparison of ratios, bounded search, the running maximum, counting and filtering of a list are defined by primitive recursion, so each is a closed program with R at the types O and $O\to O\to O$. Writing a program as a typed term with these constants and removing its variables by bracket abstraction gives a closed program with the same value, which is the code of the output by induction along the program.

3. This is classical recursion theory. By recursion on types, relate each value of type O to itself and a value of type $A \to B$ to a code e of a partial recursive program when e, run on any code related to a value a, halts with a code related to the value at a. Every constant has a related code, by the parametrization and recursion theorems, and a code related to t, run on codes of f and g and on k, returns $\mathrm{val}(t)(f)(g)(k)$ [6]. □

Item 1 is the agreement with the theorems: each program returns what the corresponding theorem asserts to exist. Item 2 places the programs in T, so they inherit everything said above about programs of T, including their values on the orbit.

The classical display of the line

A last link connects $\mathbb{R}_\delta$ with the classical real numbers. It is a statement of classical mathematics, and it is how a classical theorem about $\mathbb{R}$ is read on $\mathbb{R}_\delta$ value by value.

Theorem 28.56 (In classical mathematics, the line is the real line in exactly one way)**.** *In classical mathematics, with $\mathbb{R}$ the classical real numbers:*

1. *there is a map $D : \mathbb{R}_\delta \to \mathbb{R}$, onto, with $D(0) = 0$, $D(1) = 1$, $D(x + y) = D(x) + D(y)$ and $D(xy) = D(x)D(y)$, and with $x < y$ exactly when $D(x) < D(y)$;*
2. *any two maps with these properties are equal;*
3. *$D(\exp x) = e^{D(x)}$ for every point x, with $\exp$ the exponential of Proposition 12.88;*
4. *for a map F of $\mathbb{R}_\delta$ and a map f of $\mathbb{R}$ with $f(D(x)) = D(F(x))$ for every point x: F is continuous at x (for every k some j has $|F(y) - F(x)| \le 1/(k + 1)$ whenever $|y - x| \le 1/(j + 1)$) exactly when f is continuous at $D(x)$; and d is a derivative of F at x (Definition 28.22) exactly when $D(d)$ is the derivative of f at $D(x)$.*

Proof. 1. The stages of a regular sequence s satisfy $|s_m - s_n| \le 1/(m + 1) + 1/(n + 1)$, so they form a Cauchy sequence of rationals; let D of its point be the limit. Sequences naming the same point have stages within $2/(n + 1)$ (Lemma F.8), hence the same limit, so D is a map on points, and every stage s_n lies within $1/(n + 1)$ of $D(x)$. Sums and products of points are formed from sums and products of stages, so D preserves them, and $D(\eta(q)) = q$. A point is positive when some stage has $s_N > 2/(N + 1)$; then $D(x) \ge s_N - 1/(N + 1) > 0$. Conversely, if $D(x) = L > 0$, then $s_n \ge L - 1/(n + 1) > 2/(n + 1)$ once $3/(n + 1) < L$. So $x < y$ exactly when $D(x) < D(y)$. For $r \in \mathbb{R}$, the ratios $\lfloor 2r(n + 1) \rfloor/(2n + 2)$ lie within $1/(2n + 2)$ of r, so they form a regular sequence, whose point has $D = r$.

2. Let D' have the same properties. Both fix 0 and 1 and preserve sums, differences, products and quotients of ratios, so $D'(\eta(q)) = q = D(\eta(q))$ for every ratio q. If $D'(x) < D(x)$, a rational q between them gives $D'(x) < D'(\eta(q))$ and $D(\eta(q)) < D(x)$, so $x < \eta(q)$ and $\eta(q) < x$, which is impossible; likewise $D(x) < D'(x)$ is impossible, and so $D'(x) = D(x)$.

3. D sends the partial sums $\sum_{m<N} x^m/m!$ to the partial sums of the exponential series at $D(x)$, since it preserves sums, products and ratios. By item 1, $|x - y| \le \eta(q)$ exactly when $|D(x) - D(y)| \le q$, so D carries the limit of the partial sums on $\mathbb{R}_\delta$, which is $\exp(x)$, to their limit in $\mathbb{R}$, which is $e^{D(x)}$.

4. By item 1, $|y - x| \le 1/(j+1)$ exactly when $|D(y) - D(x)| \le 1/(j+1)$, and likewise for the values of F and f, since D preserves sums, products, the order and the ratios. Every real number is $D(y)$ for some point y, and the tolerances $1/(k+1)$ are cofinal among the positive reals. So "for every k some j has $|F(y) - F(x)| \le 1/(k+1)$ whenever $|y - x| \le 1/(j+1)$" says, value by value, that for every k some j has $|f(r) - f(D(x))| \le 1/(k+1)$ whenever $|r - D(x)| \le 1/(j+1)$, which is continuity of f at $D(x)$. The same translation turns the estimate of Definition 28.22 for F, d and x into $|f(r) - f(D(x)) - D(d)(r - D(x))| \le |r - D(x)|/(k+1)$ whenever $|r - D(x)| \le 1/(j+1)$, which is the classical statement that $D(d)$ is the derivative of f at $D(x)$. □

Proposition 28.57 (The determinant is the classical determinant)**.** *In classical mathematics, for every commutative ring R and every $n \times n$ matrix M over R, the determinant of Definition G.2, by expansion along the first column, equals*

$$\sum_{\pi} \operatorname{sgn}(\pi) \prod_{j<n} M_{\pi(j)j},$$

the sum over all permutations π of $\{0, \dots, n-1\}$.

Proof. Induct on n; for $n = 0$ both sides are 1. Group the permutations by $i = \pi(0)$. Deleting row i and column 0 turns the permutations with $\pi(0) = i$ into the permutations τ of the $(n-1) \times (n-1)$ minor $M^{(i,0)}$, with $\prod_{j \ge 1} M_{\pi(j)j}$ the corresponding product for τ and $\operatorname{sgn}(\pi) = (-1)^i \operatorname{sgn}(\tau)$, since moving row i to the top takes i transpositions of neighbours. So the sum is $\sum_{i<n} (-1)^i M_{i0} \det M^{(i,0)}$ by the induction hypothesis, which is the definition. □

Conditions and scope.

Base and premises
Classical mathematics with the classical real numbers $\mathbb{R}$; the line $\mathbb{R}_\delta$, its exponential and its determinant as defined in earlier chapters.

Conclusion
Classically, $\mathbb{R}_\delta$ is the real line in exactly one way, and under that identification its exponential, its pointwise continuity and derivative, and its determinant are the classical ones.

Not claimed
A price: the display reasons classically and identifies objects. The constructive counterpart is Theorem 12.38, which allows at most one structure-preserving map into $\mathbb{R}_\delta$ from every Archimedean ordered field.

28.12 What the mathematics of physics costs

Physics leans on a classical library: the intermediate value theorem for an equilibrium, the spectral theorem for energy levels, Fekete's lemma for a thermodynamic limit, the Picard–Lindelöf theorem for a motion. Appendix Q reads 1467 statements of that library on $\mathbb{R}_\delta$, one to a row, and gives the price of each. Most of the library costs nothing: 1166 rows are free, 14

are proved with a choice principle and no omniscience principle, 265 need an omniscience principle, Ishihara's boundedness principle or the fan theorem, and 22 are open.

The priced rows have a common shape. Each asks for an exact object, such as a root, an eigenvector, the limit of a bounded monotone sequence or a decision, that the physics using it either does not need or gets from information it already has: a gap between energy levels, a slope with a known reciprocal, a surface term of known size. This section proves the rows that show this most clearly. The quantum Ising model in a transverse field has a free energy per site and a ground energy per site in every dimension, with no omniscience principle. The spectral theorem costs exactly LLPO, with countable choice in the converse, and LLPO is the price of an eigenbasis when it is not known whether two levels coincide; when the outcomes of an observable are known to be apart, its eigenbasis is free. Perron's theorem for positive matrices, with the bound of every eigenvalue and the free energy per site of a chain, and the Schmidt decomposition of a real amplitude matrix with positive, pairwise apart coefficients are free with no choice at all.

How the table reads a price. A row is *free* when its proof uses no omniscience principle and no choice beyond the *free allowance*. This is wider than the word in Section 21.1, which allows no choice at all, by one principle: countable choice at pairs of ratios, which makes every located cut the cut of a point (Theorem 12.33) and so makes every Cauchy sequence of points converge (Corollary 12.35). The allowance contains more than it first appears to. A natural number, a yes-or-no answer and a finite table can each be written as a pair of ratios, so it chooses one of them for every n, whether or not the choice is unique; for a unique bit b it chooses the pair (b, b), so countable unique choice of yes-or-no answers is free (row 994). It chooses a regular sequence for every point of a sequence of points, by choosing rational approximations, and so collects points that are each determined uniquely into a sequence. The table applies this one rule to every row. The free rows whose proofs form a limit point say so after their price; 62 of them do. Every theorem below states which choice its proof uses, in the words of Section 21.1.

A price that names AC_ω, countable choice at every type, beside an omniscience principle, such as LLPO with AC_ω, means that the statement implies LLPO with no choice and that LLPO with countable choice proves the statement; the proof uses countable choice, which is an upper bound and is not shown to be needed. We call a price *exact in the table's sense* when both directions hold in this way: the statement implies the principle with no choice, and the principle, with the free allowance and with AC_ω where the price names it, implies the statement. This is weaker than "costs exactly" in Section 21.1, which allows no choice in either direction, so in this section we write "exactly LLPO, with countable choice in the converse". All 1445 rows that are not open are exact in the table's sense. Both directions hold for every one of them. A row with a reference is proved in this book at the result it names; most rows that this book proves give the reference, and most rows without one are not proved in this book.

What the table covers

The rows fall into eleven areas, the sections of the appendix (Table 28.4). The functions a physicist writes every day, the exponential, the logarithm, the trigonometric functions and their complex forms, take 379 rows, and 358 of them are free. Linear algebra takes 326 rows,

Table 28.4. The rows of the price table by area. "Choice" counts rows whose only price is AC_ω; "omniscience" counts rows priced at an omniscience principle, its data form, Ishihara's boundedness principle or the decidable fan theorem.

Area (section of Appendix Q)	Rows	Count	Free	Choice	Omniscience	Open
Conventions at excluded points	1–17	17	5	0	11	1
Limits, continuity and derivatives	18–156	139	113	0	26	0
Exponential, logarithm, trigonometric and complex functions	157–535	379	358	0	21	0
Integrals and measure	536–592	57	49	0	6	2
Differential equations and dynamics	593–638	46	44	0	2	0
Linear algebra and spectra	639–964	326	280	0	45	1
Spectra, lattice models and thermodynamic limits	965–994	30	29	0	1	0
Topology, compactness and fixed points	995–1103	109	34	8	55	12
Probability	1104–1192	89	71	4	14	0
Functional and Fourier analysis	1193–1256	64	40	0	23	1
A first survey across the areas	1257–1467	211	143	2	61	5
All rows		1467	1166	14	265	22

280 free. Apart from the conventions at excluded points, of whose 17 rows only 5 are free, the area with the largest share of prices is topology and compactness: of its 109 rows only 34 are free and 12 are open. The last section of the appendix is a first survey that crosses all the areas, and some of its statements reappear, in other readings, in the areas before it.

Where the prices sit

Table 28.5 shows that each principle has its own place, and that beside a priced row there is usually a free one, which is the statement the physics uses.

Markov's principle sits in hypotheses. The inverse function theorem with a slope $d \neq 0$ costs MP (row 24); with a slope that has a known reciprocal it is free (row 25). Gram–Schmidt for linearly independent vectors costs MP (row 885); for uniformly independent vectors, whose combinations are bounded below by a known $\varepsilon > 0$, it is free (row 884). A measured slope or a measured gap is a number with a known distance from 0, so the free row is the one physics meets.

LLPO sits in exact points. Every LLPO row asks for a point at which something happens, such as a root, a maximizer, an eigenvector or a stationary law, without a separation that locates it. Its approximate form is free. The supremum of a uniformly continuous function on $[0, 1]$ is free (row 1316), while a point attaining it costs exactly LLPO, with countable choice in the converse (row 1313, Theorem 12.60). Every finite Markov chain has, for every tolerance, a law that one step changes by less than the tolerance (row 1131, free), while an exact stationary law of every chain costs LLPO (row 1134); a chain in which some state is entered from every state with probability at least some $\delta > 0$ has exactly one stationary law, for free (row 1130).

Table 28.5. The 279 priced rows by the principle of their price. A row priced at a principle with AC_ω is counted under that principle; the data forms are those of Definition 21.1. Numbers in the last column are rows of Appendix Q.

Principle	Rows	Where it sits, with typical rows
LLPO	72	an exact point where approximate points are free: the intermediate value theorem (1312), a maximum attained (1313), the spectral theorem (1461), a stationary law of every finite Markov chain (1134)
MP	67	a hypothesis $x \neq 0$ used as $x \,\#\, 0$: the inverse function theorem (24), an inverse from a nonzero determinant (650), Gram–Schmidt for independent vectors (885)
LPO	58	limits without a rate, and decisions of order: monotone convergence (1302), Bolzano–Weierstrass (1304), Fekete's lemma (965), the interior point of Rolle's theorem (20), the integer floor (1270)
WLPO	20	decided equality and rank: equality of two numbers (1265), rank–nullity (1456), the least upper bound of a sequence (1307)
$\mathrm{MP}^\vee$	13	L'Hôpital's rule (32), sorting distinct numbers (1070)
FAN	10	covers: Heine–Borel (1418), the Lebesgue number lemma (1102)
LPO function, WLPO function	13	total conventions and stored decisions (rows 1–6, 9, 13–16), the field and the decided order of the line (1429, 1430)
EM, WEM	10	every inhabited set bounded above has a least upper bound (1301), compact sets are closed (1443), projection onto any subspace (1213)
BD-N	2	the uniform boundedness principle for functionals and for operators (1232, 1243)
AC_ω only	14	a member of a set chosen for every n: a supremum as a limit of members (1399), a limit point as a limit of members (1002), a closed interval is connected (1436); Chernoff's optimal constant (1171)

LPO sits in limits without a rate and in decisions of order. Monotone convergence and Bolzano–Weierstrass cost exactly LPO, with countable choice in the converse (Theorems 12.45 and 12.47), and so does Fekete's lemma (Proposition 28.63); a sequence with a known rate needs nothing. The fan theorem sits in compactness by covers: Heine–Borel is exactly the decidable fan theorem (Theorem 13.6), and the supremum of a uniformly continuous function does not need it. The Picard–Lindelöf theorem is free. For a law known only through its values the proof chooses a modulus of continuity in time and a regular sequence for every point the Euler polygons use, and both choices lie inside the free allowance (rows 616 and 617); for a law given by a formula the polygons are computed from the initial data directly (row 620). A choice principle alone is the price of a row when its proof picks a member of a set for every n, as for a supremum written as a limit of members (row 1399); that choice is an upper bound and is not shown to be needed. Baire's theorem and Cantor's intersection theorem (rows 1006 and 1005) choose rational intervals and rational approximations, inside the free allowance, and are free.

These equivalences are known in constructive mathematics, in the setting of Bishop's constructive analysis [14]: the intermediate value theorem and weak König's lemma with LLPO, monotone convergence and Bolzano–Weierstrass with LPO [40, 43], Heine–Borel with the fan theorem [32], the uniform boundedness principle with Ishihara's boundedness principle BD-N [60, 73], and the disjunctive Markov principle $\mathrm{MP}^{\vee}$ in the same order of principles [43, 73]. What the table adds is the reading on $\mathbb{R}_\delta$, the choice each proof uses, and the free statement that stands beside each priced one.

The quantum Ising model in a transverse field

The thermodynamic limit is where physics meets Fekete's lemma, and the quantum Ising model is its standard test. We first fix the levels of a symmetric matrix, the boxes of the lattice and what it means for a family of Hamiltonians to split across a cut.

Definition 28.58 (Levels and partition function)**.** Let A be a symmetric $N \times N$ matrix on $\mathbb{R}_\delta$, $N \geq 1$. A *diagonalization of A at precision* $1/(m+1)$ is an orthonormal list of vectors $v_1, \dots, v_N$ with points $\mu_1, \dots, \mu_N$ such that every coordinate of $Av_c - \mu_c v_c$ is at most $1/(m+1)$ in size. A list $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N$ is a *list of levels* of A if there is a natural number K such that, for every m and every diagonalization at precision $1/(m+1)$, the jth largest of the μ_c lies within $K/(m+1)$ of λ_j, for each j. For $\beta \geq 0$ the *partition function* of a list of levels is $Z = \sum_j e^{-\beta\lambda_j}$, its *free energy* is $-\log Z$, and its last member λ_N is the *ground energy*.

Every symmetric matrix has a list of levels, and two lists of levels of one matrix agree (rows 971 and 981). So the partition function and the ground energy are fixed by the matrix.

Definition 28.59 (Boxes and splitting across cuts)**.** A *box* in d dimensions is a list $L = (L_1, \dots, L_d)$ of natural numbers, its sides; its volume is $\mathrm{vol}\, L = L_1 \cdots L_d$. We write $L[i : a]$ for L with side i replaced by a, and $A_i(L)$ for the product of the sides other than i, the area of a cut across side i. A function F of boxes is *almost additive with constant C* if

$$\left|F(L[i : a+b]) - F(L[i : a]) - F(L[i : b])\right| \leq C\, A_i(L)$$

for every box L, side i and natural numbers a, b. A family of symmetric matrices H_L, one for each box, *splits across cuts with constant J* if for all L, i, a, b there are a bijection σ from the

basis indices of $H_{L[i:a+b]}$ onto the pairs of basis indices of $H_{L[i:a]}$ and $H_{L[i:b]}$, and a symmetric matrix E with $|x \cdot Ex| \le J A_i(L)\,(x \cdot x)$ for every vector x, such that

$$H_{L[i:a+b]}(p,q) = \big(H_{L[i:a]} \otimes 1 + 1 \otimes H_{L[i:b]}\big)(\sigma p, \sigma q) + E(p,q)$$

for all p, q. Here $A \otimes 1 + 1 \otimes B$ is the Hamiltonian of two systems that do not interact.

Definition 28.60 (The quantum Ising model in a transverse field)**.** Let J and g be points and L a box in d dimensions, whose sites are the integer points x with $0 \le x_i < L_i$; two sites are neighbours when they differ by 1 in one coordinate. A spin configuration is a map s from the sites to $\{+1, -1\}$; there are $2^{\operatorname{vol} L}$ of them. The *transverse-field Ising Hamiltonian* $H_L^{J,g}$ is the symmetric matrix indexed by spin configurations with

$$H_L^{J,g}(s,s) = -J \sum_{\{x,y\}\ \text{neighbours}} s_x s_y, \qquad H_L^{J,g}(s,s') = -g \ \text{ if } s \text{ and } s' \text{ differ at exactly one site,}$$

and all other entries 0. In the usual notation $H = -J\sum_{\langle x,y\rangle} Z_x Z_y - g\sum_x X_x$ with open boundaries, where Z_x reads the spin of site x along the coupling axis and X_x flips it. For $d = 1$ and $L = (n)$ it is the chain on n sites.

Theorem 28.61 (The Ising model splits at every cut)**.** *For all points J and g and every dimension d, the Hamiltonians $H_L^{J,g}$ on the boxes in d dimensions split across cuts with constant $|J|$. No omniscience principle and no choice principle is used.*

Proof. Cut the box $L[i:a+b]$ across side i at a. The sites with $x_i < a$ form a copy of $L[i:a]$, and the others, shifted by a in coordinate i, a copy of $L[i:b]$. A configuration of the large box is a pair of configurations of the two halves; this is σ. A flip at one site of the large box is a flip at one site of one half with the other half unchanged, so the off-diagonal entries of $H^{J,g}_{L[i:a+b]}$ are those of $H^{J,g}_{L[i:a]} \otimes 1 + 1 \otimes H^{J,g}_{L[i:b]}$. A bond inside one half is the same bond of that half. What remains is the diagonal matrix E of the bonds that cross the cut, from the layer $x_i = a-1$ to the layer $x_i = a$: one bond for each site of the cross-section, so $A_i(L)$ bonds, each contributing $+J$ or $-J$. Hence $|E(s,s)| \le |J| A_i(L)$ and $|x \cdot Ex| = \big|\sum_s E(s,s) x_s^2\big| \le |J| A_i(L)(x \cdot x)$. Every step is a finite computation with the entries, and no point is compared with another. □

Theorem 28.62 (The thermodynamic limit over boxes)**.** *Let F be a function of the boxes in d dimensions that is almost additive with constant C. Then there is a point f with*

$$\Big|\frac{F(L)}{\operatorname{vol} L} - f\Big| \le C\Big(\frac{1}{L_1} + \cdots + \frac{1}{L_d}\Big)$$

for every box L whose sides are all at least 1. No omniscience principle is used; countable choice for pairs of ratios is used once, for the limit f.

Proof. Write $x(L) = F(L)/\operatorname{vol} L$. First, multiplying one side ℓ by $q \ge 1$ moves x by at most C/ℓ: cutting the side $q\ell$ into q pieces uses almost additivity $q-1$ times, so $|F(L[i:q\ell]) - qF(L[i:\ell])| \le (q-1)CA_i(L)$, and dividing by $q\ell A_i(L)$ gives the bound. Second, multiplying every side L_i by some $q_i \ge 1$ moves x by at most $C\sum_i 1/L_i$. This is an induction on d: multiply the last side first;

at the new height y the function $M \mapsto F(M, y)$ of boxes in $d-1$ dimensions is almost additive with constant Cy, and dividing the induction bound by y gives the rest. Third, the box with sides $(m+1)L_i$ refines both L and the cube of side $m+1$, so $|x(L) - s_m| \le C\sum_i 1/L_i + Cd/(m+1)$, where s_m is the value of x at that cube. Taking L to be the cube of side $m'+1$ gives $|s_{m'} - s_m| \le Cd/(m'+1) + Cd/(m+1)$, an explicit Cauchy modulus. Corollary 12.35, with countable choice for pairs of ratios, gives the limit f of the s_m, and letting m grow in the third bound gives the theorem. □

For $d = 1$ the theorem is the bounded-defect form of Fekete's lemma. The classical lemma asks for less and pays for it.

Proposition 28.63 (Fekete's lemma and its bounded-defect form)**.**

1. *Consider the assertion: for every sequence of points u with $u(m+n) \le u(m)+u(n)$ for all m, n and with $u(n)/n$ bounded below for $n \ge 1$, the ratios $u(n)/n$ converge to a limit no larger than any of them. The assertion implies LPO, and the proof uses no choice principle. Conversely, LPO and AC_ω imply the assertion. Countable choice is used only through Theorem 12.45, for representatives and once at pairs of ratios.*

2. *If $|u(m+n) - u(m) - u(n)| \le C$ for all m, n, there is a point ℓ with $|u(n)/n - \ell| \le C/n$ for every $n \ge 1$. No omniscience principle is used; countable choice for pairs of ratios is used once, for ℓ.*

Proof. For part 1, let x be a nonincreasing sequence of points bounded below. Put $u(0) = 0$ and $u(k) = k\,x(k-1)$ for $k \ge 1$. Then $u(m+n) = m\,x(m+n-1) + n\,x(m+n-1) \le m\,x(m-1) + n\,x(n-1) = u(m) + u(n)$, and $u(n+1)/(n+1) = x(n)$. So the assertion makes every nonincreasing sequence bounded below converge, which gives LPO by Theorem 12.45 applied to $-x$. Conversely, LPO and AC_ω give monotone convergence (Theorem 12.45). Write $v_n = u(n+1)/(n+1)$; the running minimum $b_n = \min(v_0, \dots, v_n)$ converges to a point ℓ with $\ell \le b_n \le v_n$. For a tolerance ε take M with $b_M \le \ell + \varepsilon$ and, by finitely many comparisons with the tolerance, an index $j \le M$ with $v_j \le b_M + \varepsilon$. Writing $n+1 = q(j+1) + r$ with $r \le j$, subadditivity gives $u(n+1) \le q\,u(j+1) + u(r)$, so $v_n \le v_j + \varepsilon$ for every large n, and $v_n \le \ell + 3\varepsilon$.

For part 2, induction gives $|u(kN) - k\,u(N)| \le (k-1)C$. Comparing $u(p+1)$ and $u(q+1)$ with $u\big((p+1)(q+1)\big)$ gives $|v_p - v_q| \le C/(p+1) + C/(q+1)$, an explicit Cauchy modulus. The limit ℓ exists by Corollary 12.35, and the bound passes to the limit. □

The physics has the bounded defect: the two halves of a chain interact through a boundary term of known size. What remains is to show that the quantum Ising model has it, at every temperature and for the ground state.

Theorem 28.64 (Free and ground energies of quantum lattice models)**.** *Let (H_L) be a family of symmetric matrices on the boxes in d dimensions that splits across cuts with constant J, and let $\beta \ge 0$.*

1. *There is a function F of boxes with $e^{-F(L)} = \sum_j e^{-\beta\lambda_j}$ for every list of levels λ of H_L, and F is almost additive with constant βJ.*

2. *There is a function G of boxes such that $G(L)$ is the last member of every list of levels of H_L, and G is almost additive with constant J.*

No omniscience principle is used; countable choice for pairs of ratios is used to obtain the levels and to collect one value per box into a function of the box.

Proof. The levels of each H_L exist and any two lists of them agree, so the partition function and the ground energy of each box are single points. Countable choice for pairs of ratios, applied once to the boxes coded by natural numbers, makes them functions F and G of the box. The levels of $A \otimes 1 + 1 \otimes B$ are the sums of a level of A and a level of B, sorted (row 981); so the two halves side by side have partition function $Z_a Z_b$ and ground energy $G_a + G_b$, and the relabelling σ changes neither. By Weyl's bound (row 980), a symmetric E with $|x \cdot Ex| \le e\,(x \cdot x)$ moves every level by at most e. With $e = J A_i(L)$, every level of $H_{L[i:a+b]}$ lies within e of the corresponding level of the two halves side by side. So the partition function changes by at most a factor $e^{\beta e}$ either way (row 982), and F by at most $\beta J A_i(L)$; the ground energy changes by at most $J A_i(L)$. □

Corollary 28.65 (The quantum Ising model in the thermodynamic limit)**.** *Let J and g be points and d a dimension. Write F_L for the free energy of $H_L^{J,g}$ at inverse temperature β in the sense of Definition 28.58, $-\log Z$, which is β times the thermodynamic free energy, and G_L for its ground energy. The boxes have open boundaries, as in Definition 28.60.*

1. *For every $\beta \ge 0$ there is a point f, the free energy per site, with $|F_L/\operatorname{vol} L - f| \le \beta|J|\,(1/L_1 + \cdots + 1/L_d)$ for every box whose sides are all at least 1. For the chain on $n \ge 1$ sites, $|F_n/n - f| \le \beta|J|/n$.*

2. *There is a point e_0, the ground energy per site, with $|G_L/\operatorname{vol} L - e_0| \le |J|\,(1/L_1 + \cdots + 1/L_d)$ for every box whose sides are all at least 1. For the chain on $n \ge 1$ sites, $|G_n/n - e_0| \le |J|/n$.*

No omniscience principle is used; countable choice for pairs of ratios is used for the levels, to collect them over the boxes, and for the limits.

Proof. Theorem 28.61 gives the splitting with constant $|J|$. Theorem 28.64 makes F almost additive with constant $\beta|J|$ and G with constant $|J|$, and Theorem 28.62 gives f and e_0. For the chain the cut area is 1, and the bounds read $\beta|J|/n$ and $|J|/n$. □

The Hamiltonian $H_L^{J,g}$ is the quantum Ising magnet: spins on a lattice, coupled along one axis, in a field across that axis; for the chain the quantum phase transition is at $g = J$. Its free energy per site in the infinite lattice, $-\log Z$ per site, which is β times the thermodynamic free energy per site, has a value at every temperature, and so does its ground energy per site, in every dimension. A box of side L in d dimensions is within $\beta|J|d/L$ and $|J|d/L$ of them. Nothing about the spectrum is decided along the way: the bound comes from the surface alone. Fekete's lemma, which uses subadditivity and nothing else, costs LPO; the surface term of known size makes the limit free.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$; the Hamiltonian given by its matrix in the spin basis, on boxes with open boundaries; any points J, g and $\beta \geq 0$.

Conclusion

The splitting at every cut, with no choice; the free energy and the ground energy per site with the finite-size bounds above, with no omniscience principle (rows 987–992 and 993).

Not claimed

Where f fails to be analytic in g, that is, the location of the phase transition, and boxes with periodic boundaries.

The spectral theorem: the price of a coincidence

The spectral theorem in full costs LLPO, and the test that shows it is a matrix whose levels may or may not coincide.

Theorem 28.66 (The spectral theorem costs exactly LLPO, with countable choice in the converse)**.**

1. *Let $n \geq 2$. If every symmetric $n \times n$ matrix on $\mathbb{R}_\delta$ has a unit eigenvector, then LLPO holds. The proof uses no choice principle. In particular the spectral theorem for symmetric $n \times n$ matrices, an orthonormal basis of eigenvectors, implies LLPO.*

2. *LLPO and AC_ω imply that for every n every symmetric $n \times n$ matrix on $\mathbb{R}_\delta$ has an orthonormal basis of eigenvectors. Countable choice is used through weak König's lemma, to collect a finite table for every depth, and to choose rational approximations; both are instances of countable choice at pairs of ratios.*

Proof. For part 1, let x be a point, $x^+ = \max(x, 0)$ and $x^- = \max(-x, 0)$. Let T_x have the diagonal $x^+ \cdot (0, 1, \dots, n-1)$ and x^- in every off-diagonal entry. Let v be a unit eigenvector, $T_x v = \lambda v$, put $s = v_1 + \cdots + v_n$ and $R = (s^2 - n)s^2$. If $x > 0$, the matrix is $x\,\mathrm{diag}(0, 1, \dots, n-1)$; for $i \neq j$ the two eigenvalue equations give $(i - j)x v_i v_j = 0$, so $v_i v_j = 0$, $s^2 = \sum_i v_i^2 = 1$ and $R = 1 - n \leq -1$. If $x < 0$, put $c = -x > 0$; the equations read $c(s - v_i) = \lambda v_i$. Summing them gives $c(n-1)s = \lambda s$, and multiplying each by v_i and summing gives $c(s^2 - 1) = \lambda$; so $cs(n - s^2) = 0$, hence $s(n - s^2) = 0$ and $R = 0$. Since $-1 < -\frac{1}{2}$, cotransitivity gives $-1 < R$ or $R < -\frac{1}{2}$. In the first case $x > 0$ is impossible, so $x \leq 0$; in the second $x < 0$ is impossible, so $x \geq 0$. Thus $x \geq 0$ or $x \leq 0$ for every point, which is LLPO by Corollary 12.18. One matrix and one eigenvector are used.

For part 2, LLPO and AC_ω give weak König's lemma (Theorem 12.72), and weak König's lemma turns approximate zeros into exact ones: a nonnegative Lipschitz function on the box $[-1, 1]^n$ with a point of value below every tolerance vanishes at a point. The tree keeps a string of bits when, at each complete level, a rational approximation of the function at the dyadic point the string names is small; the tree is infinite because the truncations of approximate

zeros pass every test, and along a path the dyadic points converge to a zero. The eigenvectors are found one at a time. With orthonormal eigenvectors $v_1, \dots, v_r$ found, $r < n$, the function

$$h(x) = |x|^2|Ax|^2 - (x \cdot Ax)^2 + \big(|x|^2 - 1\big)^2 + \sum_{c \le r} (x \cdot v_c)^2$$

vanishes exactly at the unit eigenvectors orthogonal to $v_1, \dots, v_r$, by the equality case of the Cauchy–Schwarz inequality. It has approximate zeros with no principle. Let W be the set of vectors orthogonal to $v_1, \dots, v_r$; it is invariant under A, because the v_c are eigenvectors and A is symmetric. The projections of the n coordinate vectors onto W have squared lengths summing to $n - r \ge 1$, so finitely many comparisons find one whose squared length exceeds $1/(2n)$; normalized, it is a unit vector u_0 of W. Let a be a rational bound for the norm of A, read from its entries, take a rational $c \ge a + 1$ and put $B = A + c$. Then $x \cdot Bx \ge (c - a)|x|^2 \ge |x|^2$ for every x, so the iterates $u_{k+1} = Bu_k/|Bu_k|$ are defined, stay in W and are unit vectors. Write $\rho_k = u_k \cdot Bu_k$ and $r_k = |Bu_k - \rho_k u_k|$, so that $|Bu_k|^2 = \rho_k^2 + r_k^2$. The Cauchy–Schwarz inequality for the positive form $(x, y) \mapsto x \cdot By$ gives $|Bu_k|^4 = \big(u_k \cdot B(Bu_k)\big)^2 \le \rho_k \, (Bu_k \cdot B^2 u_k)$, hence

$$\rho_{k+1} = \frac{Bu_k \cdot B^2 u_k}{|Bu_k|^2} \ge \frac{|Bu_k|^2}{\rho_k} = \rho_k + \frac{r_k^2}{\rho_k}.$$

The Rayleigh quotients ρ_k increase and lie between 1 and $c + a$, so $\sum_{k \le K} r_k^2 \le (c + a)^2$ for every K. Given $\varepsilon > 0$, take K with $(K + 1)\varepsilon^2 > (c + a)^2$; comparing each r_k, $k \le K$, with ε and 2ε finds a k with $r_k < 2\varepsilon$. Since $Bu_k - \rho_k u_k = Au_k - (u_k \cdot Au_k)u_k$, the first two terms of h at u_k sum to r_k^2 and the other terms vanish, so $h(u_k) < 4\varepsilon^2$. Every step is a finite computation. Countable choice enters through weak König's lemma and the rational approximations; nothing else uses a choice principle. □

The test matrix shows where LLPO enters. For $x > 0$ the levels of T_x are $0, x, \dots, (n - 1)x$, pairwise apart, and the eigenvectors are the coordinate axes; for $x < 0$ the vector $(1, \dots, 1)$ is an eigenvector; at $x = 0$ every vector is one. A rule that produces an eigenvector for every x decides on which side of 0 the point lies, that is, which family of eigenvectors the coincidence at $x = 0$ breaks into. When the levels are known to be apart there is nothing to decide.

Theorem 28.67 (Apart outcomes: the eigenbasis is free)**.** *Let H be an $n \times n$ Hermitian matrix whose entries are complex numbers with real and imaginary parts on $\mathbb{R}_\delta$, and let $\lambda_1, \dots, \lambda_n$ be points with $\lambda_c - \lambda_d \,\#\, 0$ for $c \ne d$. Suppose that for every c and every k there is a unit vector v such that, for every i, the real and imaginary parts of $(Hv)_i - \lambda_c v_i$ are at most $1/(k + 1)$ in size. Then there is an $n \times n$ matrix V with $V^\dagger V = 1$ and $HV = V\,\mathrm{diag}(\lambda_1, \dots, \lambda_n)$. No omniscience principle and no choice principle is used.*

Proof. The exact eigenvectors are written by algebra from one approximate eigenvector for each value; no limit is taken.

Each λ_c is a root of the characteristic polynomial $p(t) = \det(t - H)$. Put $B = \lambda_c - H$. For a unit vector v the adjugate identity $\mathrm{adj}(B)\,B = \det(B) \cdot 1$ gives $\det B = \langle v, \mathrm{adj}(B)Bv \rangle$, so $|\det B| \le K|Bv|$ with K fixed by the entries of $\mathrm{adj}(B)$. The approximate eigenvectors make $|Bv|$ as small as we like, so $\det B = 0$, an equation between points proved from every precision.

The spectral projector. A monic polynomial of degree n that vanishes at n points whose differences are invertible is the product of the factors $t - \lambda_d$. Hence $q_c(t) = \prod_{d \neq c}(t - \lambda_d)$ satisfies $(t - \lambda_c)q_c(t) = p(t)$, and $q_c(\lambda_c) = \prod_{d \neq c}(\lambda_c - \lambda_d)$ is invertible. By the Cayley–Hamilton theorem $(H - \lambda_c)q_c(H) = p(H) = 0$. Since $q_c(t) - q_c(\lambda_c)$ is divisible by $t - \lambda_c$, the matrix $q_c(H)q_c(\lambda_c)^{-1}$ equals $1 + Q_c(H - \lambda_c)$ for a fixed matrix Q_c. So for every vector v the vector $u = v + Q_c(Hv - \lambda_c v)$ satisfies $Hu = \lambda_c u$.

One precision suffices. Take an approximate unit eigenvector v at a precision, fixed by the entries of Q_c, at which $|\langle v, Q_c(Hv - \lambda_c v)\rangle| \leq \frac{1}{4}$. Then $\langle u, u\rangle \geq \frac{1}{2}$, and $u/\sqrt{\langle u, u\rangle}$ is a unit eigenvector for λ_c. One vector for each of the n values is a finite choice, which needs no choice principle.

Orthogonality. For unit eigenvectors e_c and e_d with $c \neq d$, $\langle He_c, e_d\rangle = \langle e_c, He_d\rangle$ and the values are real, so $(\lambda_c - \lambda_d)\langle e_c, e_d\rangle = 0$; since $\lambda_c - \lambda_d$ is invertible, $\langle e_c, e_d\rangle = 0$. The matrix V with columns e_c is the one required. □

A real symmetric matrix is Hermitian, so the theorem applies to it, and the same proof carried out over $\mathbb{R}_\delta$ gives a real orthonormal basis; row 973 of the appendix states that real form, free with no choice. Everything a measurement uses is free in the same way: every level at every precision (rows 969 and 971), an exact eigenvector of a level apart from the others (row 974), and the projector onto a window of levels separated by gaps from the rest, even when levels inside the window coincide (row 977). An observable whose outcomes are apart has exact eigenstates, each fixed up to a phase, and the probabilities of its outcomes, with no omniscience principle. LLPO is the price of an eigenbasis when it is not known whether two levels coincide.

Conditions and scope.

Base and premises

$\mathbb{R}_\delta$ and the complex numbers over it; a Hermitian matrix given by its entries; values given as points, pairwise apart, each with approximate unit eigenvectors at every precision.

Conclusion

The spectral theorem in full costs exactly LLPO, with countable choice in the converse (row 1461); with apart values the exact unitary eigenbasis is free, with no choice.

Not claimed

An exact eigenbasis computed from the matrix alone when levels may coincide; that is the LLPO case.

Perron's theorem and the Schmidt decomposition

Two more theorems stand beside the table. Each is free with no choice at all, and each has a priced neighbour in the table.

Theorem 28.68 (Perron's theorem for positive matrices). *Let T be an $n \times n$ matrix on $\mathbb{R}_\delta$, $n \geq 1$, whose entries are all positive.*

1. *There are a point $\lambda > 0$ and a vector v with every entry positive and $\sum_i v_i = 1$ such that $Tv = \lambda v$.*
2. *Every eigenvalue is at most λ in size: if w is a complex vector with some entry apart from 0 and $Tw = \mu w$ for a complex number μ, then $|\mu| \leq \lambda$.*
3. *With $\mathbf{1}$ the vector of ones and $s_m = \sum_i (T^m \mathbf{1})_i$, there is a rational $q \geq 1$, read from the entries, with $0 \leq \frac{1}{m} \log s_m - \log \lambda \leq \frac{\log q}{m}$ for every $m \geq 1$; so $\frac{1}{m} \log s_m$ converges to $\log \lambda$.*

No omniscience principle and no choice principle is used.

Proof. A finite search over the entries gives rational bounds $1/(k+1) \leq T_{ij} \leq D$. With $\theta = 1/((k+1)(D+1))$ we have $0 < \theta \leq 1$ and $\theta D \leq 1/(k+1)$, and Birkhoff's contraction holds in ratio form: if $w \geq 0$, $\sum_i w_i = 1$ and $cw \leq u \leq dw$ entrywise, then

$$\big(c + \theta(\textstyle\sum_i u_i - c)\big)\, Tw \leq Tu \leq \big(d - \theta(d - \sum_i u_i)\big)\, Tw,$$

so the gap $d - c$ shrinks by the factor $1 - \theta$. The normalized iterates $x_m = T^m \mathbf{1} / \sum_i (T^m \mathbf{1})_i$ therefore satisfy $c_m x_m \leq T x_m \leq d_m x_m$ with $d_m - c_m \leq G(1-\theta)^m$ for a fixed G, and $|x_m(i) - x_{m+1}(i)| \leq (k+1)G(1-\theta)^m$. The iterates are computed from regular sequences naming the entries, by sums, products and the inverse of a sum known to be positive, so each coordinate of the limit $v = \lim x_m$ is the diagonal of computed sequences, as in part 2 of Theorem 12.93, and no choice is used. Put $\lambda = \sum_i (Tv)_i$; then $Tv = \lambda v$ by continuity. Since $\sum_i v_i = 1$ and $v \geq 0$, every $(Tv)_i \geq 1/(k+1)$, so $\lambda > 0$ and $v_i = (Tv)_i / \lambda > 0$. This is part 1.

For part 2, every $(Tv)_i$ is at most D, so $\lambda \leq nD$ and $v_i \geq 1/((k+1)nD)$. Take a rational M with $|w_i| \leq M$ for every i, which exists since every point has a rational bound, and put $c = (k+1)nD\,M$; then $|w_i| \leq M \leq c\, v_i$ for every i. Take an index i with $|w_i| > 0$. The entries of T are positive, so $|(Tx)_j| \leq (T|x|)_j$ for every complex vector x, where $|x|$ has the entries $|x_j|$; by induction $|\mu|^m |w| = |T^m w| \leq T^m |w| \leq c\, T^m v = c\lambda^m v$ entrywise. Hence $(|\mu|/\lambda)^m \leq c\, v_i / |w_i|$ for every m. If $|\mu| > \lambda$, the left side would exceed every bound; so $|\mu| \leq \lambda$.

For part 3, put $q = (k+1)nD$, a rational with $q \geq 1$, so that $v_i \geq 1/q$ and $v_i \leq 1$ for every i. Then $v \leq \mathbf{1} \leq q\, v$ entrywise, and since T^m has nonnegative entries, $\lambda^m v = T^m v \leq T^m \mathbf{1} \leq q\, T^m v = q\lambda^m v$. Summing over i gives $\lambda^m \leq s_m \leq q\lambda^m$, and taking logarithms gives the bound. □

Theorem 28.69 (The Schmidt decomposition with apart coefficients). *Let M be a real $n \times n$ matrix on $\mathbb{R}_\delta$, and let $\sigma_1, \ldots, \sigma_n$ be points with $\sigma_c > 0$ for every c and $\sigma_c - \sigma_d \# 0$ for $c \neq d$. Suppose that for every c and every k there are unit vectors u and v with $|(Mv)_i - \sigma_c u_i| \leq 1/(k+1)$ and $|(M^{\mathsf{T}} u)_i - \sigma_c v_i| \leq 1/(k+1)$ for every i. Then there are $n \times n$ matrices U and V with orthonormal columns such that $M = U \operatorname{diag}(\sigma_1, \ldots, \sigma_n) V^{\mathsf{T}}$. No omniscience principle and no choice principle is used.*

Proof. The matrix $A = M^{\mathsf{T}} M$ is symmetric, and an approximate pair (u, v) for σ_c gives an approximate eigenvector of A for σ_c^2:

$$Av - \sigma_c^2 v = M^{\mathsf{T}}(Mv - \sigma_c u) + \sigma_c (M^{\mathsf{T}} u - \sigma_c v).$$

The differences $\sigma_c^2 - \sigma_d^2 = (\sigma_c - \sigma_d)(\sigma_c + \sigma_d)$ are invertible. The four steps of the proof of Theorem 28.67, carried out over $\mathbb{R}_\delta$, give unit vectors e_c with $Ae_c = \sigma_c^2 e_c$, pairwise orthogonal. Let V have the columns e_c and U the columns Me_c/σ_c. Since $(Me_c)\cdot(Me_d) = e_c \cdot Ae_d$, the columns of U are orthonormal; and $MV = U\,\mathrm{diag}(\sigma)$ with $VV^{\mathsf{T}} = 1$ gives $M = U\,\mathrm{diag}(\sigma)V^{\mathsf{T}}$. □

A positive matrix is the transfer matrix of a one-dimensional lattice model with positive Boltzmann weights. For a chain of $m + 1$ sites with free ends the partition function is $s_m = \sum_i (T^m \mathbf{1})_i$, so by part 3 the free energy per site, $-\log Z$ per site, tends to $-\log \lambda$, with an explicit bound at every length. Perron's theorem gives the positive eigenvector v and its eigenvalue λ, which no other eigenvalue exceeds in size, all computed from the weights with no choice of approximations. Whether v is the only positive eigenvector up to scale is not claimed here. The table prices the neighbouring statement for Markov chains: every finite chain has a stationary law at exactly LLPO, with countable choice in the converse (row 1134), and a chain whose states are each entered from every state with positive probability has one for free (rows 1130 and 1135). A pure state of two n-level systems with a real amplitude matrix M is $\sum_c \sigma_c\, a_c \otimes b_c$ with orthonormal a_c and b_c. When its Schmidt coefficients σ_c are known to be positive and pairwise apart, the Schmidt bases exist with no omniscience principle and no choice, and with them the reduced density matrices and the entanglement entropy. The general Schmidt decomposition and the singular value decomposition cost exactly LLPO, with countable choice in the converse (rows 846 and 855): the price is again the coincidence of two coefficients.

Rows a course teaches

Table 28.6 lists the rows a first course in analysis teaches, with the place in this book that proves each one.

The prices LLPO and LPO in the table are exact in the table's sense: the theorems cited prove the converse with countable choice, and the choices they use, of representatives, of yes-or-no answers, of finite tables and at pairs of ratios, all lie inside the free allowance.

Two of the rows without a printed proof have short arguments. The Gaussian integral of a positive-definite form, written as $d_1 y_1^2 + d_2(y_2 + m_{21}y_1)^2 + \cdots$ with every weight d_i positive, is taken one coordinate at a time over the whole line; each step is the one-dimensional integral of Theorem 12.95 after a shift, and the value is the product of the square roots of π/d_i. For the Picard–Lindelöf theorem the Euler polygons of a Lipschitz law converge uniformly at a rate fixed by the Lipschitz constant and the bound on the law, so the motion is a limit with a known modulus. When the law is known only through its values at points, the proof chooses a modulus of continuity in time and a regular sequence for every point the polygons use; both are choices of ratios or natural numbers, inside the free allowance. When the law is a formula in the operations of the line, the polygons are computed on regular sequences of the initial data. Banach's theorem in Theorem 12.93 is the case of $[0, 1]$ with a rational factor; row 1335 is the whole line with any factor q, $0 \le q < 1$.

Table 28.6. Rows a first course teaches. Every price is exact in the table's sense. A dash means that the proof is not printed in this book; "on $[0,1]$ only" means that the theorem cited proves a special case of the row.

Statement	Row	Price	Proved in
Gaussian integral over the line	1136	free	Theorem 12.95

Spectral theorem, symmetric matrices	1461	LLPO	Theorem 28.66

The open rows

Twenty-two rows have no exact price among the letters of the table. Thirteen concern compactness and continuity at each point: the Heine–Cantor theorem on compact sets, squares and cubes (rows 1440, 1441, 1057, 1088, 1089 and 1094), closed and bounded sets, closed subsets and continuous images of compact sets (rows 1052–1054, 1447 and 1450), sequential compactness (row 1444) and Brouwer's theorem on the square for maps continuous at each point (row 1058). Four concern closed and connected sets on the line (rows 1019, 1023, 1060 and 1079), two the convergence theorems of integration (rows 552 and 553), one functional analysis (row 1221), one linear algebra (row 684), and one is the derivative convention (row 10).

Five of them have an exact price in the key's sense in a principle that is not one of the table's letters. The derivative convention costs exactly MP together with a differentiability decision, and MP with the WEM function gives it (Theorem 28.24). Dini's theorem and the bounded convergence theorem for integrals (rows 552 and 553) are equivalent over countable choice to the measure form of the Heine–Borel theorem and to continuity of measure from above, the direction from the theorem using no choice. The Heine–Cantor theorem on $[0,1]$ (row 1441) is equivalent with no choice to the decidable fan theorem together with a presentation of the local control data by countable covers, and the continuous image of a compact set (row 1447) to a margin property of covers. Two more rows have an equivalence that uses choice in the direction from the statement, so it is not exact in the key's sense: Parseval's identity from a trivial orthogonal complement (row 1221) is MP together with the double negation of LPO for sequences, taken one instance at a time, with the choice of representatives, and a complete set

has an open complement (row 1023) exactly when two principles hold, over countable choice. The rest lie between a lower and an upper bound, which each row states after its price.

Three rows that sit next to these have exact prices. The uniform boundedness principles for functionals and for operators (rows 1232 and 1243) are exactly BD-N, Ishihara's boundedness principle, which the key of the appendix defines. Every complex square matrix has a unit eigenvector at exactly LLPO, with countable choice in the converse (row 933), and so does Schur triangularization (row 934): with LLPO and countable choice the eigenvector statement holds exactly when the approximate fundamental theorem of algebra does, and the fundamental theorem of algebra itself is free (row 482). A sequence that is bounded at infinitely many indices has a convergent subsequence at exactly LPO (row 1388), by the Bolzano–Weierstrass theorem.

What this section proves

This section proves its headline rows: rows 970, 983, 987–992 and 993 through Theorems 28.61, 28.62 and 28.64 and Corollary 28.65; rows 965 and 966 through Proposition 28.63; row 1461 and the free form for apart outcomes, row 973, through Theorems 28.66 and 28.67; and, beside the table, Theorems 28.68 and 28.69. Most rows that this book proves name the result in the appendix, and the rows of Table 28.6 with a theorem in their last column are proved there. For most other rows the proofs are not printed in this book: for those rows "exact" means that both directions hold, and the book records the statement and the price.

Questions to work through

1. (Theorem 28.9, items 1 and 4.) For the sign map S built from the WLPO function in the proof of item 4, show that $S(x) = 1$ exactly when $\neg(x \leq 0)$. Then assume MP and show that $|S(y)| > 0$ implies $y \# 0$, so that the jump of S carries a test. What does Theorem 28.8 then give, and why does the argument fail without MP?

2. (Theorem 28.45.) Over the strict hypotheses $0 < a$ and $a < b$, write a cone certificate for $a \cdot a \cdot a < b \cdot b \cdot b$, and check the identity it rests on. Which part of Theorem 28.42 would apply to this statement, and what weaker conclusion would it give?

3. (Theorem 28.50.) Using $\|d_n\| = 10n + 15$, find the least n with $\|d_n\| + 1 < 2^n$, and compare $\|d_n\|$ with the lower bound for $\|t_{d_n}\|$ there. For given C and k, check that the n chosen in the proof satisfies $C(\|d_n\| + 1)^k < 2^n$.

4. (Theorem 28.52, part 2, and the count after it.) From $\|B_K\| = 14K^2 + 28K + 15$ and the reported count $5K^5 \leq 6\,\|F(B_K)\|$, show directly that F has no exponent p/q with $2p < 5q$ on the derivations of shape at most 3. Why does the same family give no information about part 3?

5. (Theorem 28.53.) Show that a function t on the numbers with $x = t(x) + t(x)$ or $x = t(x) + t(x) + 1$ for every x is $x \mapsto \lfloor x/2 \rfloor$. Which results does the proof of the theorem use, and why does it need no evaluation of the program?

6. (Theorem 28.56, Proposition 28.57.) Show, classically, that every map φ of $\mathbb{R}$ into itself that preserves 0, 1, sums and products is the identity, and deduce item 2 of Theorem 28.56 from it. Then check Proposition 28.57 for $n = 2$.

Chapter 29

Time, chance and learning

A detector has been examined a thousand times and has never fired. What does that record let us conclude? Not that it never will: the next examination may fire, and no record of zeros refutes that (Section 17.7). A record of past events confirms some questions, refutes others, and settles more in the limit if its verdict may be revised as it grows. This chapter asks two further questions. What logic do records obey, and what does it cost to learn a law from them?

Here is a small case of the second question. Four laws label the points 0, 1 and 2; we write each law as its three labels in order:

$$h_1 = 000, \qquad h_2 = 011, \qquad h_3 = 101, \qquad h_4 = 110.$$

One of them is the true law. A learner is shown the points in order, predicts each label, and is then told the true one. The *halving learner* predicts the label that at least half of the laws still consistent with what it has been told predict, and 1 at a tie. Suppose the truth is h_1. At point 0 two laws say 1 and two say 0; the learner says 1 and errs, and h_3 and h_4 are refuted. At point 1, h_1 says 0 and h_2 says 1; the learner says 1 and errs again, and only h_1 remains, so point 2 is predicted correctly. Two mistakes, and no learner of these four laws is safe from two. Whatever a learner predicts at point 0, let the truth be the opposite label: two laws remain with that label, and they disagree at point 1, so the same move costs the learner a second mistake. The halving learner is also never worse than this: each of its mistakes refutes at least half of the surviving laws, the true law always survives, and so m mistakes need $2^m \leq 4$.

Finite learning of this kind costs nothing: every step is a count. Prices appear when the candidate laws are infinitely many, or when a law is a whole infinite record. Identifying which of two worlds known to differ is the true one costs $\mathrm{MP}_{\mathrm{bin}}$, whether the learner must commit once or may settle in the limit; identifying which of two worlds that may be equal is the true one costs LPO either way (Theorem 29.24). For the worlds computed by programs of Gödel's system T, learning every one in the limit costs exactly LPO for the sequences those programs compute (Theorem 29.45). Over arbitrary systems of programs, the method that runs the least program reproducing the record costs exactly Σ_2-LPO, the form of LPO for questions one quantifier higher (Theorem 29.51); the same principle decides every question that verdicts revised without a bound confirm (Proposition 29.50). How often a learner of any kind must revise is read off its candidate laws alone (Theorem 29.58); a computable learner can need more (Theorem 29.59). The stage at which a learner held to few revisions commits is a certificate: every deeply imitated rival law already differs before it (Theorem 29.61). On a catalogue built from running times, three revisions make that stage, with a table of answers to two-quantifier questions, settle a question with three alternating quantifiers (Theorem 29.62), and for every $r \geq 1$ a catalogue built from nested sums has r revisions too few and $r+2$ enough (Theorem 29.64).

The chapter has two halves. The first concerns time and chance. Section 29.1 shows that one recorded history has exactly the logic of Gödel and Dummett and the tree of possible

records exactly intuitionistic logic, and prices the laws that hold at the start of a history. Section 29.2 derives chance from exchangeable records: finitely many are close to a mixture of coins, infinitely many are exactly one, and on $\mathbb{R}_\delta$ deciding whether the mixture is a single coin costs WLPO. Section 29.3 shows that the recognition history of Chapter 21 is the least varied record that never repeats, finds the places of δ's ratios, and reads dimension off the growth of comparisons. Section 29.4 proves Brouwer's fixed-point theorem on a triangle in $\mathbb{R}_\delta^2$: approximately for free, exactly at the price of LLPO when countable choice is assumed.

The second half concerns learning. Section 29.5 prices identification of a law from its records and the revision of verdicts; Section 29.6 counts mistakes, samples and predictions; Section 29.7 treats learners that are programs; Section 29.8 learns with the cost J of Chapter 21; Section 29.9 prices learning on the programs of Gödel's T; Section 29.10 prices the standard methods and their bounds over every system of programs, and separates decision tables from propositions; and Section 29.11 counts the changes of mind that a catalogue of laws forces.

Maps are read as in Section 21.1: rules given as data, without unique choice. A result is *free* when its proof uses no omniscience principle and no choice principle; a proof *with no choice principle* may use an omniscience principle named as a hypothesis; and a result *proved in classical mathematics* is said to be so before its statement. Worlds, records $w\restriction n$ and guessing rules are those of Section 17.7, and the principles are those of Definition 7.8. A ratio written among points of $\mathbb{R}_\delta$ stands for its point.

29.1 The logic of one recorded history

A record grows, and what it has confirmed stays confirmed: a later record keeps everything an earlier one recorded. Kripke's semantics of intuitionistic logic is built on exactly this persistence [53]. We use it to ask which logical laws records obey, and what the shape of time, a single history or a tree of possible histories, does to that logic.

Definition 29.1 (Record frames and forcing)**.**

1. A *record frame* is a set W of *stages* with a preorder $\leq$, a reflexive and transitive relation; $w \leq u$ says that u is a later record keeping everything w recorded. *One history* is $(\mathbb{N}, \leq)$. The *record tree* is the set of finite binary words, with $u \leq v$ when u is an initial segment of v.

2. *Formulas* are built from atoms $p_0, p_1, \ldots$ and $\bot$ by $\wedge$, $\vee$ and $\to$; $\neg a$ abbreviates $a \to \bot$. We name three:

$$\mathrm{lin} = (p_0 \to p_1) \vee (p_1 \to p_0), \qquad \mathrm{wem} = \neg p_0 \vee \neg\neg p_0, \qquad \mathrm{em} = p_0 \vee \neg p_0.$$

3. A *persistent valuation* V assigns to every atom p a set $V(p)$ of stages closed upward: $w \in V(p)$ and $w \leq u$ give $u \in V(p)$.

4. *Forcing* is defined by recursion on formulas: $w \Vdash p$ when $w \in V(p)$; never $w \Vdash \bot$; $w \Vdash a \wedge b$ when $w \Vdash a$ and $w \Vdash b$; $w \Vdash a \vee b$ when $w \Vdash a$ or $w \Vdash b$; and $w \Vdash a \to b$ when every $u \geq w$ with $u \Vdash a$ has $u \Vdash b$. A formula is *valid on* W when it is forced at every stage under every persistent valuation.

5. *W never branches* when $w \le u$ and $w \le v$ give $u \le v$ or $v \le u$; it is *confluent* when $w \le u$ and $w \le v$ give some z with $u \le z$ and $v \le z$; and it is *static* when $w \le u$ gives $u \le w$.

Forcing persists: if $w \le u$ and $w \Vdash a$, then $u \Vdash a$. The proof is an induction on a that uses transitivity at $\to$ and no principle.

Theorem 29.2 (Three shapes of time and their logical laws)**.** *For every record frame W:*

1. lin *is valid on W if and only if W never branches;*
2. wem *is valid on W if and only if W is confluent;*
3. em *is valid on W if and only if W is static; in particular, if some $w \le u$ has $u \not\le w$, so that a later record adds something, then* em *is not valid on W;*
4. *one history never branches, is confluent and is not static; the record tree branches and is not confluent.*

The implications from validity to shape in parts 1 and 3, the clause on a later record, and part 4 use no principle. The other implications are proved in classical mathematics.

Proof. For stages u and v let $V_{u,v}$ be the valuation in which p_0 holds exactly at the stages above u and every other atom exactly at the stages above v.

(1) Let $w \le u$ and $w \le v$, and force lin at w under $V_{u,v}$. If $p_0 \to p_1$ is forced at w, then u, which forces p_0, forces p_1, so $v \le u$. If $p_1 \to p_0$ is forced, then $u \le v$. Conversely let W never branch, and suppose $p_0 \to p_1$ is not forced at w: some $u \ge w$ forces p_0 and not p_1. Every $v \ge w$ forcing p_1 is comparable with u. If $u \le v$, then v forces p_0 by persistence; $v \le u$ would make u force p_1. So $p_1 \to p_0$ is forced at w.

(2) Let $w \le u$ and $w \le v$, under $V_{u,u}$. The stage $u \ge w$ forces p_0, so $\neg p_0$ is not forced at w, and validity gives $w \Vdash \neg\neg p_0$. So v does not force $\neg p_0$: some $y \ge v$ forces p_0, that is, $u \le y$. Conversely, let W be confluent. If some $u \ge w$ forces p_0, then every $x \ge w$ has a common upper bound with u, which forces p_0; so no $x \ge w$ forces $\neg p_0$, and $w \Vdash \neg\neg p_0$. Otherwise no stage above w forces p_0, and $w \Vdash \neg p_0$.

(3) Let $w \le u$, under $V_{u,u}$. The stage u refutes $\neg p_0$ at w, so validity gives $w \Vdash p_0$, that is, $u \le w$. If $u \not\le w$, then neither p_0 nor $\neg p_0$ is forced at w, which is the clause on a later record. Conversely, in a static frame, if p_0 is not forced at w, any $u \ge w$ forcing it has $u \le w$ and would make w force it; so $w \Vdash \neg p_0$.

(4) $\mathbb{N}$ is totally ordered, $\max(u, v)$ bounds u and v, and $0 \le 1$ while $1 \not\le 0$. In the tree, the words 0 and 1 extend the empty word, are incomparable, and have no common extension. □

A history can now be asked about events. Let an event be a binary sequence α, with $\alpha(n) = 1$ recording that it was seen at examination n.

Definition 29.3 (The history of two events)**.** For binary sequences α and β, the *history* $H(\alpha, \beta)$ is the valuation on one history in which p_0 holds at stage n when $\alpha(k) = 1$ for some $k \leq n$, and every other atom holds at n when $\beta(k) = 1$ for some $k \leq n$. We write $H(\alpha)$ for $H(\alpha, \alpha)$, and $\Sigma_1(\alpha)$ for the statement that $\alpha(n) = 1$ for some n.

At stage 0 a history has seen one examination of each event. Which laws are forced there, in every history? Each answer is an omniscience principle.

Theorem 29.4 (The prices of a history's laws at its start)**.**

1. lin *is forced at stage* 0 *of* $H(\alpha, \beta)$ *for all binary* α *and* β *if and only if LLPO holds.*
2. wem *is forced at stage* 0 *of* $H(\alpha)$ *for every binary* α *if and only if WLPO holds.*
3. *Not every* $H(\alpha)$ *forces* em *at stage* 0*.*
4. *"If* $\neg\neg p_0$ *is forced at stage* 0 *of* $H(\alpha)$*, then* $\Sigma_1(\alpha)$*" holds for every binary* α *if and only if* $\mathrm{MP}_{\mathrm{bin}}$ *holds.*
5. *The statement that* $(\Sigma_1(\alpha) \to \Sigma_1(\beta)) \vee (\Sigma_1(\beta) \to \Sigma_1(\alpha))$ *for all binary* α *and* β *is equivalent to LLPO; the statement that* $\neg\Sigma_1(\alpha) \vee \neg\neg\Sigma_1(\alpha)$ *for every binary* α*, to WLPO; and the statement that* $\Sigma_1(\alpha) \vee \neg\Sigma_1(\alpha)$ *for every binary* α*, to LPO.*

Every implication is proved with no choice principle, and part 3 uses no principle at all.

Conditions and scope.

Base and premises
One history $(\mathbb{N}, \leq)$ with the valuations $H(\alpha, \beta)$; binary sequences as events.

Conclusion
Prelinearity at the start of every history is exactly LLPO, weak excluded middle exactly WLPO, and turning "the event cannot stay unseen" into "the event is seen" exactly $\mathrm{MP}_{\mathrm{bin}}$; excluded middle fails outright, at no price.

Not claimed
Prices of formulas with atoms beyond two events, or of laws forced at later stages.

Proof. For binary α and β, call stage k *quiet* when $\alpha(i) = \beta(i) = 0$ for every $i < k$, and define the *race*

$$r(2k) = 1 \iff \alpha(k) = 1,\ \beta(k) = 0 \text{ and } k \text{ is quiet},$$
$$r(2k+1) = 1 \iff \beta(k) = 1,\ \alpha(k) = 0 \text{ and } k \text{ is quiet},$$

and $r = 0$ elsewhere: $r(2k) = 1$ says that α is seen strictly first, at stage k. The race has at most one entry 1. Two entries at stages $k \leq k'$ have $k = k'$, since k' quiet makes $\alpha(k) = \beta(k) = 0$ when $k < k'$; and at one stage only one of the two cases can hold. For every u, a search through the stages up to u either shows them all quiet or finds the first stage $m \leq u$ with $\alpha(m) = 1$ or $\beta(m) = 1$.

(1) Assume LLPO and apply it to the race. Suppose $r(2k) = 0$ for every k, and let stage u force p_0, so $\alpha(i) = 1$ for some $i \le u$. The search finds the first stage $m \le u$ at which α or β is 1; m is quiet, and $\beta(m) = 0$ would give $r(2m) = 1$. So $\beta(m) = 1$ and u forces p_1: the formula $p_0 \to p_1$ is forced at 0. If instead $r(2k+1) = 0$ for every k, then $p_1 \to p_0$ is forced. Conversely, let α have at most one entry 1, and put $e(k) = \alpha(2k)$ and $o(k) = \alpha(2k+1)$. In $H(e, o)$, suppose $p_0 \to p_1$ is forced at 0. If $\alpha(2k) = 1$, stage k forces p_0, hence p_1, so $\alpha(2i+1) = 1$ for some $i \le k$, a second entry 1. So $\alpha(2k) = 0$ for every k. The other disjunct gives the odd places.

(2) In $H(\alpha)$, stage 0 forces $\neg p_0$ exactly when α is all zero: an entry $\alpha(n) = 1$ makes stage n force p_0. Stage 0 forces $\neg\neg p_0$ exactly when α is not all zero: if α is all zero, stage 0 forces $\neg p_0$; and if α is not all zero, no stage x forces $\neg p_0$, for that would make α all zero, since $\alpha(n) = 1$ makes stage $x + n$ force p_0. So wem at stage 0 of $H(\alpha)$ says that α is all zero or not, and the equivalence with WLPO follows.

(3) Let $\alpha(n) = 1$ exactly when $n = 1$. Stage 0 does not force p_0, as $\alpha(0) = 0$, and does not force $\neg p_0$, as stage 1 forces p_0.

(4) By (2), $\neg\neg p_0$ is forced at stage 0 exactly when α is not all zero. So the statement is $\mathrm{MP}_{\mathrm{bin}}$ itself.

(5) If $p_0 \to p_1$ is forced at stage 0 of $H(\alpha, \beta)$ and $\alpha(i) = 1$, then stage i forces p_1, so $\Sigma_1(\beta)$; hence (1) gives the first equivalence from LLPO, and the argument of (1) with e and o gives LLPO back. Since $\neg\Sigma_1(\alpha)$ says that α is all zero, the other two statements are WLPO and LPO as written in Definition 7.8. □

Read with stages as the records of successive examinations, the theorem says that one linear time costs LLPO, convergent futures cost WLPO, a closed future costs LPO, and waiting for an event that cannot stay unseen costs $\mathrm{MP}_{\mathrm{bin}}$, the price that Theorem 17.17 found for a recorder. The reading is ours; the theorem is about frames and binary sequences.

The complete logics of the two frames

Which formulas are valid on one history, and which on the record tree? Two calculi answer.

Definition 29.5 (Intuitionistic logic and Gödel–Dummett logic)**.** *Intuitionistic propositional logic*, IPC, derives formulas from the axiom schemas

$$a \to (b \to a), \qquad (a \to (b \to c)) \to ((a \to b) \to (a \to c)),$$
$$a \wedge b \to a, \qquad a \wedge b \to b, \qquad a \to (b \to a \wedge b), \qquad a \to a \vee b, \qquad b \to a \vee b,$$
$$(a \to c) \to ((b \to c) \to (a \vee b \to c)), \qquad \bot \to a$$

by modus ponens. *Gödel–Dummett logic*, LC, adds every instance of $(a \to b) \vee (b \to a)$ as an axiom.

Theorem 29.6 (The tree has intuitionistic logic and one history has LC)**.**

1. *A formula is valid on the record tree if and only if IPC derives it.*
2. *A formula is valid on one history if and only if LC derives it.*
3. *IPC does not derive $p_0 \vee \neg p_0$; LC derives $(p_0 \to p_1) \vee (p_1 \to p_0)$ and IPC does not.*

The theorem is proved in classical mathematics: Lindenbaum's lemma uses Zorn's lemma, and the transfer between frames splits on whether a stage forces a formula. That every formula IPC derives is valid on every frame uses no principle.

Conditions and scope.

Base and premises
Propositional formulas, persistent valuations of atoms, the two calculi of Definition 29.5; classical metatheory.

Conclusion
The tree of possible records is a complete frame for intuitionistic logic, and one history a complete frame for Gödel–Dummett logic: no further law holds of either.

Not claimed
First-order logic, or that the propositional rules of Chapter 5 form exactly the calculus IPC; that identification is not proved here.

Proof. Soundness. Each axiom of IPC is forced at every stage of every frame, by persistence for the first two schemas and directly for the others, and modus ponens keeps a formula forced at every stage. On a frame that never branches every instance of $(a \to b) \vee (b \to a)$ is forced: the proof of Theorem 29.2(1) applies with a and b in place of p_0 and p_1.

Completeness for all frames. This is Kripke's theorem [53]; we recall the canonical model. Write $\Gamma \vdash \varphi$ for derivability from hypotheses Γ in IPC, or in LC. The first two schemas give the deduction theorem. If $\Gamma \nvdash \varphi$, Zorn's lemma gives a maximal $\Delta \supseteq \Gamma$ with $\Delta \nvdash \varphi$, since a derivation uses finitely many hypotheses. Such a Δ is closed under derivation, omits $\bot$, and is *prime*: if $a \vee b \in \Delta$ but $a, b \notin \Delta$, maximality gives $\Delta, a \vdash \varphi$ and $\Delta, b \vdash \varphi$, so $\Delta \vdash \varphi$ by the deduction theorem and the schema for $\vee$. The prime theories, ordered by inclusion, form a frame; let an atom hold at T when it belongs to T. Then $T \Vdash \psi$ exactly when $\psi \in T$, by induction on ψ; at $a \to b \notin T$, the deduction theorem gives $T \cup \{a\} \nvdash b$, and a prime $U \supseteq T \cup \{a\}$ omitting b refutes $a \to b$ at T. A formula valid on every frame therefore lies in every prime theory, and so is derivable: otherwise a prime theory omits it. For LC the canonical frame never branches. If $T \subseteq U$ and $T \subseteq V$ with $a \in U \setminus V$ and $b \in V \setminus U$, then $(a \to b) \vee (b \to a) \in T$; primeness puts $a \to b$ in $T \subseteq U$, so $b \in U$, or $b \to a$ in $T \subseteq V$, so $a \in V$. Hence a formula valid on every frame that never branches is derivable in LC.

Transfer. It remains to show that validity on the tree gives validity on every frame, and validity on one history gives validity on every frame that never branches. Fix φ and its finite set of subformulas. For a frame W with a valuation, the *type* $\mathrm{typ}(z)$ of a stage z is the set of subformulas of φ forced at z; by persistence $z \le z'$ gives $\mathrm{typ}(z) \subseteq \mathrm{typ}(z')$. Let A be a frame and $f : A \to W$ any function with

forth $x \le y$ in A gives $\mathrm{typ}(f(x)) \subseteq \mathrm{typ}(f(y))$;

back for every $x \in A$ and every $z \ge f(x)$ in W there is $y \ge x$ with $\mathrm{typ}(f(y)) = \mathrm{typ}(z)$.

Let an atom hold at $x \in A$ when it lies in $\mathrm{typ}(f(x))$; by forth this valuation is persistent. Then $x \Vdash_A \psi$ exactly when $f(x) \Vdash_W \psi$, for every subformula ψ. The induction is immediate except at $a \to b$. If $f(x)$ forces it and $y \ge x$ forces a, then $f(y)$ forces a by induction and $a \to b$ by forth, so it forces b, and so does y. If x forces it and $z \ge f(x)$ forces a, back gives $y \ge x$ of the type of z; then y forces a, hence b, and b lies in the type of z. So if φ is valid on A, it is forced at every $f(x)$.

The tree. Fix W, a valuation and a stage w_0. List the sets of subformulas as $S_0, \dots, S_{K-1}$, and for each j realized as a type pick a stage c_j of type S_j. Walk a binary word from the state $(w_0, 0)$, a stage and a counter. A letter 1 raises the counter. A letter 0 at counter $2j$ moves to $(c_j, 0)$ when c_j exists and the current type is contained in S_j, and otherwise resets the counter to 0; at an odd counter it resets. Let f send a word to the stage it reaches. No move loses a forced subformula, which gives forth. For back, let the word x end at (c, i) and let $z \ge c$ have type S_j, which contains the type of c. The word $x1^{i+1}0$ ends at $(c, 0)$, and $x1^{i+1}01^{2j}0$ ends at c_j. So the tree transfers to every frame, at every stage $w_0 = f(\varnothing)$.

One history. Let W never branch, and fix a valuation and a stage w_0. Any two stages above w_0 are comparable, so their types form a chain. Put $g(0) = w_0$, and let $g(n+1)$ be a stage above w_0 whose type is the least type strictly containing that of $g(n)$, or $g(n)$ if there is none. Types grow along g, which gives forth; and g passes through every type of a stage above $g(n)$, one at a time, which gives back. So one history transfers to every frame that never branches.

Putting the pieces together, validity on the tree gives validity on every frame, hence derivability in IPC, hence validity on the tree; and validity on one history gives validity on every frame that never branches, hence derivability in LC, hence validity on one history, which never branches. For part 3, em fails on the frame $0 < 1$ by Theorem 29.2(3), and lin, an axiom of LC, fails on the tree by Theorem 29.2(1) and (4). □

Gödel introduced the finite-valued logics from which LC descends [128], and Dummett gave LC its axiom and its semantics [125]. The new point is the transfer: two particular frames, the possible records and a single history, already carry the whole logic.

29.2 Chance from exchangeable records

A coin is tossed n times and the outcomes are recorded. Suppose nothing distinguishes the order of the tosses: every rearrangement of a record is as probable as the record. De Finetti's theorem says that such records behave as if a coin of unknown bias had been tossed. Chance is then not posited; it is derived from a symmetry of the record. We prove a finite form with an explicit bound, the exact form for unbounded runs, and then price on $\mathbb{R}_\delta$ the question whether the coin is a single coin.

Definition 29.7 (Exchangeable laws of records)**.**

1. A *law of n binary records* is a map P from $\{0,1\}^n$ to the nonnegative rationals with $\sum_x P(x) = 1$. It is *exchangeable* when $P(x \circ \sigma) = P(x)$ for every record x and every permutation σ of the positions $0, \dots, n-1$.

2. For $m \le n$, the law of the first m records is $P_m(y) = \sum P(x)$, summed over the x whose first m entries are y.

3. Write $k(x)$ for the number of entries 1 of a record x. The *coin law* of bias p on $\{0,1\}^m$ is $c_p(y) = p^{k(y)}(1-p)^{m-k(y)}$, and the *coin mixture* of P is

$$Q_m(y) = \sum_{x \in \{0,1\}^n} P(x)\, c_{k(x)/n}(y) \ :$$

   toss m times a coin whose bias is the frequency of 1 in a record drawn from P.

4. $(n)_m = n(n-1)\cdots(n-m+1)$ counts the ways to read m distinct positions of n in order.

Theorem 29.8 (Finitely many exchangeable records are nearly a mixture of coins)**.** *Let $m \le n$ and let P be an exchangeable law of n binary records. Then the sum of the absolute differences satisfies*

$$\sum_{y \in \{0,1\}^m} \left| P_m(y) - Q_m(y) \right| \ \le \ 2\Big(1 - \frac{(n)_m}{n^m}\Big) \ \le \ \frac{m(m-1)}{n}.$$

The theorem is proved in classical mathematics; the argument is finite counting over the rationals.

Both P_m and Q_m are probability laws on $\{0,1\}^m$, so the largest difference between the probabilities they give one set of records, their total variation distance, is half this sum: at most $1 - (n)_m/n^m$, hence at most $m(m-1)/(2n)$. For ten records of which two are read, $(10)_2/10^2 = 0.9$, and the sum of the absolute differences is at most 0.2.

Proof. (1) Every injective map i from $\{0, \dots, m-1\}$ to the positions extends to a permutation of the positions. By exchangeability, the records read at the positions $i(0), \dots, i(m-1)$ have the law P_m: the sum of $P(x)$ over the x with $x \circ i = y$ is $P_m(y)$.

(2) Average (1) over the $(n)_m$ injective maps. With $\mathrm{inj}(x,y)$ the number of injective i with $x \circ i = y$,

$$P_m(y) = \sum_x P(x)\, \frac{\mathrm{inj}(x,y)}{(n)_m} \ :$$

P_m is the P-mixture of reading m positions of x without repetition.

(3) Reading with repetition gives the coin law. A map i with $x \circ i = y$ sends each of the $k(y)$ entries 1 of y to one of the $k(x)$ entries 1 of x, and each entry 0 to one of the $n - k(x)$ entries 0. So the number $\mathrm{all}(x,y)$ of all maps i with $x \circ i = y$ is $k(x)^{k(y)}(n-k(x))^{m-k(y)}$, and $\mathrm{all}(x,y)/n^m = c_{k(x)/n}(y)$. Hence $Q_m(y) = \sum_x P(x)\,\mathrm{all}(x,y)/n^m$.

(4) Fix x and write all $=$ inj $+$ rep, where $\mathrm{rep}(x,y)$ counts the maps that repeat a position. Since $\sum_y \mathrm{inj}(x,y) = (n)_m$ and $\sum_y \mathrm{rep}(x,y) = n^m - (n)_m$,

$$\sum_y \Big|\frac{\mathrm{inj}}{(n)_m} - \frac{\mathrm{all}}{n^m}\Big| \le \sum_y \mathrm{inj}\Big(\frac{1}{(n)_m} - \frac{1}{n^m}\Big) + \sum_y \frac{\mathrm{rep}}{n^m} = 2\Big(1 - \frac{(n)_m}{n^m}\Big).$$

Weighting by $P(x)$ and using the triangle inequality gives the first bound.

(5) $(n)_m/n^m = \prod_{i<m}(1 - i/n)$, and $\prod_i (1-a_i) \ge 1 - \sum_i a_i$ for numbers a_i in $[0,1]$, by induction on their number. So $(n)_m/n^m \ge 1 - m(m-1)/(2n)$, which is the second bound. □

Finite forms of de Finetti's theorem with bounds of this order are due to Diaconis and Freedman [124]. When the records go on without end, the approximation becomes an identity.

Theorem 29.9 (De Finetti's theorem for binary records)**.** *Work in classical mathematics, with the classical real numbers and Borel measures. Let (P_n) be an* exchangeable run*: for every n, P_n is an exchangeable map from $\{0,1\}^n$ to the nonnegative reals with sum* 1*, and the laws are* consistent*, $P_n(x) = P_{n+1}(x0) + P_{n+1}(x1)$. Then there is exactly one Borel probability measure ν on $[0,1]$ with*

$$P_n(x) = \int_0^1 p^{k(x)}(1-p)^{n-k(x)}\, d\nu(p) \qquad \text{for every } n \text{ and every } x \in \{0,1\}^n.$$

Its jth moment is $m_j = P_j(1\cdots 1)$, and for $j \le n$ the frequency moments satisfy

$$\Big|\sum_x P_n(x)\Big(\frac{k(x)}{n}\Big)^j - m_j\Big| \le \frac{j(j-1)}{n}.$$

Proof. Frequency moments. In the notation of Theorem 29.8 for the law P_n and $m = j$, the frequency moment $\sum_x P_n(x)(k(x)/n)^j$ is $Q_j(1\cdots 1)$, and by consistency the law of the first j records of P_n is P_j, so m_j is $P_j(1\cdots 1)$. The theorem bounds their difference by $j(j-1)/n$.

Existence. Let ν_n be the law of the frequency $k(x)/n$ under P_n. The probability measures on $[0,1]$ are compact under weak convergence (Helly's selection theorem), so a subsequence of (ν_n) converges weakly to some ν. Moments are integrals of continuous functions, so the jth moment of ν is the limit of the frequency moments, which is m_j.

Representation. The family $Q_n(x) = \int p^{k(x)}(1-p)^{n-k(x)} d\nu$ is exchangeable and consistent, since $p + (1-p) = 1$, and $Q_n(1\cdots 1) = m_n = P_n(1\cdots 1)$. Two exchangeable consistent families that agree on the records of 1s agree everywhere. Indeed, by exchangeability each depends only on the length n and the number k of entries 1; write $q(n,k)$. Consistency, after a permutation moves the new entry, reads $q(n,k) = q(n+1,k) + q(n+1,k+1)$. So $q(n+1,k) = q(n,k) - q(n+1,k+1)$, and induction on the number $n-k$ of entries 0 fixes every value from the values $q(n,n)$.

Uniqueness. Two probability measures on $[0,1]$ with the same moments integrate every polynomial alike, hence every continuous function, by Weierstrass's approximation theorem, and so they are equal. □

The theorem is de Finetti's [122, 123], proved here by the route through moments [126, Chapter VII]. It speaks of the classical real numbers. On $\mathbb{R}_\delta$ we ask a sharper question: is the mixing law a single coin?

Definition 29.10 (Runs on the line)**.** A *run on* $\mathbb{R}_\delta$ assigns to every binary record x of every length n a point $P_n(x) \geq 0$ of $\mathbb{R}_\delta$, with $P_0 = 1$ on the empty record, each P_n exchangeable and the family consistent as in Theorem 29.9. Its *moments* are $m_j = P_j(1 \cdots 1)$, and its *variance* is $v = m_2 - m_1^2$. The run has a *fixed chance* when $P_n(x) = m_1^{k(x)}(1 - m_1)^{n-k(x)}$ for every record x.

Consistency gives $m_0 = 1$ and $0 \leq m_{j+1} \leq m_j$, since $m_j = P_{j+1}(1 \cdots 10) + m_{j+1}$.

Theorem 29.11 (The price of a fixed chance)**.**

1. *A run on* $\mathbb{R}_\delta$ *has a fixed chance if and only if its second moment is the square of its first,* $m_2 = m_1^2$.
2. *"Every run on* $\mathbb{R}_\delta$ *has a fixed chance or does not" is equivalent to WLPO.*
3. *"Every run on* $\mathbb{R}_\delta$ *without a fixed chance has a variance apart from* 0*" is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$.

Part 1 is free, and the equivalences of parts 2 and 3 are proved with no choice principle.

Conditions and scope.

Base and premises

Runs whose probabilities are points of $\mathbb{R}_\delta$, exchangeable and consistent; nothing else is assumed of them.

Conclusion

Second moment equal to the squared first moment is a single coin, with no omniscience. Deciding whether a run is a single coin costs WLPO; certifying, from its failure, a visible spread costs $\mathrm{MP}_{\mathrm{bin}}$.

Not claimed

The price of deciding whether the classical mixing law of Theorem 29.9 has an atom, or of comparing it with a ratio; or that a physical source is such a run, which is an identification.

Proof. (1) A fixed chance gives $m_2 = m_1^2$ at $x = 11$. For the converse, assume $m_2 = m_1^2$. Fix N and let c be the number of entries 1 of a record of length N. The expected value of the binomial coefficient $\binom{c}{r}$ under P_N is

$$\sum_x P_N(x)\binom{k(x)}{r} = \binom{N}{r} m_r \ :$$

$\binom{k(x)}{r}$ counts the sets of r positions at which x is 1, and for a fixed set the total probability of the records that are 1 there is m_r, by a permutation that moves the set to the front and by consistency. We write $E[\cdot]$ for such expected values. From $c^2 = 2\binom{c}{2} + c$ and $c\binom{c}{j} = (j+1)\binom{c}{j+1} + j\binom{c}{j}$,

$$E[(c - Nm_1)^2] = Nm_1(1 - m_1), \qquad E\Big[\binom{c}{j}(c - Nm_1)\Big] = \binom{N}{j}\big(Nd_j - j(m_{j+1} - m_j)\big),$$

where $d_j = m_{j+1} - m_1 m_j$; the first uses $m_2 = m_1^2$. Let $j \le N$, $M \ge 1$ and $e = \pm 1$. For $0 \le c \le N$ the quantity

$$V(c) = \Big(\binom{N}{j}(c - Nm_1) - eM\binom{c}{j}\Big)^2 + M^2\binom{c}{j}\Big(\binom{N}{j} - \binom{c}{j}\Big)$$

is at least 0, since $\binom{c}{j} \le \binom{N}{j}$. Expanding, the terms in $\binom{c}{j}^2$ cancel, and its expected value divided by $\binom{N}{j}^2$ gives

$$0 \le Nm_1(1 - m_1) - 2eM\big(Nd_j - j(m_{j+1} - m_j)\big) + M^2 m_j.$$

Take $N = M^2$ with $M \ge j + 1$, and divide by $2M^2$:

$$eMd_j \le \tfrac{1}{2}\big(m_1(1 - m_1) + m_j\big) + \frac{ej(m_{j+1} - m_j)}{M} \le 1 + j,$$

because $m_1(1-m_1) \le \frac{1}{4}$, $0 \le m_{j+1} \le m_j \le 1$ and $M \ge 1$. With $e = 1$ and $e = -1$, $|d_j| \le (1+j)/M$ for every $M \ge j + 1$. A point bounded so is neither positive nor negative, by the Archimedean property (Proposition 12.19), so $d_j = 0$ and $m_{j+1} = m_1 m_j$. By induction $m_j = m_1^j$. The family $m_1^k(1 - m_1)^{n-k}$ is exchangeable and consistent with the same values on records of 1s, so the induction on entries 0 in the proof of Theorem 29.9, which is algebra and uses no principle, shows that the run has the fixed chance m_1.

(2) For a point s with $0 \le s \le \frac{1}{2}$, the *two-coin run* mixes the coins of bias $\frac{1}{2} + s$ and $\frac{1}{2} - s$ with weight $\frac{1}{2}$ each. It is a run on $\mathbb{R}_\delta$, with $m_1 = \frac{1}{2}$ and $m_2 = \frac{1}{4} + s^2$, so its variance is s^2, and by (1) it has a fixed chance exactly when $s = 0$. For a binary sequence α, let s_α be half the jump point of α (Lemma 12.5, all signs +1): it is 2^{-N-1} if the first entry 1 of α is at N, and 0 if α is all zero. Deciding whether the two-coin run of s_α has a fixed chance decides whether α is all zero: that is WLPO. Conversely, WLPO decides $x = 0$ or $x \ne 0$ for every point x (Corollary 12.18); applied to $m_2 - m_1^2$, it decides the fixed chance by (1).

(3) $\mathrm{MP}_{\mathrm{bin}}$ is equivalent to "every point $x \ne 0$ is apart from 0" (Theorem 12.11), and by (1) a run without a fixed chance has $v \ne 0$. Conversely, let α be not all zero. Then the two-coin run of s_α has no fixed chance, since that would give $s_\alpha = 0$ and α all zero. So its variance s_α^2 is apart from 0, hence positive, so $s_\alpha > 0$, and a positive jump point exhibits an entry 1 of α: the regular sequence naming it has a stage above its tolerance, and that stage has found the first event. □

Theorem 29.9 provides a mixing law in classical mathematics. On $\mathbb{R}_\delta$, deciding whether it is a single coin costs WLPO, and certifying that it is not costs $\mathrm{MP}_{\mathrm{bin}}$; the criterion itself, two moments, costs nothing.

The cost of telling two frequency profiles apart

How far apart are two profiles of frequencies? The cost J of Definition 21.11 gives an answer with the properties a measure of distinguishability should have.

Theorem 29.12 (The J-cost of two profiles is half Neyman's χ^2)**.** *Work in classical mathematics. For vectors p and q with positive entries indexed by finitely many outcomes, put*

$$D_J(p\,\|\,q) = \sum_i q_i\, J\Big(\frac{p_i}{q_i}\Big), \qquad J(x) = \tfrac{1}{2}(x + x^{-1}) - 1.$$

1. *If $\sum_i p_i = \sum_i q_i = 1$, then $D_J(p\,\|\,q) = \frac{1}{2}\sum_i (q_i - p_i)^2/p_i = \frac{1}{2}\big(\sum_i q_i^2/p_i - 1\big)$, half of Neyman's χ^2 with p as the observed frequencies, equivalently half of Pearson's χ^2 with p as the expected law.*
2. *Merging outcomes never increases it: for every map g of the outcomes onto a set of cells, with g_*p summing p over each cell, $D_J(g_*p\,\|\,g_*q) \le D_J(p\,\|\,q)$.*
3. *$D_J(p + \varepsilon h\,\|\,p) = \frac{\varepsilon^2}{2}\sum_i h_i^2/(p_i + \varepsilon h_i)$ exactly, whenever every $p_i + \varepsilon h_i$ is positive.*
4. *As $\varepsilon \to 0$ with $\varepsilon \neq 0$, $D_J(p + \varepsilon h\,\|\,p)/\varepsilon^2 \to \frac{1}{2}\sum_i h_i^2/p_i$, half the Fisher information of p in the direction h.*
5. *$D_J(p\,\|\,q) \ge 0$, with equality exactly when $p = q$.*

Proof. $J(x) = (x-1)^2/(2x)$, so $J \ge 0$ with equality only at $x = 1$, which is (5). For (1), $q_i J(p_i/q_i) = \frac{1}{2}p_i + \frac{1}{2}q_i^2/p_i - q_i$; sum, with $\sum p = \sum q = 1$. For (2), the same identity writes D_J as the sum of $\frac{1}{2}p_i - q_i$, which merging does not change, and $\frac{1}{2}q_i^2/p_i$. On one cell A, the Cauchy–Schwarz inequality gives $\sum_{i\in A} q_i^2/p_i \ge (\sum_{i\in A} q_i)^2/\sum_{i\in A} p_i$. For (3), with $x_i = (p_i + \varepsilon h_i)/p_i$, $p_i J(x_i) = p_i(\varepsilon h_i/p_i)^2 p_i/(2(p_i + \varepsilon h_i))$. Part (4) follows from (3) by continuity. □

D_J is the divergence of Csiszár's family [172] generated by J, which is convex with $J(1) = 0$; data processing, part 2, is the property that family shares. What is particular to J is part 4. The calibration of the cost, unit curvature at the reference, makes its local form half the Fisher metric, which Čencov showed to be, up to a constant factor, the only metric invariant under the Markov embeddings of one set of outcomes in another [119]; part 1 identifies its global form with a classical statistic [134]. Whether J itself is forced by such an invariance is not settled here.

29.3 The golden record, the places of ratios and growth

A record that never repeats must be varied. How varied? Count the different stretches it shows. This section proves that the recognition history of Section 21.5 is as little varied as a record that never repeats can be. It then asks which notions of size δ's ratios carry, and how the dimension of a space of comparisons shows in the growth of their records.

Definition 29.13 (Windows of a record)**.** Let s be an infinite binary record, a binary sequence. Its *window* of length n at i is $(s(i), \dots, s(i+n-1))$, and $p_s(n)$ is the number of different windows of length n. The record is *eventually periodic* when some N and $p > 0$ give $s(i + p) = s(i)$ for every $i \ge N$. It is *balanced* when any two windows of the same length differ by at most one in their numbers of entries 1. A window w is *right special* when both $w0$ and $w1$ are windows.

Theorem 29.14 (A record that never repeats shows more than n windows of length n)**.** *Work in classical mathematics. For every infinite binary record s:*

1. *s is eventually periodic if and only if $p_s(n) \le n$ for some n; so a record that never repeats has $p_s(n) \ge n+1$ for every n;*
2. *if s is balanced and not eventually periodic, then $p_s(n) = n+1$ for every n.*

Proof. (1) $p_s(0) = 1$, and $p_s(n) \le p_s(n+1)$, since every window of length n is the start of one of length $n+1$. If $p_s(n) \le n$, then p_s does not increase at every step from 0 to n, so $p_s(m+1) = p_s(m)$ for some $m < n$. Then every window of length m has exactly one continuation among the windows, so the window of length m at $i+1$ is determined by the one at i. Two of the windows at $0, 1, \dots, p_s(m)$ are equal, say at $i < j$, and then $s(k+j-i) = s(k)$ for every $k \ge i$. Conversely, if s is periodic with period p from N on, the window at $i \ge N$ equals the window at $N + ((i-N) \bmod p)$, so $p_s(n) \le N + p$ for every n, and $p_s(N+p) \le N+p$.

(2) Every window of length n has one or two continuations, so $p_s(n+1) = p_s(n) + r(n)$, where $r(n)$ is the number of right-special windows of length n. In a balanced record $r(n) \le 1$: if $u \ne v$ were right special, write $u = u'az$ and $v = v'bz$ with $a \ne b$, say $a = 0$ and $b = 1$; then $0z0$ and $1z1$ are windows of the same length whose numbers of entries 1 differ by 2. In a record that never repeats $r(n) \ge 1$, since $r(n) = 0$ would give $p_s(n+1) = p_s(n)$ and, by the argument of (1), a period. So $r(n) = 1$, and $p_s(n) = n+1$ by induction. □

Part 1 is the theorem of Morse and Hedlund [132]. Part 2 goes back to Morse and Hedlund [133], and its converse, that a record with exactly $n+1$ windows of every length is balanced, is due to Coven and Hedlund [121]; these are the Sturmian records. See also [100, Chapter 2].

The recognition history h of Definition 21.24 posts debits and credits. Read a credit as 1 and a debit as 0, and call the resulting record the *golden record* g:

$$h = \mathsf{dcddcdcddcddc}\cdots, \qquad g = 0100101001001\cdots.$$

Let $c(N)$ be the number of entries 1 among its first N entries.

Theorem 29.15 (The golden record is the least varied record that never repeats)**.** *Work in classical mathematics. The golden record satisfies*

$$(N+1)(2-\varphi) - 1 < c(N) < (N+1)(2-\varphi) \qquad \text{for every } N.$$

It is balanced and not eventually periodic, and it has exactly $n+1$ windows of every length n. By Theorem 29.14, no record that never repeats has fewer windows of any length.

Proof. Section 21.5 proves, by sign tests in $\mathbb{Z}[\varphi]$, that the discrepancy $D_N = N\varphi^{-3} - b_N$ satisfies $-2/\varphi < D_N < 2/\varphi^2$, where b_N is the number of debits minus the number of credits among the first N postings. Here $b_N = N - 2c(N)$, and $\varphi^{-3} = 2\varphi - 3$, so $D_N = 2c(N) - 2N(2-\varphi)$. With $1/\varphi = \varphi - 1$ and $1/\varphi^2 = 2 - \varphi$, the bounds read $N(2-\varphi) - (\varphi - 1) < c(N) < (N+1)(2-\varphi)$, and $N(2-\varphi) - (\varphi - 1) = (N+1)(2-\varphi) - 1$.

The window of length m at a has $c(a+m) - c(a)$ entries 1, and the bounds place this number strictly between $m(2-\varphi) - 1$ and $m(2-\varphi) + 1$. Two integers in an open interval of length 2

differ by at most 1: the record is balanced. Suppose it were periodic from N on with period $p > 0$ and q entries 1 in a period. Then $c(N + kp) = c(N) + kq$, and the bounds at N and at $N + kp$ give $|k(q - p(2 - \varphi))| < 2$ for every k. But $q - p(2 - \varphi) = (q - 2p) + p\varphi$ is not 0, since $p \neq 0$ and an element $a + b\varphi$ of $\mathbb{Z}[\varphi]$ is 0 only when $a = b = 0$; so large k give a contradiction. Theorem 29.14(2) now gives $n + 1$ windows of every length. □

The frequency of credits is $2 - \varphi = \varphi^{-2} \approx 0.382$, an irrational number, and that is what forbids a period. Reading the postings as the events of the recognition hierarchy is the identification of Definition 21.24; under it, the hierarchy posts the least varied record that never repeats.

The places of δ's ratios

An *absolute value* on $\mathbb{Q}_\delta$ is a map f to the classical nonnegative reals with $f(q) = 0$ exactly when $q = 0$, $f(xy) = f(x)f(y)$ and $f(x + y) \leq f(x) + f(y)$; it is *nontrivial* when some $f(q)$ is neither 0 nor 1. Its *place cost* is $C_f = J \circ f$ on the nonzero ratios.

Theorem 29.16 (The places of δ's ratios and their costs)**.** *Work in classical mathematics.*

1. *Every nontrivial absolute value on $\mathbb{Q}_\delta$ is $q \mapsto |q|^c$ with $0 < c \leq 1$, or $q \mapsto |q|_p^c$ for a prime p and some $c > 0$, where q is read in $\mathbb{Q}$ along the unique isomorphism.*
2. *For every absolute value f and all nonzero x and y, the place cost obeys the composition law $C_f(xy) + C_f(x/y) = 2C_f(x)C_f(y) + 2C_f(x) + 2C_f(y)$.*
3. *If f is nontrivial and $C_f(2) = \frac{1}{4}$, then f is the real absolute value or the 2-adic one.*
4. *Both occur: the real and the 2-adic absolute values have $C(2) = \frac{1}{4}$, and the 2-adic one has $C(3) = 0$.*
5. *If f is nontrivial, $C_f(2) = \frac{1}{4}$ and $C_f(3) \neq 0$, then $C_f(q) = J(q)$ for every positive ratio q.*

Proof. (1) $\mathbb{Q}_\delta$ maps uniquely and isomorphically onto $\mathbb{Q}$ (Theorem 4.15), so an absolute value on one is an absolute value on the other, and Ostrowski's theorem [135] classifies those on $\mathbb{Q}$. (2) f is positive and multiplicative on nonzero ratios, and $J(ab) + J(a/b) = 2J(a)J(b) + 2J(a) + 2J(b)$ for $a, b > 0$: with $a = e^s$ and $b = e^t$ this is $\cosh(s + t) + \cosh(s - t) = 2\cosh s \cosh t$, since $J(e^t) = \cosh t - 1$. (3) $J(z) = \frac{1}{4}$ with $z \geq 0$ gives $2z^2 - 5z + 2 = (2z - 1)(z - 2) = 0$, so $f(2)$ is 2 or $\frac{1}{2}$. In the real case $2^c = 2$ gives $c = 1$. In a p-adic case $|2|_p = 1$ for $p \neq 2$ gives $C(2) = 0$, and for $p = 2$, $2^{-c} = \frac{1}{2}$ gives $c = 1$. (4) $J(2) = J(\frac{1}{2}) = \frac{1}{4}$ and $|3|_2 = 1$. (5) $C_f(3) \neq 0$ excludes the 2-adic place, so f is the real absolute value. □

The reference value $J(2) = \frac{1}{4}$ of Chapter 21 (Theorem 21.22, part 3) therefore leaves exactly two places of the ratios, the real one and the 2-adic one, and one nonzero value at 3 selects the real place, on which the place cost is J itself. Which physical datum supplies $C(3) \neq 0$ is not addressed here.

Dimension as growth

Take D independent comparisons, each of which can step forward or back. After at most n steps the record of where they stand is a point of $\mathbb{Z}^D$ with $|v_1| + \cdots + |v_D| \le n$. How many such points are there, and does their number reveal D?

Definition 29.17 (Balls of steps)**.** For a finite set $S \subseteq \mathbb{Z}^D$ of steps, $W_S(n)$ is the set of sums of at most n elements of S, repetitions allowed; S *generates* when every point of $\mathbb{Z}^D$ lies in some $W_S(n)$. The ball $B(D,n)$ is the set of $v \in \mathbb{Z}^D$ with $\sum_i |v_i| \le n$. A function f from the natural numbers to the reals has *growth degree* D when there are $c, C > 0$ with $cn^D \le f(n) \le Cn^D$ for every $n \ge 1$.

Theorem 29.18 (Dimension is read off the growth of comparisons)**.** *Work in classical mathematics.*

1. $|B(D,n)| = \sum_{k=0}^{D} 2^k \binom{D}{k}\binom{n}{k}$*, the Delannoy number of* D *and* n*.*
2. *For every finite generating* $S \subseteq \mathbb{Z}^D$*,* $n \mapsto |W_S(n)|$ *has growth degree* D*.*
3. *A function has at most one growth degree.*

Proof. (1) Write $F(D,n)$ for the sum. Splitting off the first coordinate t, the points of $B(D+1,n)$ with first coordinate t form a copy of $B(D, n-|t|)$, so

$$|B(D+1,n)| = |B(D,n)| + 2\sum_{s<n} |B(D,s)|,$$

and subtracting this at n from this at $n+1$ gives $|B(D+1,n+1)| = |B(D+1,n)| + |B(D,n+1)| + |B(D,n)|$. Both $|B(0,n)|$ and $|B(D,0)|$ are 1. F has the same boundary values, and Pascal's rule $\binom{D+1}{k} = \binom{D}{k} + \binom{D}{k-1}$, with the same rule for n, gives $F(D+1,n+1) - F(D+1,n) - F(D,n+1) = \sum_k 2^k \binom{D}{k-1}\binom{n}{k-1} - F(D,n) = F(D,n)$.

(2) Let L bound the sums $\sum_i |s_i|$ for $s \in S$. Then $W_S(n) \subseteq B(D,nL)$, which lies in a cube with $(2nL+1)^D \le (3L)^D n^D$ points, since $L \ge 1$ when $D \ge 1$; for $D = 0$ there is one point. For the lower bound with $D \ge 1$, let each unit vector e_i be a sum of at most $K \ge 1$ steps. A point with coordinates in $\{0, \dots, a\}$ is a sum of at most KDa steps, so the cube with $a = \lfloor n/(KD) \rfloor$ lies in $W_S(n)$, and it has $(a+1)^D \ge (KD)^{-D} n^D$ points.

(3) If $cn^D \le f(n) \le C' n^E$ for every $n \ge 1$ with $D > E$, then $cn^{D-E} \le C'$ for every n, which fails for large n. □

With the steps $\pm e_i$, $W_S(n)$ is the ball itself, and D independent reversible comparisons reach exactly the Delannoy number of states within n steps [113]. Its leading term $2^D n^D / D!$ is the volume of the cross-polytope. Dimension is therefore an invariant of the growth of comparison records. The theorem forces no value of D; the topological reason for $D = 3$ is Chapter 23.

29.4 Fixed points on δ's triangle

Stir a cup of coffee: some point of the surface ends where it began. That is Brouwer's fixed-point theorem, and Chapter 12 priced its one-dimensional case, the intermediate value theorem: an approximate root costs nothing, and an exact root costs LLPO, given countable choice: the root gives LLPO with no choice principle, and LLPO gives the root when countable choice is assumed (Theorems 12.55 and 12.54). The same holds on a triangle in the plane of $\mathbb{R}_\delta$.

Definition 29.19 (The triangle and its maps)**.** The *triangle* T is the set of $(x, y) \in \mathbb{R}_\delta^2$ with $x \geq 0$, $y \geq 0$ and $x + y \leq 1$. Points p and q are *k-near* when $|p_1 - q_1| \leq 1/(k+1)$ and $|p_2 - q_2| \leq 1/(k+1)$. A map F from $\mathbb{R}_\delta^2$ to itself is *uniformly continuous on T with modulus ω* when points of T that are $\omega(k)$-near have k-near images, and it is a *self-map of T* when it sends T into T.

The proofs label a grid. Write $b_0 = 1 - x - y$, $b_1 = x$ and $b_2 = y$ for the *barycentric coordinates* of (x, y); on T they are at least 0 and sum to 1. The grid of side N has the vertices $(i/N, j/N)$ with $i, j \geq 0$ and $i + j \leq N$, and its *small triangles* have the vertices (i, j), $(i+1, j)$, $(i, j+1)$ with $i + j + 1 \leq N$, or $(i+1, j)$, $(i, j+1)$, $(i+1, j+1)$ with $i + j + 2 \leq N$, in grid units.

Lemma 29.20 (Sperner's lemma for the triangle)**.** *Let $N \geq 1$, and label every vertex of the grid of side N with 0, 1 or 2, so that no vertex of the bottom row $j = 0$ has label 2, no vertex of the left edge $i = 0$ has label 1, and no vertex of the hypotenuse $i + j = N$ has label 0. Then an odd number of small triangles carry all three labels; in particular one does. The proof uses no principle.*

Proof. Call an edge between adjacent vertices labelled 0 and 1 a *door*. A small triangle with all three labels has exactly one door; any other has none or two. So the number of fully labelled small triangles has the parity of the total number of doors counted triangle by triangle. An inner edge lies in two small triangles and a boundary edge in one, so that total has the parity of the number of doors on the boundary. The left edge has no label 1 and the hypotenuse no label 0, so their edges are not doors. The bottom row has labels 0 and 1 only; its first vertex has label 0, being on the left edge, and its last has label 1, being on the hypotenuse. So the labels change an odd number of times along it. □

Theorem 29.21 (Approximate fixed points on the triangle are free)**.** *Let F be a self-map of T, uniformly continuous on T with modulus ω. For every k there is a point $p \in T$ such that $F(p)$ and p are k-near. Moreover, for every $n \geq \max(4k + 3, \omega(4k + 3))$ such a p can be found among the vertices of the grid of side $n + 1$. The proof uses no omniscience principle and no choice principle.*

Proof. Put $t = 1/(4k + 4)$ and fix n as stated. At a vertex v and for each c, cotransitivity, applied to $b_c(v) < b_c(v) + t$ at the point $b_c(F(v))$, gives *good*, $b_c(F(v)) < b_c(v) + t$, or *raised*, $b_c(v) < b_c(F(v))$. Exclude the labels c with $b_c(v) = 0$: 0 on the hypotenuse, 1 on the left edge and 2 on the bottom row. If every remaining coordinate were raised, then, since the excluded ones have $b_c(v) = 0 \leq b_c(F(v))$, the sums would give $1 = \sum_c b_c(v) < \sum_c b_c(F(v)) = 1$. So some remaining coordinate is good; label v with the first. The grid is finite, so the labels are collected by induction over the vertices, and no choice principle enters. They meet the conditions of

Lemma 29.20, which gives vertices P_0, P_1, P_2 with labels 0, 1, 2, pairwise within $1/(n+1) \le t$ in each coordinate. Since $n \ge \omega(4k+3)$, their images are pairwise within t. Good labels give

$$F(P_0)_1 \le F(P_1)_1 + t < (P_1)_1 + 2t \le (P_0)_1 + 3t, \qquad F(P_0)_2 < (P_0)_2 + 3t,$$
$$(P_0)_1 + (P_0)_2 < F(P_0)_1 + F(P_0)_2 + t,$$

the last from label 0 at P_0. Hence $(P_0)_1 < F(P_0)_1 + (F(P_0)_2 - (P_0)_2) + t < F(P_0)_1 + 4t$, and likewise for the second coordinate. With $4t = 1/(k+1)$, $F(P_0)$ and P_0 are k-near. Every step compares given points with ratio margins, and no exact sign is decided. □

Theorem 29.22 (An exact fixed point costs LLPO, given countable choice)**.**

1. *If every uniformly continuous self-map of T has a fixed point, then every uniformly continuous f on $[0,1]$ with $f(0) \le 0 \le f(1)$ has a root, and LLPO holds. No choice principle is used.*
2. *Assume countable choice AC_ω (Definition 12.21). If LLPO holds, every uniformly continuous self-map of T has a fixed point. No further choice is used.*

So, assuming countable choice, the exact fixed-point theorem on T is equivalent to LLPO.

Conditions and scope.

Base and premises
The triangle in $\mathbb{R}^2_\delta$; maps uniformly continuous on it with a modulus. Part 2 assumes AC_ω.

Conclusion
Approximate fixed points are free (Theorem 29.21). An exact fixed point implies LLPO with no choice, and LLPO gives it at the rung of countable choice, as for the intermediate value theorem.

Not claimed
That LLPO alone, without countable choice, gives exact fixed points; that question is open here.

Proof. (1) Let $\mathrm{cl}(z) = \max(0, \min(z, 1))$ and $F(x, y) = (\mathrm{cl}(x - f(\mathrm{cl}(x))), 0)$. It maps the plane into T and is uniformly continuous, since cl moves points by no more than their distance. A fixed point is $(x, 0)$ with $x \in [0, 1]$ and $x = \mathrm{cl}(x - f(x))$. If $f(x) > 0$, then $x > 0$ is impossible, since $\min(x - f(x), 1) < x$ and $0 < x$ would make $\mathrm{cl}(x - f(x)) < x$; so $x = 0$ and $f(0) > 0$, against the hypothesis. So $f(x) \le 0$, and symmetrically $f(x) \ge 0$. Theorem 12.54(1) turns roots into LLPO.

(2) Let F have modulus ω. *Tests.* For a tolerance t and a corner $v = (a/2^d, b/2^d)$ in T, cotransitivity in each coordinate shows that there is a bit that is 1 only if $F(v)$ and v are t-near and 0 only if they are not $(2t+1)$-near. Which bit it finds depends on the regular sequences that name $F(v)$, so countable choice is what collects these bits into one table $B(t, v)$. Say that t is *open* at depth d when $2^d \ge \max(\omega(6t+5) + 1, 6t + 6)$.

The tree. A node of depth d is a word of d letters from $\{0,1,2,3\}$; each letter halves the current dyadic square in both directions, and the node names the lower left corner $(a/2^d, b/2^d)$ of its square. Keep a node when, at every depth $d' \le d$ along it, the corner lies in T $(a+b \le 2^{d'})$ and passes $B(t,\cdot) = 1$ for every $t \le d'$ open at d'. The tree is decided by finitely many integer comparisons and table entries, and each node has at most four children.

It has nodes at every depth. Given D_0, apply Theorem 29.21 with $k = 6D_0 + 5$ on the grid of side 2^M, M large, to get a vertex $p = (i/2^M, j/2^M)$ of T with $F(p)$ and p $(6D_0+5)$-near. Its binary digits give the nested dyadic squares containing it, whose corners at depth $d' \le D_0$ lie in T and within $2^{-d'}$ of p. If $t \le d'$ is open at d', such a corner v has $|F(v) - F(p)| \le 1/(6t+6)$ by the modulus, $|F(p) - p| \le 1/(6t+6)$ and $|p - v| \le 1/(6t+6)$ in each coordinate. So $F(v)$ and v are $(2t+1)$-near, the bit 0 is impossible, and $B(t,v) = 1$. The word of p's digits up to D_0 is a node.

A path and its limit. Writing each letter as two binary digits turns the tree into a decidable binary tree with members of every length. LLPO with AC_ω gives weak König's lemma (Theorem 12.72), hence a path. Its corners c_d are ratios with $|c_d - c_{d'}| \le 2^{-d}$ for $d \le d'$, so they form a regular sequence and name a point q, with no choice; $q \in T$ since T is closed. For each t, the tolerance t is open at every large depth, where the path's corner passes the test, so $F(c_d)$ and c_d are t-near. By the modulus, $|F(q) - q| \le 1/(t+1) + 1/(k+1) + 2^{-d}$ in each coordinate for every k and all large d. So $|F(q) - q| \le 1/(t+1)$ for every t, and $F(q) = q$. □

Sperner's lemma [136] and the approximate fixed point it gives are the standard constructive route to Brouwer's theorem [117]. On $\mathbb{R}_\delta$ the route ends at an approximate fixed point; the last step, to an exact one, is a compactness step, and it costs exactly what weak König's lemma costs.

29.5 What identifying a law costs

Section 17.7 priced the decision of a question from records. A learner faces a different task: it must name the law that produces the record. Its candidates are listed in advance, and it must end up naming the right one.

Definition 29.23 (Learners and identification)**.** Worlds are binary runs, read by themselves. A *prior* is a sequence $h = (h_0, h_1, \ldots)$ of worlds.

1. A *learner* is a rule M that assigns an index to every finite binary record. It *identifies ω in the limit*, relative to h, when some j and N give $h_j = \omega$ and $M(\omega{\restriction}n) = j$ for every $n \ge N$. A class of worlds is *learnable* when some prior and some learner identify each of its members in the limit.

2. A *certain learner* assigns to every finite record an index or the mark $\circ$, "silent". It *identifies ω with certainty* when it announces an index at some record of ω, and every index j it announces at a record of ω has $h_j = \omega$.

3. The *pair prior* of two worlds h_0 and h_1 lists h_0 at index 0 and h_1 at every other index.

4. The *zero world* is the run of zeros. The *flag world* of a binary sequence α has entry 1 at n when $\alpha(k) = 1$ for some $k \le n$.

Table 29.1. The price of identifying one of two worlds (Theorem 29.24).

	Worlds known to differ	Worlds that may be equal
With certainty	$\mathrm{MP}_{\mathrm{bin}}$	LPO
In the limit	$\mathrm{MP}_{\mathrm{bin}}$	LPO

Like recorders, learners are arbitrary rules; nothing requires them to be computable. The flag world of α is the zero world exactly when α is all zero, and the two have the same record of length n exactly when $\alpha(k) = 0$ for every $k < n$. Comparing the two worlds through a learner is the engine of every lower bound below.

Theorem 29.24 (Learning a pair costs $\mathrm{MP}_{\mathrm{bin}}$ or LPO)**.** *Each of the following equivalences is proved in both directions with no choice principle.*

1. *Every pair of different worlds is identified with certainty, relative to its pair prior, by some certain learner, if and only if* $\mathrm{MP}_{\mathrm{bin}}$ *holds.*
2. *Every pair of different worlds is identified in the limit if and only if* $\mathrm{MP}_{\mathrm{bin}}$ *holds.*
3. *Every pair of worlds, equal or not, is identified with certainty if and only if LPO holds.*
4. *Every pair of worlds is identified in the limit if and only if LPO holds.*
5. *Every prior has a learner that identifies each of its members in the limit if and only if LPO holds.*

Conditions and scope.

Base and premises
Binary worlds read by themselves; learners are arbitrary rules on finite records, not required to be computable.

Conclusion
The price of naming the true one of two candidate laws is $\mathrm{MP}_{\mathrm{bin}}$ when they are known to differ and LPO when they may be equal, for certain and for convergent identification alike.

Not claimed
Prices for classes of more than two worlds other than part 5, or for learners restricted to programs (Sections 29.7 and 29.9).

Table 29.1 arranges the first four. What costs is not certainty as against convergence. It is whether the two candidate worlds are known to differ.

Proof. Upper bounds. Let $h_0 \neq h_1$. The sequence that is 1 where they differ is not all zero, so $\mathrm{MP}_{\mathrm{bin}}$ finds a place k with $h_0(k) \neq h_1(k)$. The learner that stays silent on records shorter than $k + 1$ and then names 0 or 1 by the entry at k identifies both worlds with certainty, and, naming 0 while silent, in the limit. Under LPO two worlds are equal or differ at a place found;

for equal worlds announce 0 at once. For a prior h, the *enumeration learner* names, at a record σ, the least $i \le |\sigma|$ with $h_i{\restriction}|\sigma| = \sigma$, and $|\sigma| + 1$ if there is none. On ω, LPO finds the least i with $h_i = \omega$ and, for each $j < i$, a place where h_j and ω differ; past these finitely many places the learner names i.

Lower bounds. For (3), let α be binary and take the pair of the zero world, at index 0, and the flag world of α. The certain learner announces on the zero world at some record of length n, an index j. If $j \neq 0$, the announcement is correct, so the flag world is the zero world and α is all zero. If $j = 0$, inspect $\alpha(0), \dots, \alpha(n-1)$: an entry 1 settles the matter; if there is none, the flag world has the same record of length n, the learner announces 0 there too, and correctness makes the flag world the zero world. This is LPO. For (1), let α be not all zero; the two worlds then differ, the first and last cases are contradictions, and an entry 1 remains: $\mathrm{MP}_{\mathrm{bin}}$.

For (4), take the pair of the flag world of α, at index 0, and the zero world. The learner settles on the zero world at j from stage N and on the flag world at j' from stage N'. If $j = 0$, the index 0 names the zero world, and if $j' \neq 0$, the index j' names the flag world; either way the two worlds are equal and α is all zero. Otherwise $j \neq 0 = j'$; inspect α below $N + N'$. An entry 1 settles the matter, and if there is none the two records of length $N + N'$ coincide, so the learner names j and j' at one record and $j = j'$, a contradiction. For (2) the first two cases are contradictions when α is not all zero. Part 5 contains part 4, since a pair prior is a prior. Every case split is on natural numbers and bits. □

Theorem 29.25 (What the limit buys and what no prior covers)**.**

1. *Let s_n be the world whose only entry* 1 *is at n. The enumeration learner of the prior $(0, s_0, s_1, \dots)$ identifies each of its members in the limit, with no principle; no certain learner identifies all of them with certainty relative to this prior.*
2. *For every prior and every learner, some binary world is not identified in the limit.*
3. *Every learnable class lies in some prior, and, under LPO, every class that lies in a prior is learnable. In classical mathematics a class of worlds is learnable exactly when it injects into the natural numbers.*

All but the last statement are proved with no choice principle; the last is classical.

Proof. (1) Any two members differ at a known place: s_n and 0 at n, s_n and s_m at n. On s_n, the record of length $n + 1$ refutes the indices $0, \dots, n$, so from then on the learner names $n + 1$; on the zero world it names 0 throughout. A certain learner that announces an index on the zero world at a record of length n announces the same index on s_n, whose record of length n is the same; that index cannot name both worlds. (2) A world identified relative to h is some h_j, and the world $\omega(n) = 1 - h_n(n)$ is none of them. (3) The first statement is (2)'s observation, and the second is the enumeration learner of Theorem 29.24. Classically LPO holds, and a class lies in a prior exactly when it injects into the natural numbers: send a member to its least index, or list the members along the inverse of an injection. □

The spike class separates the two notions on a single class: convergence is free there, while certainty is impossible at any price. The four cells of Table 29.1 measure something else, the

knowledge whether two candidates differ. Gold's identification in the limit [63] is the notion priced here, and the enumeration learner is his identification by enumeration.

The price of revising a verdict

Theorem 17.20 showed that verdicts revised as the record grows confirm exactly the Σ_2 questions. What does it cost to know, now, what the verdicts will settle on? It depends on how often they may change.

Definition 29.26 (Revisions and Σ_2 excluded middle)**.** A guessing rule g (Definition 17.19) *changes at most k times* on w when there are at most k numbers m with $g(w{\restriction}m) \neq g(w{\restriction}(m+1))$. Σ_2 *excluded middle*, Σ_2-LEM, states that for every binary double sequence β, either some m has $\beta(m,n) = 0$ for every n, or no m does.

Theorem 29.27 (The prices of revisable verdicts)**.**

1. *If a guessing rule confirms Q in the limit and changes at most k times on every world, then LPO decides Q at every world.*
2. *On binary runs, "some entry is 1" is confirmed in the limit by a rule that changes at most once, and deciding it for every run is LPO.*
3. *For each k, "the number of entries 1, capped at $k+1$, is eventually odd" is confirmed in the limit by a rule that changes at most $k+1$ times, and by no rule that changes at most k times on every run.*
4. *Σ_2-LEM decides every question that a guessing rule confirms in the limit.*
5. *On binary runs, finiteness, $\exists N \forall n \geq N\, \alpha(n) = 0$, is confirmed in the limit, and deciding it for every run is equivalent to Σ_2-LEM.*

The negative half of part 3 is proved in classical mathematics; everything else is proved with no choice principle.

Proof. (1) Fix w. At a stage s, apply LPO to the sequence that is 1 at i when $g(w{\restriction}(s+i)) \neq g(w{\restriction}s)$. If it is all zero, the verdicts have settled on $g(w{\restriction}s)$, which answers Q. Otherwise move to the stage $s+i$ found, having used one change. After at most $k+1$ steps no change remains, and the first case answers.

(2) "Yes once a 1 has appeared" changes at most once, and Proposition 17.18(1) prices the decision.

(3) Saying *yes* when the capped count so far is odd changes only when the capped count rises, at most $k+1$ times. Against a rule with at most k changes, start from the zero world: its capped count is even, so the verdicts settle on *no* from some stage. Place an entry 1 after that stage: the count becomes odd, and the verdicts must settle on *yes*, after a change. Repeating $k+1$ times forces $k+1$ changes along one run.

(4) If g confirms Q in the limit, $Q(w)$ says that some m has $g(w{\restriction}(m+n)) =$ yes for every n. Apply Σ_2-LEM to $\beta(m,n) = 1$ exactly when $g(w{\restriction}(m+n))$ is *no*.

(5) "Yes when the record is empty or ends in 0" confirms finiteness, and (4) gives the decision from Σ_2-LEM. Conversely, let β be a binary double sequence. Let cand(s) be the least $m \leq s$ with $\beta(m, n) = 0$ for every $n \leq s$, or $s + 1$ if there is none, and let $c(s) = 1$ exactly when cand$(s + 1) \neq$ cand(s). If c has finitely many entries 1, the candidate is eventually constant, and since a missing candidate changes at every stage it is a real one, whose row is 0 everywhere. If some row m is 0 everywhere, then cand$(s) \leq m$ for $s \geq m$, and it never decreases from there; a bounded sequence of numbers that never decreases cannot fail forever to become constant, so c cannot fail to be finite. So a decision of finiteness for c decides whether some row of β is 0 everywhere. □

Part 1 and part 4 refine Theorem 17.20: a Σ_2 question confirmed with a bounded number of revisions costs at most LPO, and the event question shows that LPO is needed; with no bound the price is Σ_2 excluded middle, attained by finiteness. Σ_2-LEM is equivalent, with no choice principle, to the principle Σ_2-LPO of Section 29.10 (Proposition 29.50), the price of Harrington's learning method.

29.6 Mistakes, dimensions and samples

The opening case counted mistakes. Here the count is made exact for every finite class of laws, and the same counting answers how large a sample must be and how well a law can be predicted from its program.

Definition 29.28 (Online learning)**.** Let X be a set of points; a *law* is a map $f : X \to \{0, 1\}$. An *online learner* L maps a finite history of labelled points and a new point to a predicted label. On a list of points labelled by f, it predicts each label from the history of the earlier points with their true labels, and mist$(L, f, x_1 \dots x_r)$ is the number of wrong predictions. For a finite list H of laws, repetitions allowed, with length $|H|$, the *version space* of a history is the list of laws in H consistent with it. The *halving learner* of H predicts 1 exactly when at least half of the version space predicts 1. The *labellings* of n points are the 2^n laws on $\mathbb{N}$ that are 0 from n on.

Theorem 29.29 (Mistakes are distinctions)**.**

1. *If f is in H, the halving learner of H makes m mistakes on a list of points only if $2^m \leq |H|$.*
2. *For every online learner and every n, some labelling of the points $0, \dots, n-1$ makes it err at each of them.*
3. *The halving learner of the 2^n labellings of n points errs at most n times on every list of points; the labellings correspond one-to-one with the binary words of length n.*
4. *Let* dec *send some binary words to laws, and let $f =$ dec(w) with $|w| \leq b$. The halving learner of the laws* dec(w')*, $|w'| \leq b$, errs at most b times on every list of points.*

The theorem is free.

Proof. (1) When the halving learner errs, the true label is given by at most half of the version space, so at most half survives; f always survives. After m mistakes, $1 \le |H|/2^m$. (2) Label each point with the opposite of the prediction. (3) is (1) with $|H| = 2^n$, and a labelling is its word of first n values. (4) There are $2^{b+1} - 1$ words of length at most b, so $2^m \le |H| < 2^{b+1}$. □

Part 4 is a mistake-bound form of Occam's razor, whose sample-size form is due to Blumer, Ehrenfeucht, Haussler and Warmuth [116]: a law with a b-bit description costs at most b mistakes. A halving learner can be far from optimal, and the exact worst case is a dimension.

Definition 29.30 (Littlestone dimension)**.** Let X_0 be a finite list of points. A point x *splits* a list H of laws when both labels occur at x; $H_{x,b}$ is the list of laws in H with label b at x. The *dimension* $\mathrm{ldim}(H)$ is 0 when no point of X_0 splits H, and otherwise the largest, over splitting points x of X_0, of $1 + \min(\mathrm{ldim}(H_{x,0}), \mathrm{ldim}(H_{x,1}))$. The *rank* of a list is 0 when it is empty and ldim + 1 otherwise. The *standard optimal learner* predicts at x the label b whose part of the version space has the larger rank, and 1 at a tie.

Theorem 29.31 (The Littlestone dimension is the exact worst case)**.** *Let H be a finite list of laws and X_0 a finite list of points.*

1. *If $f \in H$, the standard optimal learner makes at most* $\mathrm{ldim}(H)$ *mistakes on every list of points from X_0.*
2. *If H is not empty, every online learner makes at least* $\mathrm{ldim}(H)$ *mistakes on some law of H and some list of points from X_0.*
3. *If H is not empty, $2^{\mathrm{ldim}(H)} \le |H|$.*
4. *The 2^n labellings of the points $0, \dots, n-1$ have dimension n.*

The theorem is free.

Proof. (1) A mistake at x means that the true label's part of the version space has the smaller rank, or the equal rank when the prediction was 1. If x splits the version space V, that part has dimension at most $\mathrm{ldim}(V) - 1$, by the definition of ldim. If it does not, the true part is all of V and the other is empty, with rank 0, so the prediction was right. So each mistake lowers the dimension of the version space, which never becomes empty. (2) Answer each prediction at a point x that realizes the dimension with the label of the other part, and continue inside that part, whose dimension is at least $\mathrm{ldim}(H) - 1$. (3) By induction on $|H|$: at a point realizing the dimension both parts have dimension at least $\mathrm{ldim}(H) - 1$, hence at least $2^{\mathrm{ldim}(H)-1}$ laws each. (4) By (3) the dimension is at most n, and splitting at $0, 1, \dots$ in turn reaches n. □

The theorem is Littlestone's [131]. For the four laws of the opening the dimension is 2, equal to $\log_2 4$; for the n laws with a single 1 among n points it is 1, far below $\log_2 n$, since one mistake reveals the position of the 1.

Samples, counted

How many examples must a learner see to be probably nearly right? The standard answer is a statement about probability. It is, underneath, a count.

Theorem 29.32 (Probably approximately correct learning is counting)**.** *Let X_0 be a list of N points, repetitions allowed, f a law and H a finite list of laws. A* sample *is a list of m points of X_0; there are N^m. Write* $\mathrm{err}(h)$ *for the number of points of X_0 at which h differs from f.*

1. *A law h agrees with f on exactly $(N - \mathrm{err}(h))^m$ samples.*
2. *At most $|H|(N - e - 1)^m$ samples have a law in H with more than e errors that agrees with f on the sample.*
3. *Let a learner return, for every sample labelled by f, a law of H consistent with it. Then its law has more than e errors on at most $|H|(N - e - 1)^m$ samples.*

The theorem is free.

Proof. A sample on which h agrees with f is a list of m points chosen among the $N - \mathrm{err}(h)$ points of agreement, which is (1). Summing (1) over the laws with more than e errors gives (2), and (3) follows since the returned law agrees with f on its sample. □

Dividing by N^m, a sample drawn uniformly from X_0 misleads a consistent learner by at least $\varepsilon = (e + 1)/N$ with frequency at most $|H|(1 - \varepsilon)^m$, the bound of Valiant's model [137]. Read as frequencies over all samples, the bound needs no posit of probability.

Predicting from programs

A *predictor* sees the record $\omega{\restriction}k$ and predicts $\omega(k)$; its mistakes up to n are the $k < n$ at which it is wrong. A *system of programs* is a partial evaluation $\mathrm{Run}(c, k)$, defined at some pairs, with the bits encoded injectively as values; program c *computes* ω when $\mathrm{Run}(c, k)$ is defined and encodes $\omega(k)$ for every k. A *halting table* for it is a map d with $d(c, k) = 1$ exactly when $\mathrm{Run}(c, k)$ is defined. The *elimination predictor* follows the least program $c \le k$ that agrees with the record and halts at k, read through d. The *phased halving predictor* works in phases: in phase q it takes the majority vote, 1 at a tie, of the programs below 2^q that agree with the record and halt at k, and the phase is the least $q \le k$ for which some program below 2^q agrees with the record.

Theorem 29.33 (Universal prediction needs a halting table)**.**

1. *For every computable predictor there is a computable binary world on which it errs at every examination.*
2. *For any system of programs with a halting table given as data, the elimination predictor makes at most $2j$ mistakes on every world that program j computes, at every stage.*
3. *The phased halving predictor makes at most $p(p + 1)/2 + 2p + 1$ mistakes there, where p is the number of binary digits of j.*

Part 1 is proved in classical mathematics; parts 2 and 3 are free.

Proof. (1) Let $\omega(k)$ be the opposite of the prediction at $\omega{\restriction}k$; the recursion is computable. (2) Before stage j there are at most j mistakes. From stage j on, program j is a candidate that agrees and halts, so the followed program c is at most j; if $c = j$ the prediction is right, and if $c < j$ errs, c disagrees with the record from then on. So at most j further mistakes occur. (3) Program j lies below 2^p and always agrees, so the phase is at most p once $k \geq p$, and it never decreases, since a program that disagrees with a record disagrees with its extensions. Before stage p there are at most p mistakes. A program that does not halt at k disagrees with every longer record, and at a mistake the majority of those that halt were wrong; so each mistake in phase q at least halves the agreeing programs below 2^q, of which there are at most 2^q. Phase q therefore sees at most $q + 1$ mistakes, and $\sum_{q \leq p}(q + 1) = p(p + 1)/2 + p + 1$. □

No computable predictor is universal, by part 1; with a halting table, even a crude one is, with a mistake bound set by the size of the program. The size of the shortest program is itself out of reach: the length of the shortest description of a number is not computable, and a consistent formal system certifies lower bounds on it only up to a constant [130, 120].

29.7 Learners that are programs

So far learners were arbitrary rules. Suppose instead that the learner must be a program, and the laws to be learned are the computable binary worlds. Gold proved that no single program then identifies every law in the limit [63]. Weaker criteria of success were studied by Bārzdiņš and by Case and Smith [114, 118]. This section prices them. Recognition Science's processes enter through an identification: if its native processes are the computable functions, which we do not prove here, the theorems below say what a native learner can learn. Section 29.9 takes a narrower reading, under which every program halts.

Definition 29.34 (Criteria of success)**.** Fix a standard numbering $\varphi_0, \varphi_1, \ldots$ of the partial computable functions [19]. A *code e computes* a binary world ω when $\varphi_e(x)$ is defined and equals $\omega(x)$ for every x. A learner M assigns a code to every finite binary record, and its *conjecture* at stage n on ω is $M(\omega{\restriction}n)$. M identifies ω

EX when its conjectures settle on one code that computes ω;

BC when from some stage on every conjecture computes ω;

BC* when from some stage on every conjecture computes ω at all but finitely many inputs;

BC^k when from some stage on every conjecture computes ω at all but at most k inputs;

EX* when its conjectures settle on one code that computes ω at all but finitely many inputs.

EX implies BC and EX*, and each of BC, BC^k and EX* implies BC*. The lower bounds below all use the zero world and the flag worlds, and they do not use the particular numbering.

Theorem 29.35 (A learner of the zero world and its flags yields LPO)**.**

1. *Let G be a class of binary worlds that contains the zero world and the flag world of each of its members. Let hypotheses be drawn from any set, with any relation "h computes ω" under which two worlds computed by one hypothesis agree from some input on. If a learner M, a rule from records to hypotheses, has for every $\omega \in G$ a stage from which every conjecture computes ω, then every $\alpha \in G$ is all zero or has an entry* 1*.*

2. *Hence every learner, computable or not, that EX-, BC- or BC*-identifies every computable binary world yields LPO for computable binary sequences.*

3. *Conversely, for any system of programs* Run *with a halting table given as data, LPO makes the learner that names the least code consistent with the record, consistency read through the table, EX-identify every world that some program computes.*

Parts 1 and 3 are proved with no choice principle, for every system of hypotheses or programs; part 2 is their instance for the codes φ_e, stated in classical mathematics.

Proof. (1) Let the conjectures compute the zero world from stage N and the flag world of α from stage N'. Inspect α below $N + N'$. If an entry 1 appears, we are done. If not, the two worlds have the same record of length $N + N'$, so the conjecture there computes both, and they agree from some input B on. Then α is all zero: $\alpha(k) = 1$ would put a 1 into the flag world at $\max(k, B)$. (2) The computable worlds contain the zero world and the flag world of each member. A code computes at most one world, and a code that computes two worlds at all but finitely many inputs makes them agree from some input on; EX gives BC, and BC gives BC*. (3) LPO decides, for each code below the least code of the target, whether it reproduces the target everywhere, reading definedness through the table, or finds a place where it does not; past these finitely many places the learner settles, as the enumeration learner does in Theorem 29.24. □

So identifying every computable law, by any of these criteria and by any means, is at least as strong as deciding every computable binary sequence, and with a halting table in hand LPO suffices for the strongest criterion. Which programs can do it is classical computability theory.

Theorem 29.36 (What a computable learner can do)**.** *Work in classical mathematics.*

1. *No computable learner EX-identifies every computable binary world.*

2. *No computable learner BC-identifies every computable binary world.*

3. *No computable learner EX*-identifies every computable binary world, and for each k none BC^k-identifies every computable binary world.*

4. *One computable learner BC*-identifies every computable binary world: at a record σ its conjecture is the program that, on input x, finds the least $e \le |\sigma|$ whose computation, run for x steps, reproduces every recorded value, and returns $\varphi_e(x)$.*

Proof. (1) Let M be computable and EX-identify every computable world. For a finite record σ, M settles on a code of $\sigma 0^\infty$, say from $\sigma 0^K$ on, and on a different code of $\sigma 0^K 10^\infty$, a different world. So a search finds k and m with $M(\sigma 0^k 10^m) \neq M(\sigma 0^k)$. Iterating from the empty record builds a computable world along which M changes its conjecture infinitely often. (2) From σ, search for k and t such that the conjecture at $\sigma 0^k$ returns 0 at input $|\sigma| + k$ within t steps; the search succeeds because $\sigma 0^\infty$ is computable and identified. Extend by $\sigma 0^k 1$. Along the limit world infinitely many conjectures are wrong at their next input. (3) The same method, with blocks: for BC^k, find a stage at which the conjecture returns values at $k+1$ of the next inputs, and let the world contradict all of them; for EX^*, run the construction of (2). Its search still succeeds, since from some stage on the conjectures on $\sigma 0^\infty$ are one code, which returns 0 at all large inputs; and once M has settled along the limit world on one code, every later round makes that code wrong at a new input. (4) Let E be the least code of ω. Each $e < E$ fails to reproduce ω at some input, where it is wrong or undefined, so once the record contains all these inputs no $e < E$ is selected at any x. The finitely many recorded values of φ_E are computed within some number of steps, so for all large x the selection is E, and the conjecture returns $\varphi_E(x) = \omega(x)$. □

Part 1 is Gold's theorem [63], part 2 is due to Bārzdiņš and to Case and Smith [114, 118], and part 4 is Harrington's theorem as reported by Case and Smith [118]. Of the standard criteria only the weakest, finitely many errors with changing codes, is within reach of one computable learner, and by Theorem 29.35 any learner that meets it yields LPO for computable sequences. Harrington's learner therefore cannot be justified without that much omniscience; Section 29.10 prices his method exactly.

Learning from examples alone

A learner may see only members of a language $L \subseteq \mathbb{N}$, never non-members. A *text* for L is a sequence of members of L and pauses in which every member appears. A family (L_i) of languages, each decided by a map $F(i, x)$, is *learnable from text* when some learner, given the finite pieces of any text for any L_i, settles on an index j with $L_j = L_i$. A *tell-tale* for L_i is a finite set $T \subseteq L_i$ such that no L_j with $T \subseteq L_j$ is a proper subset of L_i.

Theorem 29.37 (Positive data need finite tell-tales)**.**

1. *No learner learns from text the family consisting of* $\mathbb{N}$*, at index* 0*, and the segments* $\{0, \dots, s\}$*, at index* $s+1$*. The proof uses no choice principle.*
2. *In classical mathematics, a family of decided languages is learnable from text if and only if each of its members has a finite tell-tale.*

Proof. (1) Build a text for $\mathbb{N}$ in stages. Having written a text piece listing $0, \dots, s$, repeat s until the learner names $s+1$; it must, since the continuation that repeats s forever is a text for $\{0, \dots, s\}$, whose only index is $s+1$, and whether it names $s+1$ is decided. Then write $s+1$. The result is a text for $\mathbb{N}$ on which the learner names $1, 2, 3, \dots$ in turn, so it never settles on 0. (2) If the family is learnable, every member L_i has a *locking sequence*, a finite text piece τ of L_i after which the learner names a code of L_i on every extension within L_i, by an argument by contradiction; the members of τ form a tell-tale. Conversely, the learner that names the least

$i \le n$ whose tell-tale has appeared and whose language contains everything seen learns the family. □

Part 1 is Gold's theorem on superfinite classes [63], part 2 is Angluin's [112], and locking sequences are due to Blum and Blum [115].

29.8 Learning with the cost J

A system compares each new record with a frame, a positive point m against which records are read, and pays $J(x/m)$ for a record x. Which frame makes a history cheapest, and what does a learner pay that must choose its frame before each record arrives? Everything in this section takes place on $\mathbb{R}_\delta$ and uses no choice principle; the frame, the regret and Heron's update are free, and only exact tests carry a price.

Definition 29.38 (The cost of a frame and the J-centre)**.** Let records $x_0, \dots, x_{n-1} > 0$ carry weights $w_i > 0$, with $S = \sum_i w_i x_i$ and $T = \sum_i w_i/x_i$. The *cost* of a frame $m > 0$ is $C(m) = \sum_i w_i J(x_i/m)$. A *$J$-centre* is a point $m_* > 0$ with $m_*^2 T = S$, and we put $\tau = m_* T$.

The centre is the geometric mean of the weighted arithmetic mean $S/\sum w$ and the weighted harmonic mean $\sum w/T$ of the records.

Theorem 29.39 (The J-centre, and regret as the cost of re-framing)**.**

1. *The J-centre of a nonempty weighted history exists on $\mathbb{R}_\delta$ and is unique.*
2. *For every frame $m > 0$, $C(m) = C(m_*) + \tau\, J(m/m_*)$, and $C(m_*) = \tau - \sum_i w_i$.*
3. *Hence $C(m_*) \le C(m)$, with equality only at $m = m_*$.*
4. *Let a learner start from any frame $f_0 > 0$ and use, for record n, the centre f_n of the records before it, and write T_{n+1} for the sum T of the first $n+1$ records. Then*

$$\sum_{n<N} w_n\, J\Big(\frac{x_n}{f_n}\Big) = C_N(f_N) + \sum_{n<N} f_{n+1} T_{n+1}\, J\Big(\frac{f_n}{f_{n+1}}\Big),$$

where C_N is the cost of the first N records.

The theorem is free; the identities of parts 2 and 4 hold in every commutative ring in which 2, the records and the frames are invertible.

Proof. (2) $C(m) = \frac{1}{2}\sum_i w_i(x_i/m + m/x_i) - \sum_i w_i = S/(2m) + mT/2 - \sum_i w_i$. With $S = m_*^2 T$, $S/(2m) + mT/2 = \frac{m_* T}{2}(m_*/m + m/m_*) = \tau(J(m/m_*) + 1)$. (1) $S/T > 0$ has a positive square root (Lemma F.12). If two positive points have $m_1^2 T = m_2^2 T$, then $(m_1 - m_2)(m_1 + m_2)T = 0$ with $(m_1 + m_2)T > 0$, so $m_1 = m_2$. (3) $2aJ(a) = (a-1)^2$ is a square, so $J \ge 0$, and $J(a) = 0$ gives $(a-1)^2 = 0$, hence $a = 1$; and $\tau > 0$. (4) Write C_n for the cost of the first n records, so $C_{n+1}(m) = C_n(m) + w_n J(x_n/m)$ and $C_0 = 0$. Part 2 for the first $n+1$ records gives $C_{n+1}(f_n) = C_{n+1}(f_{n+1}) + f_{n+1}T_{n+1}J(f_n/f_{n+1})$, so $w_n J(x_n/f_n) = C_{n+1}(f_{n+1}) - C_n(f_n) + f_{n+1}T_{n+1}J(f_n/f_{n+1})$, and the sum telescopes. □

By part 3, $C_N(f_N)$ is the least cost of the whole history, so the learner's *regret*, its cost minus the least cost, is exactly the sum of the J-costs of its own changes of frame. How large can that be?

Theorem 29.40 (Logarithmic regret, and no better)**.** *Write $H_N = \sum_{n<N} 1/(n+1)$.*

1. *Let $R \geq 1$, let unit-weight records x_n and the start f_0 lie in $[1/R, R]$, and let the learner follow the centre as in Theorem 29.39(4). Its regret after N records satisfies $0 \leq \mathrm{Reg}_N \leq R^{10} H_N$.*
2. *On the alternating records $2, \frac{1}{2}, 2, \frac{1}{2}, \ldots$ the same learner has $H_K \leq 20\,\mathrm{Reg}_{2K} + 1$.*
3. *There are numbers K_c and K_d ($K_c = 12$, $K_d = 48$ will do) such that for every learner, a rule that gives a positive frame for each finite record, and every horizon N, some records $y_0, \ldots, y_{N-1} \in \{2, \frac{1}{2}\}$ and some frame $m > 0$ satisfy*

$$H_N \leq K_c\Big(\sum_{n<N} J\big(y_n / L(y_0 \ldots y_{n-1})\big) - C_N(m)\Big) + K_d.$$

By Theorem 29.39(3) the same holds with the least cost in place of $C_N(m)$, so every learner has regret at least $(H_N - 48)/12$ on some history.

The theorem is free.

Proof. (1) By Theorem 29.39(4) the regret is $\sum_{n<N} r_n$ with $r_n = f_{n+1} T_{n+1} J(f_n/f_{n+1}) = T_{n+1}(f_n - f_{n+1})^2/(2f_n) \geq 0$. The centres lie in $[1/R, R]$. For $n \geq 1$, $f_n^2 T_n = S_n$ gives $f_{n+1}^2 - f_n^2 = (x_n^2 - f_n^2)/(x_n T_{n+1})$, so

$$r_n = \frac{(x_n^2 - f_n^2)^2}{2 f_n x_n^2 T_{n+1}(f_n + f_{n+1})^2} \leq \frac{R^4}{2 \cdot R^{-1} \cdot R^{-2} \cdot (n+1) R^{-1} \cdot 4R^{-2}} = \frac{R^{10}}{8(n+1)},$$

and $r_0 = (f_0 - x_0)^2/(2 f_0 x_0) \leq R^4/2$, since $f_1 = x_0$.

(2) After $2k$ records the centre is 1, and after $2k+1$ records $f^2 = (5k+4)/(5k+1)$, so for $k \geq 1$, $r_{2k} = \frac{5k+1}{2}(f-1)^2/2 = 9/(4(5k+1)(f+1)^2) \geq 1/(4(5k+1)) \geq 1/(20(k+1))$, using $f \leq 2$. Summing over $1 \leq k < K$ gives $\mathrm{Reg}_{2K} \geq (H_K - 1)/20$.

(3) Count one extra record of each kind: after n records with k twos, let $K = k+1$, $L = n-k+1$, $D = K + L = n+2$, $U = 2K + L/2$ and $V = K/2 + 2L$, the sums of the records and of their inverses plus $\frac{5}{2}$; let $G = \sqrt{UV}$ and $e = K - L$. Put $c = \frac{1}{8}$,

$$\alpha_n = \frac{c}{(n+2)(n+3)} \sum_{n \leq j < N} \frac{1}{j+2}, \qquad \Phi_n = \mathrm{Loss}_n + n - G - \alpha_n e^2,$$

where Loss_n is the learner's cost on the first n records. Let f be the learner's frame for record n, and X_+ and X_- the increase of Φ if the record is 2 or $\frac{1}{2}$. We show $K X_+ + L X_- \geq D Y$ with $Y = c/(n+3) - \alpha_{n+1}$. Write $G_\pm$ for the new G. Then $K X_+ + L X_- = t_1 + t_2 + (D\alpha_n - (D+2)\alpha_{n+1}) e^2 - c\,D/(D+1) + DY$, where $t_1 = \frac{1}{2}(U/f + Vf) - G$ and $t_2 = (D+1)G - K G_+ - L G_-$, because $K(e+1)^2 + L(e-1)^2 = (D+2)e^2 + D$ and the learner's step costs, weighted by K and L, add up to $\frac{1}{2}(U/f + Vf) - D$. Three identities, each with $G^2 = UV$, finish:

$$t_1 \cdot Vf = \tfrac{1}{2}(Vf - G)^2, \qquad \tfrac{25}{4} D^2 - 4G^2 = \tfrac{9}{4}(K-L)^2,$$
$$2D(D+1) G t_2 = \tfrac{9}{4} DKL + K\big(DG_+ - (D+1)G\big)^2 + L\big(DG_- - (D+1)G\big)^2.$$

The first gives $t_1 \geq 0$. The other two give $G \leq \frac{5}{4}D$ and then $D(D+1)t_2 \geq \frac{9DKL}{8G} \geq \frac{9KL}{10} \geq 4cKL$. By the choice of α, $D\alpha_n - (D+2)\alpha_{n+1} = c/(D(D+1))$, and $4KL + e^2 = D^2$; so $KX_+ + LX_- \geq DY$. Since $K, L > 0$, cotransitivity gives $X_+ \geq Y - \varepsilon$ or $X_- \geq Y - \varepsilon$ for $\varepsilon = 1/(N+1)$, with no decision of a sign; choose that record. From $\Phi_0 = -\frac{5}{2}$, after N steps $\Phi_N \geq \sum_{n<N}(c/(n+3) - \alpha_{n+1}) - \frac{5}{2} - 1 \geq \frac{H_N}{12} - \frac{15}{4}$, using $\sum_n \alpha_{n+1} \leq cH_N/3$. Finally $\alpha_N = 0$, and the frame $m = G/V$ costs at most $G - N$ on the records, since their sums are $U - \frac{5}{2}$ and $V - \frac{5}{2}$; so $\mathrm{Loss}_N - C_N(m) \geq \Phi_N$. □

Parts 1 and 3 together say that the minimax regret of learning a frame under J is of order $\log N$: following the centre achieves it, and no learner does better than a constant fraction of it. This is the logarithmic regret known for strongly convex losses [129], here with J as the loss and with no averaging over sequences.

The centre can be reached without a square root. Heron's update $m \mapsto \frac{1}{2}(m + m_*^2/m)$ is Newton's method for $m^2 T = S$, and also the gradient step on C with step size m/T, since $C'(m) = \frac{T}{2}(1 - m_*^2/m^2)$; reading it as the natural gradient step of the frame is an interpretation.

Theorem 29.41 (Heron's update is free and converges)**.**

1. *For $m, m_* > 0$, $\frac{1}{2}(m + m_*^2/m) - m_* = m_* J(m/m_*) = (m - m_*)^2/(2m)$: the overshoot of Heron's update is the J-cost of the frame it leaves.*
2. *On $\mathbb{R}_\delta$, for $q \geq 0$ and $h_0 > 0$ the iterates $h_{k+1} = \frac{1}{2}(h_k + q/h_k)$ exist and are positive. If $m > 0$ and $m^2 = q$, then $0 \leq h_{k+1} - m \leq 2^{-k}(h_1 - m)$ and $h_{k+2} - m \leq (h_{k+1} - m)^2/(2m)$ for every k.*

The theorem is free.

Proof. (1) is algebra. (2) A positive point has an inverse, so the iterates exist, and $h_{k+1} - m = (h_k - m)^2/(2h_k) \geq 0$ by (1). For $k \geq 1$, $0 \leq (h_k - m)/h_k \leq 1$, so the error at least halves; and $1/h_{k+1} \leq 1/m$ gives the quadratic bound. □

The error falls geometrically at first and then quadratically, and the limit m is not needed to run the iteration, only to measure it.

When to stop, and what exact steps cost

An optimizer stops when its residual is small. A residual is a point of $\mathbb{R}_\delta$, and an exact test of smallness is a comparison of points. Theorem 29.42 prices the tests, and Table 29.2 the step rules.

Theorem 29.42 (The prices of stopping)**.** *Let $r_0, r_1, \ldots$ be points of $\mathbb{R}_\delta$, the residuals of a run.*

1. *If $a < b$ and some $r_k < a$, there is a k with $r_k < b$ and $a < r_j$ for every $j < k$: a test with a tolerance band stops, and stops in time. This is free.*
2. *"Whenever some $r_k < b$, there is a least k with $r_k < b$", for all runs and points b, is equivalent to LPO.*

Table 29.2. Prices of the step rules of an optimizer on $\mathbb{R}_\delta$. Each row asks for every g (or a, b) a choice with the stated guarantees; the tolerance $\varepsilon > 0$ is a point.

Step rule	Price	Source
Sign step: a bit, 0 only if $g \geq 0$, 1 only if $g \leq 0$	LLPO	Corollary 12.18
Three-way step: down if $g > 0$, stay if $g = 0$, up if $g < 0$	LPO	Corollary 12.18
Exact stop: 1 only if $g = 0$, 0 only if $g \neq 0$	WLPO	Corollary 12.18
Exact acceptance: 1 only if $a < b$, 0 only if not	LPO	Table 12.2
Tolerance step: 0 only if $g > -\varepsilon$, 1 only if $g < \varepsilon$	free	cotransitivity
Tolerance acceptance: 1 only if $a < b + \varepsilon$, 0 only if $b < a$	free	cotransitivity

3. *For runs given by regular sequences naming the residuals, "$\neg\neg\exists k\, r_k < b$ implies $\exists k\, r_k < b$", for all such runs and points b, is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$.

The equivalences are proved with no choice principle.

Proof. (1) For $j = 0, 1, \ldots$ apply cotransitivity to $a < b$ at r_j: $r_j < b$ or $a < r_j$. Stop at the first j with $r_j < b$; at the given k the second case is impossible, so the search ends by k. (2) LPO decides $r_j < b$ for each j (Table 12.2), and a search below the given k finds the least. Conversely, for points x and y take the run $x,\ y - 1$ and $b = y$: the least k is 0 exactly when $x < y$, so the rule decides $x < y$, which is LPO. (3) A strict inequality $r_k < b$ holds exactly when, at some stage, the regular sequences show a gap larger than their tolerance, a decided condition on the pair of the residual's index and the stage; $\mathrm{MP}_{\mathrm{bin}}$ applied to the pairs finds one. Conversely, for binary α, the run $r_k = -1$ if $\alpha(j) = 1$ for some $j \leq k$ and $r_k = 1$ otherwise, with $b = 0$, turns $\neg(\alpha$ all zero) into an entry 1. □

For residuals that are bare points, not given by their sequences, the rule of part 3 still implies $\mathrm{MP}_{\mathrm{bin}}$, and whether the converse holds is not settled here. Steps that branch on exact signs carry the prices of Chapter 12; Table 29.2 lists them, together with the free rules that use a tolerance instead.

An optimizer on exact points therefore uses overlapping tolerance guards, as Theorem 17.22 found for tests of a law: every exact branch costs an omniscience principle, and every guarded branch is free.

29.9 Learning on the programs of Gödel's T

Section 29.7 read Recognition Science's processes as the computable functions. A narrower reading takes its execution layer to be the closed programs of Gödel's system T with their evaluation, the system of Chapter 28. Either reading is an identification, and the two are different: the closed programs of T compute only some of the total computable functions, and the computable functions include partial ones. The theorems of each section are about its own programs, and this section's do not apply to partial programs. The programs here halt on every input, and this changes the prices of Section 29.7.

Recall the system. Its programs are built by application from the constants K, S, 0, Succ and the recursors R at every finite type, and a program t of type $O \to O$ has a value $\mathrm{val}(t)$, a function from numbers to numbers defined at every input. Programs are finite trees labelled by constants and types, so they can be coded by numbers. Decoding a number is a bounded computation, and it lists the programs of type $O \to O$ as $t_0, t_1, \ldots$ with every program occurring.

Definition 29.43 (Worlds of the layer and learning on it)**.** A binary world ω is a *world of the layer* when some program t of type $O \to O$ *computes* it: $\mathrm{val}(t)(x)$ is 1 when $\omega(x) = 1$ and 0 otherwise. LPO_T and MP_T are LPO and $\mathrm{MP}_{\mathrm{bin}}$ for the binary sequences that are worlds of the layer. A *learner on the layer* maps finite binary records to programs; EX and BC^* are as in Definition 29.34, with programs in place of codes. It *changes its mind* at k on ω when its conjectures at the records of lengths k and $k+1$ differ. A learner *commits once* on ω when, for some stage N, it gives no program at the records shorter than N and one fixed program computing ω at all the others. The *fixed learner* E names, at a record σ, the program t_i for the least $i \le |\sigma|$ whose values reproduce σ, and $t_{|\sigma|+1}$ if there is none.

Theorem 29.44 (No program of the layer evaluates the layer)**.** *No program U of type $O \to (O \to O)$ satisfies $\mathrm{val}(U)(j)(y) = \mathrm{val}(t_j)(y)$ for all j and y. This is free. In classical mathematics, $(j, y) \mapsto \mathrm{val}(t_j)(y)$ is a computable function, and the fixed learner E is computable through the indices it names.*

Proof. Bracket abstraction turns $y \mapsto \mathrm{val}(U)(y)(y) + 1$ into a program, which is t_j for some j; at $y = j$ it would give $\mathrm{val}(U)(j)(j) = \mathrm{val}(U)(j)(j) + 1$. For the classical statement, a code a *realizes* a value v of type O when $a = v$, and one of type $\sigma \to \rho$ when $\varphi_a(b)$ is defined and realizes $v(w)$ for every b realizing a value w of type σ. One code realizes K at every type, one S, one Succ, 0 realizes 0, and one code realizes every recursor R, its run on a numerical argument n halting by induction on n. A realizer of v applied to one of w realizes $v(w)$, so the code assembled along a program's tree, computed from its index, realizes its value. Hence $(j, y) \mapsto \mathrm{val}(t_j)(y)$ is computable, and so is E's search through $i \le |\sigma|$. □

So the layer cannot run its own interpreter, while a program outside it can. That is why the prices below stop at LPO for the layer's own sequences.

Theorem 29.45 (Learning the layer costs exactly LPO for its own sequences)**.** *Each of the following is equivalent to LPO_T, with no choice principle in either direction:*

1. *some learner EX-identifies every world of the layer;*
2. *some learner BC^*-identifies every world of the layer;*
3. *the fixed learner E EX-identifies every world of the layer;*
4. *some learner EX-identifies every world of the layer while changing its mind at most $c + 1$ times on every world that t_c computes.*

With no hypothesis at all, E changes its mind at most c times on every world that t_c computes.

Conditions and scope.

Base and premises
The closed programs of Gödel's T of type $O \to O$ and the binary worlds they compute; learners of any kind.

Conclusion
Learning every world of the layer in the limit costs exactly LPO for the layer's own sequences, by one fixed learner, and costs no more with a count of revisions attached.

Identification
That these programs are Recognition Science's execution layer is an identification; the theorem is about the programs.

Proof. Upper bounds. Let ω be computed by t. For each j, the world that is 1 where $\mathrm{val}(t_j)$ and $\mathrm{val}(t)$ disagree is a world of the layer, since comparing two numbers is primitive recursive. So LPO_T decides whether t_j computes ω or finds an input where it does not. It therefore finds the least i with t_i computing ω and, for each $j < i$, a refuting input; past these finitely many inputs E names t_i. *The count.* The index named by E never decreases, since a refuted index stays refuted; it never exceeds c when t_c computes ω, since t_c is never refuted; and it rises at every change. A nondecreasing sequence of numbers bounded by c rises at most c times. This gives (4) from (3). *Lower bounds.* The worlds of the layer contain the zero world and the flag world of each member, by primitive recursion, and two worlds that one program computes at all but finitely many inputs agree from some input on. So Theorem 29.35(1) turns a BC^* learner into LPO_T, and each of (1), (3) and (4) gives (2). □

Why is the layer priced by LPO_T alone, while the learners of Section 29.7 use a halting table or, for Harrington's method, Σ_2-LPO (Section 29.10)? Whether a program of the layer computes a given world of the layer is a question about one decided sequence: LPO answers it. Whether a code computes a world asks also whether it halts, a question one level higher.

Theorem 29.46 (Revisions on the layer)**.**

1. *For every m, no learner EX-identifies every world of the layer while changing its mind at most m times on each.*

2. *Some learner EX-identifies, with at most one change of mind, every world of the layer that has at most one entry* 1*, if and only if* LPO_T *holds.*

3. *For a finite list s of numbers, let ω_s have its entries* 1 *exactly at the members of s. One learner EX-identifies every ω_s with at most $|s|$ changes of mind, and for every k no learner identifies every ω_s with $|s| \le k + 1$ within k changes.*

Part 2 is proved with no choice principle, and parts 1 and 3 are free.

Proof. (1) Run the learner on the zero world until it has settled on a program, then let the world change from a later stage on; worlds that differ need different programs, so the learner must change its mind. The worlds built are eventually constant, hence worlds of the layer, and

$m + 1$ rounds force $m + 1$ changes. (2) The learner that names the program of the first entry 1 seen, and the zero program before, changes its mind at most once and identifies the zero world and every world with a single entry 1. Under LPO_T every world of the layer with at most one entry 1 is one of these. Conversely, let a learner identify such worlds, and let α be a world of the layer. The world that has its only entry 1 at the first entry 1 of α is a world of the layer with at most one entry 1. The learner has settled on the zero world by some stage N and on this world by N'; if α is 0 below $N + N'$, the two records agree there, the shared conjecture computes both worlds, and α is all zero. (3) Name the program of the set of positions of the entries 1 seen so far; this changes only at a new entry 1. Against a learner with k changes, add a new entry 1 after each settling, $k + 1$ times. □

Committing once

A learner that commits once must know when it has seen enough. Here the price sits in knowing what form a world has.

Theorem 29.47 (Committing once on the layer)**.**

1. *No learner commits once correctly on a class that contains the zero world and, for every N, a world that is* 0 *below N and has an entry* 1*. In particular no learner commits once correctly on every world of the layer.*
2. *One learner, defined with no hypothesis, commits once correctly on every* headed *world:* 0 *below some j,* 1 *at j, and from there on the values of t_j, shifted to begin at $j + 1$.*
3. *For a world ω of the layer, some learner commits once correctly on both the zero world and ω if and only if ω is all zero or has an entry* 1*. Hence committing once on the zero world and the flag world of α, for every world α of the layer, is equivalent to* LPO_T*, and on the zero world and ω, for every world ω of the layer that is not all zero, to* MP_T*.*

Parts 1 and 2 are free, and part 3 is proved with no choice principle.

Proof. (1) On the zero world the learner commits at some stage N to a program z. A member that is 0 below N has the same record of length N, so the learner commits to z there as well, and z cannot compute a world with an entry 1. (2) Stay silent until the first entry 1, at j; then commit to the program that writes j zeros, a 1, and then the values of t_j. (3) If ω is all zero, commit to the zero program at once; if $\omega(m) = 1$, stay silent below $m + 1$ and commit by the entry at m. Conversely, let the learner commit on the zero world at N_0 and on ω at N_1. If ω is 0 below $N_0 + N_1$, the records agree there, the learner commits to one program on both, and ω is the zero world. The flag world of α is all zero or has an entry 1 exactly when α is. □

Theorem 29.48 (Catalogues, limits and locking functions)**.** *Let $W_0, W_1, \ldots$ be a* catalogue*: worlds given with programs P_i computing each W_i.*

1. *Some learner EX-identifies every W_i if and only if any two members are equal or differ at some place; some learner BC^*-identifies every W_i if and only if any two members agree from some place on or differ at some place. The two conditions are equivalent.*

2. *A finite catalogue admits a learner that commits once correctly on each member if and only if any two members are equal or differ at some place.*

3. *A catalogue admits a learner that commits once correctly on each member if and only if it has a* locking function*: a map g such that whenever W_j agrees with W_i below $g(i)$, $W_j = W_i$.*

4. *The zero world with the worlds that have a single entry* 1 *form a catalogue that a learner defined with no hypothesis EX-identifies with at most one change of mind, and on which no learner commits once correctly.*

5. *Let W_i be* 0 *below $d_i = \mathrm{val}(t_i)(i)$ and* 1 *from d_i on. This catalogue has the locking function $i \mapsto d_i + 1$, so a learner commits once correctly on it, but no program of the layer computes a locking function for it.*

Each statement is proved with no choice principle.

Proof. (1) Let a learner identify W_i and W_j, settled from stages N and N'. If the members differ below $N + N'$, a search finds the place; if not, the conjecture at the shared record of length $N + N'$ computes both, exactly or from some input on. Agreement from B on, with a search below B, decides equality, which gives the equivalence of the two conditions. Conversely, the learner that names the least index consistent with the record identifies every member, as in Theorem 29.24, the decisions refuting smaller indices. (2) Two members learned by committing once are decided, by the argument of Theorem 29.47(3). Conversely, choose a stage m beyond one place of difference of every pair that differs; stay silent below m, then commit to the program of the first listed member that agrees with the record below m. (3) Given such a learner, let $g(i)$ be the stage at which it commits on W_i, found by search; if W_j agrees with W_i below $g(i)$, the learner commits on W_j to the program of W_i, so $W_j = W_i$. Given g, commit at the first stage n at which some $i \le n$ has $g(i) \le n$ and agrees with the record below $g(i)$, to P_i. (4) Name the program of the first entry 1 seen, and the zero program before; Theorem 29.47(1) excludes committing once. (5) If W_j agrees with W_i below $d_i + 1$, its step is at d_i, so $W_j = W_i$. Every program $c \mapsto v$ with a constant value is some t_j, so for each i some member steps at $d_i + 1$ and agrees with W_i below d_i; a locking function g therefore has $g(i) > d_i$. If t_k computed one, then $\mathrm{val}(t_k)(k) > d_k = \mathrm{val}(t_k)(k)$. □

Part 4 separates convergence from commitment on one catalogue at no price: the learner may change its mind once, and nobody can know when. The omniscience sits in knowing which form a world has: LPO_T is equivalent to every world of the layer with at most one entry 1 belonging to that catalogue. Part 5 shows that a locking function can exist although the layer cannot compute it. Locking sequences go back to Blum and Blum [115], and counted mind changes to Case and Smith [118], with ordinal counts due to Freivalds and Smith [127].

29.10 Methods, bounds and decision tables

Harrington's learner (Theorem 29.36(4)) and the learner that reads a halting table (Theorem 29.35(3)) are methods, and a method makes sense for any system of programs whose runs may fail to stop. This section prices each method over all such systems at once, then prices the bounds that say when a method has become right.

Definition 29.49 (Systems of programs, the two methods and decision tables)**.**

1. A *system of programs* is an evaluation $\mathrm{ev}(s, e, y)$, the value of program e at input y after s steps, or none yet; a value once given stays given at later steps. Program e *computes* ω when for every y some s gives the encoded value $\omega(y)$.

2. The *selection method* is any rule $\mathrm{sel}(\sigma, x)$ that returns the least $e \le |\sigma|$ whose computation, run x steps, reproduces the record σ, whenever there is one. Its conjecture at σ answers input x with the value of program $\mathrm{sel}(\sigma, x)$ at x. It *succeeds* on ω when, from some record length on, each conjecture answers correctly at all large inputs.

3. The *oracle method*, for a partial evaluation with a halting table, names the least $c \le |\sigma|$ whose values, read through the table, reproduce σ; it succeeds when it settles on a program computing ω.

4. Σ_2*-LPO* states that for every binary double sequence R, either every row y has some s with $R(y, s) = 1$, or some row y has $R(y, s) = 0$ for every s.

5. A Σ_1 *table* exists when every binary double sequence R has a map D with $D(r) = 1$ exactly when $R(r, s) = 1$ for some s. A Σ_2 *table* exists when every binary triple sequence R has a map T with $T(r) = 1$ exactly when every y has some s with $R(r, y, s) = 1$.

6. A method has a *bound* on a system when some map F gives, for every program c and every world ω that c computes, a record length $F(c)$ from which the method is right on ω.

Σ_2-LPO decides, for a whole array, whether every row eventually fires or some row never does. It is the same principle as Σ_2-LEM of Definition 29.26, which asks only whether some row never fires.

Proposition 29.50 (Σ_2 excluded middle is Σ_2-LPO)**.** Σ_2*-LEM and* Σ_2*-LPO are equivalent. Both directions are proved with no choice principle.*

Proof. Let Σ_2-LPO hold, and let β be a binary double sequence. Applied to $R = \beta$, it says either that every row of β has an entry 1, and then no row is 0 everywhere, or that some row is 0 everywhere. Either way the alternative of Σ_2-LEM is decided.

Conversely, let Σ_2-LEM hold. For a binary sequence α, apply it to $\beta(m, n) = 1 - \alpha(m)$: row m of β is 0 everywhere exactly when $\alpha(m) = 1$, so either α has an entry 1 or none, which is LPO. Now let R be a binary double sequence, and apply Σ_2-LEM to R itself. If some row is 0 everywhere, that is the second alternative of Σ_2-LPO. Otherwise no row is 0 everywhere. Then, for each row y, LPO applied to the row finds an entry 1 or shows that the row is 0 everywhere, and the second case is excluded. So every row has an entry 1, the first alternative. □

Theorem 29.51 (The price of the two methods)**.**

1. *The selection method succeeds on every world that some program computes, for every system of programs and every rule meeting its specification, if and only if Σ_2-LPO holds.*
2. *The oracle method succeeds on every world that some program computes, for every system with a halting table, if and only if LPO holds.*
3. *Σ_2-LPO implies LPO.*

Each implication is proved with no choice principle.

Proof. *Σ_2-LPO buys selection.* Let c compute ω. For each $e \le c$, Σ_2-LPO applied to $R(y, s) = 1$ when $\mathrm{ev}(s, e, y)$ is the value $\omega(y)$ says that e computes ω or names an input y_e at which e never gives $\omega(y_e)$. Let E be the least program that computes ω. Once the record is longer than every y_e with $e < E$, no $e < E$ is selected at any x, and once x exceeds the steps E needs on the recorded inputs, E is selected; its value at x is $\omega(x)$.

Selection gives LPO. Use the system in which program 0 computes the flag world of α and every other program answers 0 at once. The method succeeds on the zero world from some record length N. If α has an entry 1 below N, we are done. Otherwise program 0 reproduces the zero record of length N at every x, so it is selected, and its values must be 0 at all large x: the flag world is eventually 0, and α is all zero.

Selection gives Σ_2-LPO. Given R, let program 0 answer 0 at y within s steps once every row $y' \le y$ has a witness up to s, and let the other programs answer 0 at once. The method succeeds on the zero world from some length N. By the previous step, LPO decides each of the rows up to N. If one has no witness, that is the answer. Otherwise all have witnesses up to some S, program 0 reproduces the record of length N within S steps, and it is selected at every $x \ge S$; its value must then exist at all large x, so every row has a witness.

The oracle method. LPO buys it by Theorem 29.35(3). Conversely, let program 0 compute the flag world of α, the others the zero world, with the table saying that every program halts. The method names a program of the zero world from some length N. If α is 0 below N, program 0 is consistent and least at that record, so it computes the zero world, and α is all zero.

(3) Apply Σ_2-LPO to $R(y, s) = \alpha(s)$. □

Harrington's method thus costs Σ_2-LPO, the Σ_2 form of LPO. It implies LPO, the price of the halting-table method. Whether it is strictly stronger under this chapter's reading of maps is open; with countable choice LPO gives it, since LPO then decides every row and the answers can be collected, and under the default reading, which contains unique choice, LPO gives it as well (Theorem 29.53). Both prices imply LPO_T, the price on the layer of Section 29.9, where programs always halt. By Proposition 29.50, Σ_2-LPO is also the price of deciding finiteness of every run (Theorem 29.27(5)): the selection method and verdicts revised without a bound cost one principle.

Theorem 29.52 (Bounds on the methods are decision tables)**.**

1. *The selection method has a bound on every system of programs if and only if Σ_2 tables exist.*
2. *The oracle method has a bound on every system with a halting table if and only if Σ_1 tables exist.*
3. *Σ_2 tables give Σ_1 tables, and Σ_1 tables give LPO and $\mathrm{MP}_{\mathrm{bin}}$; so a bound for either method gives LPO and $\mathrm{MP}_{\mathrm{bin}}$.*

Each implication is proved with no choice principle.

Proof. Bounds give Σ_1 tables. Given R, take the system in which program 0 computes the zero world and program $r+1$ the flag world of row r, every program halting at once. Let F be a bound, for either method, and put $D(r) = 1$ when row r has a witness below $F(0) + F(r+1)$. If it has none, the zero world and the flag world of row r have the same record of that length, past both bounds, so one conjecture is right on both from some input on, as in Theorem 29.35(1), and row r has no witness at all. With Theorem 29.53(4) below, a bound for the selection method also gives Σ_2 tables.

Tables give bounds. For the oracle method, a Σ_1 table on the pairs (j, c) decides whether program j differs from program c somewhere, reading definedness through the halting table; let $F(c)$ exceed c and the first such place of every $j < c$ that differs. For the selection method, a Σ_2 table decides for $e < c$ whether e computes the world of c, and the Σ_1 table it contains, with the LPO that it gives, finds the first input up to which e fails to agree; let $F(c)$ exceed c and these inputs. In both cases the argument of Theorem 29.51 then runs from $F(c)$ on.

(3) A Σ_1 question is a Σ_2 question with an idle universal quantifier. A Σ_1 table for the family whose every row is α decides, at row 0, whether α has an entry 1: that is LPO, and LPO gives $\mathrm{MP}_{\mathrm{bin}}$. □

A decision table answers a whole family of questions at once and is data; LPO answers one question at a time. Without unique choice the two differ, and by exactly unique choice.

Theorem 29.53 (Decision tables and propositions differ by unique choice)**.** *Say that* unique choice holds for Σ_1 families *when every binary double sequence R whose rows are each decided, $\exists s\, R(r,s) = 1$ or not, has a map D with $D(r) = 1$ exactly when $R(r,s) = 1$ for some s; define it for Σ_2 families in the same way.* Boolean unique choice *says: if for every n exactly one bit b has $P(n,b)$, then some map f has $P(n, f(n))$ for every n.*

1. *Σ_1 tables exist if and only if LPO holds and unique choice holds for Σ_1 families.*
2. *Σ_2 tables exist if and only if Σ_2-LPO holds and unique choice holds for Σ_2 families.*
3. *Boolean unique choice gives unique choice for Σ_1 and for Σ_2 families.*
4. *Σ_1 tables give Σ_2-LPO, and Σ_1 tables exist if and only if Σ_2 tables do.*

The theorem uses no choice principle; parts 1 to 3 use no principle of any kind.

Conditions and scope.

Base and premises
The narrower reading of maps of Section 21.1, in which a map is a rule given as data.

Conclusion
A decision table is exactly its principle together with unique choice for the family; Σ_1 and Σ_2 tables are equivalent.

Not claimed
Any difference between tables and principles under the default reading of maps, which contains unique choice and makes them coincide.

Proof. (1) A Σ_1 table gives LPO by Theorem 29.52(3), and it is itself the map that unique choice asks for. Conversely, LPO decides every row, and unique choice collects the decided rows into a map. (2) is the same argument, with Σ_2-LPO obtained from the table as in (4). (3) For a decided row, the relation "$b = 1$ exactly when the row has a witness" holds of exactly one bit. (4) Given R, a Σ_1 table D on its rows and LPO applied to $y \mapsto 1 - D(y)$ show that every row has a witness or name a row y with $D(y) = 0$, which has none. For Σ_2 tables, a Σ_1 table on the pairs (r, y) gives $E(r, y) = 1$ exactly when row (r, y) has a witness, and a second Σ_1 table on "some y has $E(r, y) = 0$" gives the complement of the Σ_2 table. □

This is the separation that Theorem 16.27 exhibits in δ's calculus, where LPO decides each question but cannot collect the answers. Under the default reading of maps of this book, which contains unique choice (Appendix C and Section 21.1), the tables and the principles coincide: Σ_1 tables are LPO, and Σ_2 tables are Σ_2-LPO. The distinction is a statement about the narrower reading of Section 21.1.

Bounds for learners of computable laws

For the codes of Section 29.7, a *bound* for a learner M is a map F from codes to record lengths such that, whenever c computes ω and $n \geq F(c)$, the conjecture $M(\omega{\restriction}n)$ computes ω at all but finitely many inputs. A *halting table* is a map d with $d(c, k) = 1$ exactly when $\varphi_c(k)$ is defined, and a *totality table* a map T with $T(c) = 1$ exactly when $\varphi_c(k)$ is defined for every k. A *catalogue* is a sequence of worlds $W_0, W_1, \ldots$, and a locking function is as in Theorem 29.48.

Theorem 29.54 (Bounds on learners, and halting questions as the price)**.**

1. *Let W be any catalogue with an index z of the zero world and, for each i, an index $f(i)$ of the flag world of W_i, and let hypotheses be as in Theorem 29.35(1). If a learner has a map F such that from stage $F(i)$ on its conjectures compute W_i, then some map D has $D(i) = 1$ exactly when W_i has an entry* 1*. Hence, in classical mathematics, every learner that BC*-identifies every computable world with a bound given as a map on codes yields a halting table.*

2. *In classical mathematics, a map F on codes is the bound of some BC* learner of every computable world if and only if it* separates*: whenever codes c and c' compute worlds that agree below* $\max(F(c), F(c'))$*, those worlds agree from some input on. The implication from bound to separation holds for every system of hypotheses with no choice principle.*

3. *In classical mathematics, for every catalogue that is computable and has a locking function, a computable learner commits once correctly on every member of it, naming indices, by asking at each record of length n some $n+1$ halting questions fixed by n; neither the questions nor the learner read the locking function. And there is a computable catalogue of worlds of the layer of Section 29.9 that has a locking function given a halting table, on which no computable learner commits once correctly naming indices.*

Proof. (1) Put $D(i) = 1$ when W_i has an entry 1 below $F(z) + F(f(i))$. If it has none, the records of W_i's flag world and of the zero world agree up to that length, past both bounds, so one conjecture computes both from some input on, and W_i is all zero. For the instance, list as W the worlds that record when the computation of $\varphi_c(k)$ halts; its flag worlds and zero world are computable worlds with codes found from c and k, and D is a halting table. (2) If F is a bound and the worlds of c and c' agree below $\max(F(c), F(c'))$, the conjecture at that shared record computes both from some input on. Conversely, let F separate. At σ the learner names the least code c with $F(c) \leq |\sigma|$ that computes a world whose record of length $|\sigma|$ is σ, and 0 if there is none; classical mathematics allows this test. If c_0 computes ω and $n \geq F(c_0)$, then c_0 qualifies at $\omega{\restriction}n$, so the named code c_1 computes a world that agrees with ω below $n \geq \max(F(c_1), F(c_0))$, and separation makes the two agree from some input on. (3) The learner asks, for each place $\langle m, i\rangle \leq n$, whether the search for a member agreeing with W_i below m and differing later halts. Its answers tell, for each i, whether m locks W_i, and the learner commits to the first i that the record and a locking stage confirm. For the second statement, list for each code e the world that is 1 below e, and, when $\varphi_e(0)$ halts in exactly $s+1$ steps, the same world with one more entry 1 at $e+s+1$. A halting table bounds the steps and gives a locking function, while a computable learner committing once on every member would make non-halting a computably enumerable property, against Turing's theorem [21]. □

Theorem 29.54(2) says which maps are bounds but not what a bound costs. The cheapest costs exactly a halting table: every bound, of any learner, gives one back by a finite check, and a halting table builds a separating map, which is the bound of some learner.

Theorem 29.55 (The cheapest bound costs exactly a halting decision)**.** *Work in classical mathematics. The* halting trace *of code c at input k is the world $\tau_{c,k}$ with $\tau_{c,k}(s) = 1$ exactly when the computation of $\varphi_c(k)$ halts within s steps; codes* $\mathrm{tc}(c,k)$ *of these worlds exist.*

1. *Let d be a halting table. For codes $c' < c$, consider the search through the pairs (x, s) for the first at which $\varphi_c(x)$ and $\varphi_{c'}(x)$ have both returned within s steps with different values, returning x. Let $F(c)$ be 1 plus the largest input returned by these searches over the $c' < c$ for which d says the search halts. Then two worlds computed by codes c and c' that agree below $\max(F(c), F(c'))$ agree everywhere; in particular F separates.*

2. *Let F separate, let z be a code of the zero world, and let* tc *give codes of the halting traces. Then $\varphi_c(k)$ is defined if and only if $\tau_{c,k}(s) = 1$ for some $s < \max(F(z), F(\mathrm{tc}(c,k)))$.*

3. *Let W be a catalogue with $(i, x) \mapsto W_i(x)$ computable. The learner that names, at a record σ, the least place $i \leq |\sigma|$ whose world agrees with σ, and 0 if there is none, is computable. Given a halting table, let $b(k)$ be $k+1$ plus the largest first place of difference between W_i and W_k over the $i < k$ for which the table says that the search for such a place halts. On W_k, from stage $b(k)$ on, the learner names a place holding W_k.*

Once the searches and the table's answers are given, each argument uses no choice principle.

Proof. (1) Let c and c' compute ω and ω', which agree below $\max(F(c), F(c'))$. If $c = c'$ the worlds are equal. Otherwise let $c' < c$, say. Were the worlds to differ somewhere, the search for (c, c') would halt, both codes being defined everywhere; d would say so, and the search would return an input at which they differ and which lies below $F(c)$, against the agreement. So they differ nowhere, and since bits are decided, $\omega = \omega'$.

(2) If $\tau_{c,k}(s) = 1$ the computation halts. Conversely, let it halt within s_0 steps, so that $\tau_{c,k}(s) = 1$ for every $s \geq s_0$, and inspect the s below $m = \max(F(z), F(\mathrm{tc}(c, k)))$. If none has $\tau_{c,k}(s) = 1$, the trace agrees with the zero world below m, so the two agree from some input B on, and $\tau_{c,k}(\max(s_0, B))$ would be both 1 and 0.

(3) Agreement of W_i with a finite record is a finite computation, so the learner is computable. Let $n \geq b(k)$. Then $k \leq n$ and W_k agrees with its own record, so the least agreeing place is at most k. A place $i < k$ with $W_i \neq W_k$ makes the search halt, since both worlds are total, and their first difference lies below $b(k) \leq n$; so W_i does not agree with the record. The least agreeing place therefore holds W_k. □

With Theorem 29.54(2), a halting table builds the bound of some learner, of any kind, that BC*-identifies every computable world, and the bound of any such learner yields a halting table. Part 3 builds, in the same way from a halting table, a bound for a computable learner on catalogues of total worlds. A stronger demand on the bound, or a particular learner, can ask for more.

Theorem 29.56 (Stronger bounds carry a totality decision)**.** *Work in classical mathematics. A map F on codes is a* strong bound *when, whenever c computes ω, every code $e < c$ that reproduces ω at the inputs below $F(c)$ computes ω at all but finitely many inputs.*

1. *For each code p there are, found from p, a code $\mathrm{tr}(p)$ of the program that at input x waits until φ_p has halted at every input $y \leq x$ and then returns 0, and a code $\mathrm{za}(p) > \mathrm{tr}(p)$ of the zero world. If F is a strong bound and d a halting table, then φ_p is total if and only if $d(p, y) = 1$ for every $y < F(\mathrm{za}(p))$.*

2. *If F is a strong bound, then $c \mapsto \max(F(c), c + 1)$ is a bound for Harrington's learner of Theorem 29.36(4).*

3. *A totality table, together with $\mathrm{MP}_{\mathrm{bin}}$, yields a strong bound.*

4. *Fix a pairing of numbers, and let $\mathrm{col}_{p,j}$ be the world that is 1 exactly at the inputs whose first coordinate is the pair (p, j). The* trap (p, j) *is the program that at input x waits until φ_p has halted at every input $y \leq x$ and then returns $\mathrm{col}_{p,j}(x)$. List the programs in blocks $0, 1, 2, \ldots$, block p being program p followed by the traps (p, j) for $j < p + 2$. The* trap-first learner *conjectures at σ the program that at input x runs the first entry of blocks $0, \ldots, |\sigma|$ whose computation, run x steps, reproduces σ, and diverges if there is none. It is computable and BC*-identifies every computable world. If F is a bound for it and d a halting table, then φ_p is total if and only if $d(p, y) = 1$ for every $j < p + 2$ and every $y < F(w_{p,j})$, where $w_{p,j}$ is a code of $\mathrm{col}_{p,j}$ found from p and j.*

The construction of part 3 uses no choice principle once the table is given.

Proof. (1) If φ_p is total, $d(p, y) = 1$ for every y. Conversely, let $d(p, y) = 1$ for every $y < N = F(\mathrm{za}(p))$. Then φ_p halts at every $y < N$, so $\mathrm{tr}(p)$ returns 0 at every $x < N$ and reproduces the zero world below N. Since $\mathrm{tr}(p) < \mathrm{za}(p)$ and $\mathrm{za}(p)$ computes the zero world, $\mathrm{tr}(p)$ returns 0 at all large x. So φ_p halts at every $y \leq x$ for arbitrarily large x: it is total.

(2) Let c compute ω and $n \geq \max(F(c), c + 1)$. The code $c \leq n$ reproduces ω below n, so the least code $e \leq n$ that does is at most c; if $e < c$, it reproduces ω below $F(c)$, and by strength it computes ω at all but finitely many inputs. Every code below e is wrong or undefined at some recorded input and is never selected, while e is selected once x exceeds the steps it needs on the record. So the conjecture returns $\varphi_e(x) = \omega(x)$ at all large x.

(3) For codes e and c, let $A(e, c)$ say that $\varphi_e(y)$ and $\varphi_c(y)$ are defined and equal for every y, and $A_y(e, c)$ that they are at y. Each is a totality question, the second about a program that ignores its input, so the table decides them. If $A(e, c)$ fails, not every $A_y(e, c)$ holds, and $\mathrm{MP}_{\mathrm{bin}}$ gives a y at which $A_y(e, c)$ fails; let $y(e, c)$ be the least, and $y(e, c) = 0$ when $A(e, c)$ holds. Put $F(c) = \max_{e<c}(y(e, c) + 1)$. If c computes ω and $e < c$ reproduces ω below $F(c)$, then $A_y(e, c)$ holds at every $y < F(c)$, in particular at $y(e, c)$; so $A(e, c)$ holds, and e computes ω.

(4) The learner is computable because the list up to block $|\sigma|$ and the runs are finite computations. Fitting a record within x steps persists as x grows, so for a fixed record the selected entry is, for all large x, the first entry that fits within some number of steps. Let ω be computable; program c computing it heads block c. Let q be the first entry of the whole list that computes ω. Each earlier entry is wrong or undefined at some input; once the record contains these inputs and has length at least c, no earlier entry is selected and q is, at all large x. So every late conjecture computes ω at all large inputs.

For the totality test, the forward direction is clear. Conversely, let $d(p, y) = 1$ for all $j < p + 2$ and $y < F(w_{p,j})$. Two different column worlds differ at infinitely many inputs, so each of the $p + 1$ programs $0, \ldots, p$ computes, at all but finitely many inputs, at most one of the $p + 2$ worlds $\mathrm{col}_{p,j}$. Choose j such that none of them does so for $\mathrm{col}_{p,j}$, and let $n = F(w_{p,j})$ and σ the record of $\mathrm{col}_{p,j}$ of length n. The conjecture at σ computes $\mathrm{col}_{p,j}$ at all large inputs, so for all large x it runs one entry q of blocks $0, \ldots, n$, and q computes $\mathrm{col}_{p,j}$ at all but finitely many inputs. A trap of another pair computes another column or is undefined from some input on, so q is not one, and by the choice of j it is none of the programs $0, \ldots, p$. If $n < p$, every entry of blocks $0, \ldots, n$ is excluded, which is impossible; so $n \geq p$, and the trap (p, j) is in the list. Since φ_p halts at every input below n, the trap reproduces σ, so q is the trap or an earlier entry. The earlier entries are programs $0, \ldots, p$ and traps of other pairs, all excluded; so q is the trap (p, j). It is defined at all large inputs, so φ_p is total. □

Harrington's learner sits between the two prices. A bound for it is exactly a map past which the least code consistent with the record computes the world from some input on; it separates, and a strong bound raised above the code is one. A learner that differs from Harrington's only at records of a narrow kind has bounds worth exactly a totality table, given $\mathrm{MP}_{\mathrm{bin}}$, and the bounds of the trap-first learner, which runs Harrington's rule on another list, carry a totality decision. Whether Harrington's own bounds, in the standard order of codes, carry one is open.

29.11 How many revisions a catalogue forces

The catalogue of Theorem 29.48(4) needs one change of mind because every record of the zero world is also a record of a world with a late entry 1. This section turns that observation into an exact count for every catalogue, and prices one or two changes on catalogues built from the halting problem.

Definition 29.57 (Place learners and derived catalogues)**.** Let $W = (W_0, W_1, \ldots)$ be a catalogue of binary worlds, and write $W_i \neq W_{i'}$ when the two worlds differ at some input.

1. A *place learner* assigns a place $M(\sigma)$ to every finite binary record. It *identifies* ω when some j with $W_j = \omega$ and some N give $M(\omega{\restriction}n) = j$ for every $n \geq N$. It *changes its mind at* m on ω when $M(\omega{\restriction}(m+1)) \neq M(\omega{\restriction}m)$. It *learns* W *with at most* k *changes* when it identifies every W_i and changes its mind at no more than k stages on each.

2. The *derived catalogues* are sets of places: D^0 holds every place, and $i \in D^{j+1}$ when $i \in D^j$ and, for every N, some $i' \in D^j$ with $W_{i'} \neq W_i$ agrees with W_i below N.

3. The *halting catalogue* H uses a pairing $\langle a, b\rangle$ of numbers. Place $\langle e, 0\rangle$ holds the *header world* A_e, which is 1 below e and 0 from e on. Place $\langle e, s+1\rangle$ holds A_e with one more entry 1, at $e + s + 1$, when $\varphi_e(0)$ halts in exactly $s+1$ steps, and A_e otherwise.

By induction on j, places with the same world lie in the same derived catalogues, and $D^{j+1} \subseteq D^j$. For the catalogue of the opening paragraph, D^1 holds the places of the zero world, since the world with its only 1 at N agrees with it below N; a world with its only 1 at n is not in D^1, since only that world agrees with it below $n+1$; and D^2 is empty. The halting catalogue is the one of Theorem 29.54(3).

Theorem 29.58 (Revision bounds are read off derived catalogues)**.** *Let W be a catalogue and k a number.*

1. *Some place learner learns W with at most k changes if and only if D^{k+1} is empty and all places in D^k hold one world.*

2. *Let each W_i be a world of the layer of Section 29.9, given with a program P_i computing it. Then some learner on the layer EX-identifies every W_i while changing its mind at most k times on each if and only if D^{k+1} is empty and all places in D^k hold one world.*

3. *The halting catalogue has D^1 empty. So some place learner learns it with at most one change, and none with no change.*

In parts 1 and 2, the implication from a learner to the condition on the derived catalogues is proved with no choice principle; the converse, which builds the learner, and part 3 are proved in classical mathematics.

Conditions and scope.

Base and premises

Any catalogue of binary worlds; learners of any kind that name places, or, in part 2, programs of the layer, read as in Section 29.9.

Conclusion

The fewest changes of mind that suffice for a catalogue, when some number does, is the least k with D^{k+1} empty and D^k holding one world: how deeply the candidate laws accumulate on one another.

Not claimed

That the learner built in the proof is computable; membership in a derived catalogue is not decided by a record.

Proof. The adversary. Let M identify every W_i. Suppose $a \in D^{j+1}$ and M changes its mind on W_a at the stages of a finite set S, all below n. Let M name t on W_a from stage N on, and take $a' \in D^j$ with $W_{a'} \neq W_a$ that agrees with W_a below $N + n$. On $W_{a'}$ the records up to length $N+n$ are those of W_a, so M changes its mind at the stages of S and names t at stage $N+n$. From some stage it names a place t' holding $W_{a'}$, and $t' \neq t$ because the two places hold different worlds. So M changes its mind at some stage at or after $N + n$, a stage not in S. One step thus passes from a place of D^{j+1} to a place of D^j and adds a change; j steps from a place of D^j add j changes.

From a learner to the condition. Let M learn W with at most k changes. A place in D^{k+1}, with S empty, would give $k + 1$ changes on one world. If two places i, i' of D^k held worlds that differ at some input, the place M names on the empty record would hold at most one of them, say not W_i; then M changes its mind on W_i before it settles, and k steps from i give $k + 1$ changes. Each case split compares numbers or bits. For part 2 the same argument runs with programs in place of places: programs of the layer are finite trees, so whether two are equal is decided, and two programs computing different worlds differ.

From the condition to a learner. At a record σ, let its *level* be the largest $j \leq k$ for which some place of D^j holds a world extending σ, and call σ *unambiguous* when all such places of that level hold one world. The learner names the least such place at an unambiguous record, and otherwise what it named at the record one shorter (place 0 at an ambiguous empty record); in part 2 it names that place's program. Along a world of W the level never rises, since a world extending a record extends its shorter records; while the level stays, an unambiguous record stays unambiguous with the same least place. So the potential, the level plus 1 at an ambiguous record, never rises, and it falls at every change of mind. At the empty record it is at most k: the level is at most k, and at level k the record is unambiguous because D^k holds one world. Hence at most k changes.

For identification, let r be the largest j with $i \in D^j$; it is at most k, since D^{k+1} is empty. As $i \notin D^{r+1}$, some N makes every place of D^r whose world agrees with W_i below N hold W_i. From stage N on, a place of a higher level extending the record would lie in D^r, hold W_i, and put i into D^{r+1}; so the level is r, the record is unambiguous, and the learner names the least place of D^r holding W_i, from then on.

(3) A world of H agreeing with A_e below $e+1$ has header e. Of these, at most one differs from A_e, the one with its extra 1 at $e+s+1$ for the s with $\varphi_e(0)$ halting in exactly $s+1$ steps, and agreement below $e+s+2$ excludes it. That world, in turn, is the only world of H that agrees with it below $e+s+2$. So no place is in D^1. Part 1 with $k=1$ gives the learner; with $k=0$ it would need all places to hold one world, but $A_0 \neq A_1$. □

For a computable learner on the halting catalogue the count is two, and a halting table buys back one.

Theorem 29.59 (One change on the halting catalogue costs a halting decision)**.** *Work in classical mathematics.*

1. *A computable place learner learns the halting catalogue with at most two changes.*
2. *A halting table yields a place learner that learns it with at most one change.*
3. *No computable place learner learns it with at most one change.*
4. *Let a place learner learn the halting catalogue with at most one change, let the place it names at the empty record not hold A_e, and let it name a place holding A_e at the record of A_e of length n. Then $\varphi_e(0)$ is defined if and only if it halts within fewer than n steps.*
5. *Let W be a catalogue with $(i,x) \mapsto W_i(x)$ computable. If some place learner learns W with at most one change, then there are computable maps Q, giving a finite list of codes for each record, and L such that, for every halting table d, the learner that names $L(\sigma, b)$, where b lists the answers $d(c,0)$ for the codes c in $Q(\sigma)$, learns W with at most one change.*

The counting in parts 4 and 5 uses no choice principle.

Proof. (1) Name place 0 until the record shows an entry 0. With the first 0 at e, name $\langle e, 0\rangle$; once an entry 1 appears at some $p > e$, name $\langle e, p-e\rangle$. An extra 1 at p occurs only in the world of $\langle e, p-e\rangle$, so the last place named holds the world, and the learner names at most three places in turn.

(2) With the table, find for each e the number k_e of steps in which $\varphi_e(0)$ halts exactly, and $k_e = 0$ if it does not halt. Name place 0 until the record shows its first 0, at e, and its entry at $e+k_e$; then name $\langle e, k_e\rangle$ if that entry is 1 and $\langle e, 0\rangle$ if it is 0. An extra 1 can sit only at $e+k_e$, so the place is right, and it is named after at most one change.

(4) If $\varphi_e(0)$ halts within fewer than n steps, it halts. Conversely, let it halt in exactly $k \geq n$ steps. The world of $\langle e, k\rangle$ has its extra 1 at $e+k \geq n$, so its record of length n is that of A_e. On it the learner has left its opening place by stage n, which is one change, and it names a place holding A_e; it must end at a place holding the world of $\langle e, k\rangle$, a second change, which the bound forbids. So $\varphi_e(0)$ halts in fewer than n steps.

(3) Let the learner be computable and j_0 its place at the empty record; at most one header world is held by j_0. Whether a place holds A_e is decided by running $\varphi_{e'}(0)$ for at most $s+1$ steps, for place $\langle e', s+1\rangle$. For every other e, part 4 and the convergence of the learner on A_e give: $\varphi_e(0)$ diverges if and only if some n has the learner naming a place holding A_e at the

record of length n while $\varphi_e(0)$ has not halted within n steps. That makes divergence on input 0 a property that a computable search confirms, for all codes but one; with halting also so confirmed, halting would be decided, against Turing's theorem [21].

(5) Let M be the given learner and j_0 the place it names at the empty record. Every place i with $W_i \neq W_{j_0}$ has a *locking length* m: every place agreeing with W_i below m holds W_i. Indeed, let M name t on W_i from stage m on; $t \neq j_0$, since $W_t = W_i \neq W_{j_0}$. A place agreeing with W_i below m has the same record of length m, so M names t there after one change, and it cannot change again; it ends at t, and the world is $W_t = W_i$. For a pair $\langle m, i\rangle$, the search for a place agreeing with W_i below m and differing from it somewhere is a program found from m and i; it fails to halt exactly when m locks W_i. Let $Q(\sigma)$ list these programs for the pairs up to $|\sigma|$, and let L name i for the least pair $\langle m, i\rangle \leq |\sigma|$ such that W_i agrees with σ below m and the answer is "does not halt", and j_0 if there is none. A pair that qualifies keeps qualifying as the record grows, and later pairs are larger, so the learner names j_0 and then one place. If a pair $\langle m, i\rangle$ qualifies on W_{i_0}, then W_{i_0} agrees with W_i below m, so $W_{i_0} = W_i$. If none ever qualifies, then $W_{i_0} = W_{j_0}$, since otherwise W_{i_0} has a locking length m and the pair $\langle m, i_0\rangle$ qualifies. □

A second level of the same construction moves the price from halting to totality.

Theorem 29.60 (Running times and revision counts)**.** *Work in classical mathematics. Let $L_{e,k}$ be A_e with one more entry* 1*, at $e+1+k$, and $P_{e,k,s}$ be $L_{e,k}$ with one more entry* 1*, at $e+2+k+s$. The catalogue C holds at place $\langle e, 0\rangle$ the world A_e; at $\langle e, \langle k, 0\rangle+1\rangle$ the world $L_{e,k}$; and at $\langle e, \langle k, s+1\rangle+1\rangle$ the world $P_{e,k,s}$ when, within s steps, φ_e has halted at every input below k and not at k, and $L_{e,k}$ otherwise.*

1. *A computable place learner learns C with at most three changes.*
2. *Some place learner learns C with at most two changes, and none with at most one.*
3. *Let a place learner learn C with at most two changes, let the place it names at the empty record not hold A_e, and let it name a place holding A_e at the record of A_e of length n. Then φ_e is total if and only if it is defined at every input below n.*

The counting in part 3 uses no choice principle.

Proof. (1) Name place 0 until an entry 0 appears, at e; then $\langle e, 0\rangle$; once an entry 1 appears at some $p_1 > e$, the place $\langle e, \langle p_1 - e - 1, 0\rangle + 1\rangle$ of a line; once a further 1 appears at some $p_2 > p_1$, the place $\langle e, \langle p_1 - e - 1, p_2 - p_1\rangle + 1\rangle$ of a point. A second 1 past the header occurs only in a point, and a point is a member only when its condition holds, so the last place named holds the world; at most four places are named in turn.

(2) Every header world is in D^1, since $L_{e,k}$ agrees with A_e below $e + 1 + k$. No point is: a world agreeing with $P_{e,k,s}$ below $e + 3 + k + s$ is that point. A line $L_{e,k}$ is in D^1 only when its point condition holds for arbitrarily large s, that is, when φ_e halts at every input below k and never at k; this happens for at most one k, since for $k < k'$ the condition for k' makes φ_e halt at k. So each header has at most one line in D^1. Then D^2 is empty. Among the worlds held in D^1, a line $L_{e,k}$ is the only one agreeing with it below $e + 2 + k$, and A_e is the only one agreeing with A_e below $e + 2 + k$, for its line $L_{e,k}$ in D^1, or below $e + 1$ if it has none. Theorem 29.58(1)

with $k = 2$ gives the learner; with $k = 1$ it would need the header worlds $A_0 \neq A_1$ of D^1 to coincide.

(3) If φ_e is total, it is defined below n. Conversely, let it be defined below n but not everywhere, and let $y_0 \geq n$ be the least input at which it is undefined. For all large s, within s steps φ_e has halted below y_0 and not at y_0. The line $L = L_{e,y_0}$ agrees with A_e below n, so on L the learner has left its opening place by stage n and names a place holding A_e; from some stage $N \geq n$ on it names a place holding $L \neq A_e$, so it changes its mind a second time in between. Take s large with $e + 2 + y_0 + s \geq N$. The point $P_{e,y_0,s}$ is a member that agrees with L below N, so on it the learner makes both changes and then a third, to a place holding the point. □

Only $\langle e, 0\rangle$ holds A_e, and the opening place holds at most one header world; so a learner of C with two changes, with a halting table, decides by a finite check which programs halt on every input. For the catalogue $C_2(\mathbf{t}_0)$ of Section 29.12, which is C with each input read as a coded list, a halting table alone does not buy two changes, even for learners that choose each question from the answers so far; the answers to "does some row of φ_e never halt?" do (Theorem 29.68). The read-offs in Theorems 29.59(4) and 29.60(3) are two cases of one fact about every catalogue.

Theorem 29.61 (Committing early certifies the deep laws)**.** *Let W be a catalogue and k a number, and let a place learner learn W with at most $k + 1$ changes. Let the place it names at the empty record not hold W_a, and let it name a place holding W_a at the record of W_a of length n. Then every $b \in D^k$ with $W_b \neq W_a$ has $W_b(x) \neq W_a(x)$ for some $x < n$. The theorem is free.*

Proof. Comparing the entries below n one at a time, W_b and W_a differ below n or agree below n. If they agree, then on W_b, whose records up to length n are those of W_a, the learner leaves its opening place before stage n and names a place holding $W_a \neq W_b$ at stage n; it ends at a place holding W_b, a second change. The adversary in the proof of Theorem 29.58, applied k times from $b \in D^k$, then gives a world with $k + 2$ changes, more than $k + 1$. □

With $k = 2$, a catalogue one level deeper than C reads off a question one quantifier higher.

Theorem 29.62 (Three revisions on running times read off a third-level question)**.** *Work in classical mathematics. Row y of φ_e is* total *when φ_e halts at every input $\langle y, j\rangle$. With A_e and $L_{e,y}$ as in Theorem 29.60, let $S_{e,y,m}$ be $L_{e,y}$ with one more entry* 1*, at $e+2+y+m$, and $P_{e,y,m,s}$ be $S_{e,y,m}$ with one more entry* 1*, at $e+3+y+m+s$. The catalogue C_3 holds at $\langle e, 0\rangle$ the world A_e; at $\langle e, \langle y, 0\rangle + 1\rangle$ the world $L_{e,y}$; at $\langle e, \langle y, \langle m, 0\rangle + 1\rangle + 1\rangle$ the world $S_{e,y,m}$; and at $\langle e, \langle y, \langle m, s + 1\rangle + 1\rangle + 1\rangle$ the world $P_{e,y,m,s}$ when the condition $c(e, y, m, s)$ holds, and $S_{e,y,m}$ otherwise: within s steps, φ_e has halted at every input $\langle y, j\rangle$ with $j \leq m$, and for every $y' < y$ some $j \leq m$ has φ_e not halted at $\langle y', j\rangle$.*

1. *A computable place learner learns C_3 with at most four changes.*
2. *Some place learner learns C_3 with at most three changes, and none with at most two.*
3. *If row y of φ_e is total and no row $y' < y$ is, then $L_{e,y} \in D^2$.*
4. *Let a place learner learn C_3 with at most three changes, let the place it names at the empty record not hold A_e, and let it name a place holding A_e at the record of A_e of length n. Then no row of φ_e is total if and only if no row $y < n$ is.*

Conditions and scope.

Base and premises

The catalogue C_3, built from the running times of programs on rows of inputs; place learners of any kind, computable in part 1; classical mathematics. Reading computable learners as native ones is the identification of Section 29.7.

Conclusion

Four changes computably; three, not two, for some learner; a three-change learner's commitment to A_e bounds the search for a total row.

Not claimed here

That "no row of φ_e is total" is complete at the third level for the coding of this theorem. For the coded rows of Section 29.12 the decided question is complete at every level (Theorem 29.66), and no learner computable from a table of the row answers, listed or adaptive, manages three changes on $C_3(\mathbf{t}_1)$ (Theorem 29.68).

Proof. (1) Name place 0 until an entry 0 appears, at e; then $\langle e, 0\rangle$; at an entry 1 at some $p_1 > e$, the place of $L_{e,y}$ with $y = p_1 - e - 1$; at a further 1 at $p_2 > p_1$, the place of $S_{e,y,m}$ with $m = p_2 - p_1 - 1$; at a further 1 at $p_3 > p_2$, the place of $P_{e,y,m,s}$ with $s = p_3 - p_2 - 1$. A third 1 past the header occurs only in a point $P_{e,y,m,s}$, a member only when $c(e, y, m, s)$ holds, so the last place named holds the world, after at most four changes.

(2) Every world is 1 below its header e and 0 at e. Header worlds and lines lie in D^1: $L_{e,N}$ agrees with A_e below N, and $S_{e,y,N}$ with $L_{e,y}$. No point does, since a world agreeing with $P_{e,y,m,s}$ below $e + 4 + y + m + s$ is that point. The members agreeing with $S_{e,y,m}$ below $e + 3 + y + m$ are $S_{e,y,m}$ and its points, so $S_{e,y,m} \in D^1$ only when $c(e, y, m, s)$ holds for arbitrarily large s. Hence every A_e lies in D^2; no $S_{e,y,m}$ does; and $L_{e,y} \in D^2$ only when, for arbitrarily large m, $c(e, y, m, s)$ holds for arbitrarily large s. Two rows $y_1 < y_2$ cannot both have this property: take such an m for y_2, then $m_1 \geq m$ and s_1 with $c(e, y_1, m_1, s_1)$, then $s \geq s_1$ with $c(e, y_2, m, s)$; the last gives $j \leq m$ with φ_e not halted at $\langle y_1, j\rangle$ within $s \geq s_1$ steps, against the second. So D^2 holds the header worlds and at most one line per header. A line $L_{e,y}$ in D^2 is the only world of D^2 agreeing with it below $e + 2 + y$, and A_e the only one agreeing with A_e below $e + 2 + y$, for its line $L_{e,y}$ in D^2, or below $e + 1$. So D^3 is empty, and Theorem 29.58(1) with $k = 3$ gives the learner; with $k = 2$ it would need $A_0 \neq A_1$, both in D^2, to coincide.

(3) $L_{e,y} \in D^1$. Each row $y' < y$ has an input $\langle y', d_{y'}\rangle$ at which φ_e never halts; let M_0 exceed every $d_{y'}$. For $m \geq M_0$, φ_e halts at the inputs $\langle y, j\rangle$ with $j \leq m$ within some number of steps, and from there on $c(e, y, m, s)$ holds; so the points $P_{e,y,m,s}$ put $S_{e,y,m}$ in D^1, and S_{e,y,M_0+N} differs from $L_{e,y}$ and agrees with it below N.

(4) If no row is total, none below n is. Conversely, let some row be total and y_0 the least. By part 3, $L_{e,y_0} \in D^2$, and it differs from A_e only at $e + 1 + y_0$. Theorem 29.61 with $k = 2$ gives $e + 1 + y_0 < n$, so row $y_0 < n$ is total. □

"No row of φ_e is total" has three alternating quantifiers: every y has a j at which, for every s, φ_e has not halted within s steps. As only $\langle e, 0\rangle$ holds A_e, a learner of C_3 with three changes and a table of the total rows decide it by a finite check, for every e but one.

Definition 29.63 (Sums and nested sums)**.** A *test* b assigns 0 or 1 to every finite list of numbers; b_u is b with u put in front of each list, and $[u]$ is the list with the single entry u. The *shift* $\mathrm{sh}_u w$ of a world w is 0 below u, 1 at u, and $w(z-u-1)$ at $z>u$. Given catalogues K_u and a set E of enabled parts, the *sum* holds the zero world, its *head*, at place 0, and at place $\langle u,i\rangle+1$ the shift sh_u of the world at place i of K_u if $u\in E$, and the zero world otherwise. The *nested sums*: $G_0(b)$ holds only the zero world, and $G_{j+1}(b)$ is the sum of the $K_u=G_j(b_u)$, with every part enabled when $j\geq 1$ and the parts u with $b([u])=1$ when $j=0$. $\mathrm{IO}^0(b)$ says that b gives 1 on the empty list, and $\mathrm{IO}^{j+1}(b)$ that for every N some $u\geq N$ has $\mathrm{IO}^j(b_u)$. For $k\geq 2$ and a family $\mathbf{b}=(b^{(x)})_x$ of tests, the catalogue $C_k(\mathbf{b})$ holds at place $\langle x,i\rangle$ the world that is 1 below x, 0 at x, and from $x+1$ on the world at place i of $G_k(b^{(x)})$.

So $\mathrm{IO}^1(b)$ says $b([u])=1$ for arbitrarily large u, IO^j has $2j$ alternating quantifiers, and places $\langle x,0\rangle$ and $\langle x,\langle y,0\rangle+1\rangle$ of $C_k(\mathbf{b})$ hold A_x and $L_{x,y}$.

Theorem 29.64 (Catalogues of every depth)**.** *Let b be a test and $\mathbf{b}=(b^{(x)})_x$ a family of tests.*

1. *For every j, no place of $G_j(b)$ lies in D^{j+1}, and every place of $G_j(b)$ in D^j holds the zero world. The head of $G_{j+1}(b)$ lies in D^j, and it lies in D^{j+1} if and only if $\mathrm{IO}^{j+1}(b)$.*
2. *Let $k\geq 2$. In $C_k(\mathbf{b})$, D^{k+1} is empty, so some place learner learns it with at most $k+1$ changes; every A_x lies in D^{k-1}, so none learns it with at most $k-1$; and $L_{x,y}\in D^{k-1}$ if and only if $\mathrm{IO}^{k-1}(b^{(x)}_y)$. With at most one such y for each x, some place learner manages k changes.*
3. *Let a place learner learn $C_k(\mathbf{b})$ with at most k changes, let the place it names at the empty record not hold A_x, and let it name a place holding A_x at the record of A_x of length n. Then no y has $\mathrm{IO}^{k-1}(b^{(x)}_y)$ if and only if no $y<n$ does.*

Part 1 is free; parts 2 and 3 are proved in classical mathematics.

Proof. (1) In a sum, a world of an enabled part u is 0 below u and 1 at u; the zero world is 0 at u, and a world of part $u'\neq u$ differs from it at the smaller of u,u'. So a member agreeing with a world of part u up to u lies in part u, and two worlds of part u agree below $u+1+N$, or differ, exactly when the worlds of K_u they shift do. By induction on r, for enabled u, place $\langle u,i\rangle+1$ lies in D^r of the sum exactly when place i lies in $D^r(K_u)$ (part transfer). A member agreeing with the zero world below N and differing from it lies in an enabled part $u\geq N$, and every such member agrees with it below u. By part transfer, the head lies in D^{r+1} exactly when it lies in D^r and for every N some enabled $u\geq N$ has a place of $D^r(K_u)$.

Now induct on j. $G_0(b)$ holds one world. In $G_{j+1}(b)$, a place of an enabled part in D^{j+1} would give by part transfer a place of $G_j(b_u)$ in D^{j+1}; so the places in D^{j+1} hold the zero world, and none lies in D^{j+2}. Next, the head of $G_{j+1}(b)$ lies in D^r for $r\leq j$, by induction on j and then r: for $r+1\leq j$ every part is enabled, and the head of $G_j(b_u)$ lies in D^r, for every u. Last, by the head criterion, the head of $G_{j+1}(b)$ lies in D^{j+1} exactly when for every N some enabled $u\geq N$ has a place of $G_j(b_u)$ in D^j. For $j=0$ this says $b([u])=1$ for arbitrarily large u, which is $\mathrm{IO}^1(b)$. For $j\geq 1$ such a place holds the zero world, as the head does, so it may be taken to be the head, and by induction the condition reads $\mathrm{IO}^j(b_u)$ for arbitrarily large u, which is $\mathrm{IO}^{j+1}(b)$.

(2) Worlds of different columns differ at the smaller index, so columns transfer like parts: place $\langle x, i\rangle$ lies in $D^r(C_k(\mathbf{b}))$ exactly when place i lies in $D^r(G_k(b^{(x)}))$. Part 1 then gives D^{k+1} empty and $A_x \in D^{k-1}$; and as part y of $G_k(b^{(x)})$ is enabled, $L_{x,y} \in D^{k-1}$ exactly when the head of $G_{k-1}(b_y^{(x)})$ lies in D^{k-1}, which is $\mathrm{IO}^{k-1}(b_y^{(x)})$. Theorem 29.58(1) gives the learner with $k+1$ changes, and excludes $k-1$ as $A_0 \neq A_1$ both lie in D^{k-1}. Under the uniqueness condition D^k is empty: a place of D^k in column x holds A_x (part 1), so $A_x \in D^k$, which is $\mathrm{IO}^k(b^{(x)})$ and gives two values of y. Theorem 29.58(1) with k gives the learner. (3) If $\mathrm{IO}^{k-1}(b_y^{(x)})$, then $L_{x,y} \in D^{k-1}$ differs from A_x only at $x+1+y$, and Theorem 29.61 with $k-1$ gives $y < n$. □

So for every $r \geq 1$, r changes are too few on $C_{r+1}(\mathbf{b})$ and $r+2$ suffice. Section 29.12 answers the two questions this raises: the tests built from the rows of programs make the question of part 3 complete at every level, and one computable learner manages $k+1$ changes on every $C_k(\mathbf{b})$ (Theorems 29.66 and 29.67).

So, in this half of the chapter: identifying one of two laws costs $\mathrm{MP}_{\mathrm{bin}}$ or LPO; learning a layer whose programs always halt costs LPO for its own sequences; a method that must survive programs that run forever costs Σ_2-LPO, which also prices what verdicts revised without a bound confirm; a guarantee of when a learner is right costs a decision table: for some learner of every computable law exactly a halting table, for the trap-first learner a decision of which programs halt on every input. The changes of mind a catalogue forces on learners of any kind are read off its derived catalogues; computable learners can need more; and a learner held to few changes commits only after every deep rival has differed.

29.12 Catalogues at every level of the arithmetical hierarchy

Theorem 29.64 built, for every family $\mathbf{b}$ of tests, a catalogue $C_k(\mathbf{b})$ that needs at least k changes of mind and admits $k+1$, and read off from every learner with k changes the answer to a question with $2k-2$ alternating quantifiers. Three questions were left: which tests make that question as hard as its quantifiers allow, whether a computable learner manages $k+1$ changes, and what information a learner needs for k. This section answers all three for the tests built from programs. The answer is exact: a learner computable from an oracle joined with the row table manages the least number of changes exactly when the joined oracle computes one decided question of the arithmetical hierarchy. All results of the section are proved in classical mathematics, as in Section 29.11; programs are those of Section 29.7, with φ_e the function computed by program e.

Definition 29.65 (Row questions, decided questions and their tests)**.** Code finite lists of numbers by $\ulcorner[\,]\urcorner = 0$ and $\ulcorner a :: l\urcorner = \langle a, \ulcorner l\urcorner\rangle + 1$. For a program e, a list l and $n \geq 0$ put

$$R_0(e,l) \;:\; \varphi_e(\ulcorner l\urcorner) \text{ never halts}, \qquad R_{n+1}(e,l) \;:\; \forall m\, \neg R_n(e, m :: l).$$

The *row question* $R_n(e,y)$ is $R_n(e,[y])$, a Π_{n+1} question about row y of φ_e; $R_1(e,y)$ says that φ_e halts at every input $\ulcorner[m,y]\urcorner$. The *decided question* at level n is $\mathrm{Dc}_n(e) \;:\; \forall y \neg R_n(e,y)$, a Π_{n+2} question, and $U_n(e)$ is its negation, "some row of φ_e satisfies R_n". The bounded form $R_n(e,l;u_1,\dots,u_{n+1})$ replaces each quantifier, from the outside in, by one bounded by u_i, the

innermost bound being a number of steps; it is decided by running programs. The *test* $t_n(e)$ holds of a list that begins with $y, u_1, \dots, u_{n+1}$ when row y satisfies the bounded form with these bounds and no row $y' < y$ does, and fails on every list with fewer than $n+2$ entries. The catalogue $C_{n+2}(\mathbf{t}_n)$ is the catalogue of Definition 29.63 for the family $\mathbf{t}_n = (t_n(x))_x$.

Row questions are complete, at every level

Theorem 29.66 (The row questions and the hierarchy)**.**

1. Limits. *For all n, e and y, $\mathrm{IO}^{n+1}(t_n(e)_y)$ holds exactly when y is the first row of φ_e with $R_n(e, y)$.*

2. Completeness. *Call a question $P(x)$ Σ_{k+1}* in normal form *when it reads*

$$\exists m_1 \, \neg \exists m_2 \, \neg \cdots \exists s \; R(x, \dots),$$

with $k+1$ quantifiers over a computable Boolean matrix R. For every n and every computable matrix R there is a computable f with $\neg R_n(f(x), y)$ exactly when the Σ_{n+1} normal form of R holds at (x, y). Hence every Π_{n+2} question in normal form is Dc_n at a computable program.

3. Normal forms. *At every level the questions in normal form contain the decidable ones and are closed under substitution of a computable map, conjunction, disjunction, an existential quantifier, a bounded universal quantifier with a computable bound, and passage to the next level; and a Σ_{k+2} question is exactly $\exists m \, \neg Q(\langle x, m \rangle)$ for a Σ_{k+1} question Q.*

4. Every formula. *Let an arithmetical formula be built from computable Boolean atoms by negation, conjunction, disjunction and the two quantifiers, and classified by its shape as Σ_{k+1} or Π_{k+1}. A Σ_{k+1} formula, and the negation of a Π_{k+1} formula, are Σ_{k+1} in normal form; every Π_{n+2} formula is $\mathrm{Dc}_n(f(x))$ for a computable f; and Dc_n is itself a Π_{n+2} formula with computable atoms.*

5. The hierarchy. *There is a computable h such that program $h(x)$ runs program x on input x and then runs the program it returns. For every n and every such computable h, the question $\mathrm{Dc}_n(h(x))$ is not Σ_{n+2} in normal form. Similarly, "program x halts on every input $\langle x, m \rangle$" is not Σ_2 in normal form.*

6. Neither enumerable. *For every n, neither the set of e with $\mathrm{Dc}_n(e)$ nor its complement is computably enumerable.*

Proof. (1) Induct on n. Running longer never undoes a halt, so "not halted within s steps" is antitone in s, and it holds for arbitrarily large s exactly when the program never halts: this is the case $n = 0$ for one row. At each level the bounded form of row y is antitone in the outer bound, and "no row $y' < y$ satisfies the bounded form" is monotone in it. For such a pair the conjunction $A(u) \wedge B(u)$ holds for arbitrarily large u exactly when A holds for every u and B for some u. Applied level by level, this turns "infinitely often, $n+1$ times over" into the unbounded alternating question for row y and its failure for every earlier row.

(2) Let program $f(x)$, on input $\ulcorner l \urcorner$, search for an s with $R(x, s :: l)$ true and halt when it finds one; f is computable by the parameter theorem [19]. Then $\neg R_0(f(x), l)$ holds exactly when

some s has $R(x, s{:}:l)$, and by induction on n, $\neg R_n(f(x), l)$ holds exactly when the Σ_{n+1} normal form of R holds at x and l: both sides add the alternation $\exists m\,\neg$ in front. For the last sentence, a Π_{n+2} question in normal form is the negation of $\exists y \neg \Sigma_{n+1}$, which is $\neg\exists y\, R_n(f(x), y)$, that is, $\mathrm{Dc}_n(f(x))$.

(3) and (4) are induction on the level and on the formula. Conjunction and disjunction interleave the witnesses of the two normal forms by pairing, an existential is absorbed into the outermost one by pairing, and a bounded universal is moved inside by collecting the finitely many witnesses into one number, which the computable bound permits. Each step produces a computable matrix from the given ones.

(5) The program $h(x)$ exists by composition of programs. Suppose $\mathrm{Dc}_n(h(x))$ held exactly when a Σ_{n+2} normal form $S(x)$ does. By (2) there is a computable g with $\mathrm{Dc}_n(g(x))$ exactly when $\neg S(x)$. By the recursion theorem [19] some program c returns $g(c)$ on input c. Then $h(c)$ runs $g(c)$, so it computes the same function, and $\mathrm{Dc}_n(h(c))$ holds exactly when $\mathrm{Dc}_n(g(c))$ does, that is, exactly when $\neg S(c)$, that is, exactly when $\neg\mathrm{Dc}_n(h(c))$. That is impossible: Kleene's diagonal argument, at every level. The last sentence of (5) is the same argument at $n = 0$ with another program: if "program x halts on every input $\langle x, m\rangle$" held exactly when a Σ_2 normal form $S(x)$ does, take g from (2) with $\mathrm{Dc}_0(g(x))$ exactly when $\neg S(x)$, and by the recursion theorem a program c that on every input $\langle z, m\rangle$ runs $g(c)$ on $\ulcorner[m]\urcorner$. Then c halts on every input $\langle c, m\rangle$ exactly when $g(c)$ halts on every $\ulcorner[m]\urcorner$, that is, exactly when $\mathrm{Dc}_0(g(c))$, that is, exactly when $\neg S(c)$.

(6) A computably enumerable set is Σ_1 in normal form, and the complement of one is Π_1, which is Σ_2 in normal form; by (3) both are Σ_{n+2} in normal form. So if the set of e with $\mathrm{Dc}_n(e)$, or its complement, were enumerable, Dc_n would be Σ_{n+2} in normal form, and so would $\mathrm{Dc}_n(h(x))$ by substitution, against (5). □

The catalogue of each level

Theorem 29.67 (The construction at every level)**.** *Let $n \geq 0$.*

1. *Some place learner learns $C_{n+2}(\mathbf{t}_n)$ with at most $n + 2$ changes, and none with at most $n + 1$.*
2. *Let a place learner learn $C_{n+2}(\mathbf{t}_n)$ with at most $n + 2$ changes, let the place it names at the empty record not hold A_e, and let it name a place holding A_e at the record of A_e of length N. Then $\mathrm{Dc}_n(e)$ holds exactly when no row $y < N$ of φ_e satisfies R_n.*
3. One computable learner for every catalogue. *Let* lrn *name place* 0 *until the record shows an entry* 0*, and from then on the place $\langle x, \ulcorner g\urcorner\rangle$, where x is the position of the first* 0 *and g lists the gaps between the entries* 1 *seen after it. Then* lrn *is computable, and for every k and every family $\mathbf{b}$ of tests it learns every member of $C_k(\mathbf{b})$ with at most $k + 1$ changes.*

Proof. (1) and (2). By Theorem 29.66(1), at most one y has $\mathrm{IO}^{n+1}(t_n(x)_y)$ for each x: the first row with R_n. So Theorem 29.64(2) gives a learner with $n + 2$ changes and excludes $n + 1$, and Theorem 29.64(3) gives the read-off, since some y has $\mathrm{IO}^{n+1}(t_n(e)_y)$ exactly when some row satisfies R_n.

(3) A world of $C_k(\mathbf{b})$ is 1 below its column x, 0 at x, and from $x + 1$ on a nested shift: each level of the nested sum puts one entry 1 at the start of its part, so the world after the header

is determined by the gaps between its entries 1, and there are at most k of them. The place $\langle x, \ulcorner g \urcorner \rangle$ is a place of that world once all its entries 1 have appeared. Along a world the learner moves from place 0 once, at the header, and once at each further entry 1: at most $k+1$ changes. The rule reads a finite record, so it is computable. □

Part 3 settles the second question left after Theorem 29.64: computable learners do manage $k+1$ changes, on every catalogue of that kind. Part 2 says what $n+2$ changes know: a commitment to the header world A_e at stage N answers the Π_{n+2} question $\mathrm{Dc}_n(e)$ by a check of the rows below N. By Theorem 29.66(5) that question is not Σ_{n+2}, and this is what makes learners with $n+2$ changes expensive.

What a learner needs for the least number of changes

A learner *computable from an oracle O*, a map from numbers to bits, is given by one procedure that reads the record and a finite prefix of O, answers or not, answers on every long enough prefix, and never answers wrongly. A learner *asking a table* asks at each record a computable list of questions chosen from the record alone and names a place computed from the record and the answers; an *adaptive* learner chooses each question from the record and the answers so far, by an oracle machine whose run ends on every record. The *row table* at level n answers every row question $R_n(e, y)$; the *decided answers* U_n answer $U_n(e)$ for every e.

Theorem 29.68 (The least number of changes costs the decided question)**.** *Let $n \geq 0$, and let learning mean learning every member of $C_{n+2}(\mathbf{t}_n)$ with at most $n+2$ changes.*

1. Computable learners fail. *No computable place learner learns $C_2(\mathbf{t}_0)$ with at most two changes, and none computable learns $C_{n+2}(\mathbf{t}_n)$ at any level.*
2. The row table does not suffice. *No learner asking the row table at level n, and no adaptive learner with the row table, learns $C_{n+2}(\mathbf{t}_n)$.*
3. The decided answers suffice. *There are computable rules such that the learner asking the decided answers U_n learns $C_{n+2}(\mathbf{t}_n)$; it suffices to give it the row table and, at each record, the one decided answer about the record's column. At level two the learner that asks U_0 at its column and the row answers below the record's length learns $C_2(\mathbf{t}_0)$.*
4. Exactly. *For every oracle T, joined with the row table, some learner computable from the joined oracle learns $C_{n+2}(\mathbf{t}_n)$ if and only if U_n is computable from it. One procedure, given one bit, the learner's first guess, a program e, the learner's places on the records of A_e and the row answers of e, decides $U_n(e)$ for every learner with $n+2$ changes.*
5. Prefixes are oracle machines. *A function is computable from an oracle through finite prefixes, as above, exactly when an oracle machine that asks one value at a time computes it.*

Conditions and scope.

Base and premises

The catalogues $C_{n+2}(\mathbf{t}_n)$ of Definition 29.65; learners computable, asking a table, adaptive, or computable from an oracle; classical mathematics.

Conclusion

Among learners computable from an oracle joined with the row table, the least number of changes, $n + 2$, is bought exactly by the joined oracles that compute the Σ_{n+2} question U_n: the decided question, not the row questions below it.

Not claimed

The same for a bare oracle, not joined with the row table (Remark 29.70).

Proof. Lower bounds. Let M learn with $n + 2$ changes. For every program e except at most one (the column of the place named at the empty record), Theorem 29.67(2) gives: $\mathrm{Dc}_n(e)$ holds exactly when there is an N at which M names a place holding A_e on the record of A_e of length N and no row $y < N$ satisfies R_n. Whether a place holds A_e is decided, since only $\langle e, 0\rangle$ holds it. If M is computable, the condition is Σ_{n+2} in normal form by Theorem 29.66(3): an existential over N of a computable check and a bounded universal over Π_{n+1} failures. If M asks the row table, or adaptively uses it, its answers are Π_{n+1} and their negations Σ_{n+1}, and writing "these answers are the true ones" into the condition keeps it Σ_{n+2}. Either way Dc_n would be Σ_{n+2} at all programs but one, hence at the composed programs $h(x)$ after a finite patch, against Theorem 29.66(5).

Upper bounds. By Theorem 29.66(1) and Theorem 29.64, column x has a line in D^{n+1} exactly when some row of φ_x satisfies R_n, and then it is the line of the first such row. The learner of Theorem 29.58(1) with $k = n + 2$ needs, at a record of column x, only this information. With the decided answer $U_n(x)$ it knows whether the line exists: if not, it names A_x at once; if so, it keeps its opening place until the row answers show the first row with R_n and the record has passed that row, and from then on it follows the worlds of the column as the learner of Theorem 29.67(3) does, with one change saved at the header. Its questions and its place are computable from the record and the answers, and the potential argument of Theorem 29.58 bounds its changes by $n + 2$.

Exactness. If U_n is computable from the oracle, the upper-bound learner is. Conversely, given a learner computable from the oracle, the lower-bound condition, now read with the oracle, decides $U_n(e)$ by a search that ends: wait until the learner names A_e on the record of A_e and the row answers below that stage are in. The single exceptional column is handled by one built-in bit, the answer at the column of the first guess; that bit is why the procedure is uniform in everything except one bit.

(5) A prefix procedure is simulated by a machine that asks for the next value whenever the procedure has not answered on the prefix so far; conversely a machine's run asks finitely many values, which a long enough prefix contains. □

A column's own rows are not enough above level two

At level two the learner of Theorem 29.68(3) asks only about the program of the record's own column. From level three on that fails, even with the decided answer at the column.

Theorem 29.69 (Own rows at levels three, four and five)**.** *For $n = 1, 2, 3$, consider learners that receive at each record the decided answer U_n about the record's column and row answers R_n about the program of that column only: either a computable list of rows chosen from the record (*listed*), or rows chosen one at a time from the record and the answers so far by a computable oracle machine whose run ends on every record (*adaptive*). No such learner, listed or adaptive, learns $C_{n+2}(\mathbf{t}_n)$ with at most $n + 2$ changes. Moreover, for $n = 1, 2, 3$, a learner that, on every record showing an entry 0 whose column's program has no row with R_n, names a value of a fixed partial computable function at that record does not learn $C_{n+2}(\mathbf{t}_n)$ with at most $n + 2$ changes.*

Proof. We give the argument at level three for listed learners; the other cases change it as described at the end. Fix the rules of a learner of the stated kind, and let M' be the computable map that names, at a record, the place the learner would name if every answer it receives were "no". By the recursion theorem [19] build a program x that, on the input $\ulcorner[m, y]\urcorner$, searches for the least stage $N_0 > x$ at which M' names the place of A_x on the record of A_x; then, if $y = N_0 - x - 1$, searches for the least stage N_1 at which M' names the place of the line $L_{x,y}$ on the record of that line; and halts exactly when $m \leq N_1 - (x + 2 + y)$. Every row of x halts on at most finitely many inputs, so no row satisfies R_1: the true decided answer at column x and every true row answer about x are "no", and on the records of column x the learner acts as M'. Two such programs that differ at the input 0 exist, and one of them is not the column of the place the learner names at the empty record; take x to be that one.

Suppose the learner learns $C_3(\mathbf{t}_1)$ with three changes. To learn A_x it names its place from some stage on, so the search for N_0 ends; to learn the line $L_{x,y}$ with $y = N_0 - x - 1$ it names that line's place from some stage on, and the search for N_1 ends. The point world of that line whose next entry 1 comes after N_1 is a member, so the learner leaves the line's place at some stage $N_2 > N_1$; and a full world of column x whose last entry 1 comes after N_2 is a member too, because row y halts below the bound and the earlier rows never halt. On that world the learner changes its mind in $[0, N_0)$, in $[N_0, N_1)$, in $[N_1, N_2)$ and after N_2: four changes.

An adaptive learner is handled in the same way: every question it asks is about a row of x, the answer is "no", and its run on all-"no" answers is a computable map M'.

At level four the program x is built one quantifier higher. On the input $\ulcorner[m_2, m_1, y]\urcorner$ it runs the two searches of level three, each bounded by m_2: for the least stage $N_0 > x$ at which M' names the place of A_x on the record of A_x, and, if $y = N_0 - x - 1$, for the least stage N_1 at which M' names the place of the line $L_{x,y}$ on the record of that line. It fails to halt exactly when both stages are found, $N_1 \leq m_2$ and $m_1 \leq N_1$, and halts otherwise; with the searches bounded, this is decided by running M'. Every row y has an m_1, any $m_1 > N_1$, or any m_1 at all when the stages do not exist, at which every input $\ulcorner[m_2, m_1, y]\urcorner$ halts; so no row satisfies R_2, the true answers about x are all "no", and on the records of column x the learner acts as M'. Suppose it learns $C_4(\mathbf{t}_2)$ with four changes. Then N_0 and N_1 exist, as at level three. The point world of the line whose second entry 1 comes at N_1 is a member, so the learner leaves the line's place for that world's place at some stage $N_2 > N_1$; the world of the next kind whose third gap is N_2 is a member, so it leaves that place at some stage $N_3 > N_2$; and the full world of column x whose fourth entry 1 comes after N_3, far enough for every row below y to have halted at the inputs the test reads, is a member too, because row y fails to halt at the inputs $\ulcorner[m_2, m_1, y]\urcorner$ with $m_1 \leq N_1 \leq m_2$. On it the learner changes its mind in $[0, N_0)$, in $[N_0, N_1)$, in $[N_1, N_2)$, in $[N_2, N_3)$ and after N_3: five changes. At level five the program is

built one quantifier higher again, with one more search and one more world, so that no row satisfies R_3. For a learner that agrees, on the columns without a row satisfying R_n, with a fixed partial computable function, take M' to be that function: the searches of x run it, and they end because the learner, which equals it there, must name the places in question. □

Learner on $C_{n+2}(\mathbf{t}_n)$	With at most $n+2$ changes
any place learner	yes; $n+1$ changes never (Theorem 29.67)
computable	no, at every level; $n+3$ changes yes (Theorem 29.67(3))
asking the row table, listed or adaptive	no, at every level
asking the decided answers U_n	yes, at every level
row table and one decided answer per record	yes, at every level
computable from an oracle joined with the row table	exactly when U_n is computable from the joined oracle
own column's rows and its decided answer	yes at $n = 0$; no at $n = 1, 2, 3$, listed or adaptive

Table 29.3. What buys the least number of changes on the catalogue of level $n+2$ (Theorems 29.67, 29.68 and 29.69). All entries are proved in classical mathematics.

Remark 29.70 (What is not settled)**.** Theorem 29.69 is proved at the levels $n = 1, 2, 3$; at $n \geq 4$ the statement for own rows is not proved here. The read-off of Theorem 29.68(4) uses one built-in bit, so the reduction from a learner to U_n is not uniform in the learner. And part (4) is proved for oracles joined with the row table. For a bare oracle O the lower-bound argument still needs the row answers below the stage at which the learner commits, so it shows only that U_n is computable from O joined with the row table; whether every bare oracle from which some learner with $n+2$ changes is computable must itself compute U_n is not settled here.

Questions to work through

1. In the history $H(\alpha)$ of Definition 29.3, let α have its first entry 1 at 3. At which stages are p_0, $\neg p_0$ and $\neg\neg p_0$ forced? Use the answer to explain why em fails at stage 0 while wem holds there for this α (Theorem 29.4).

2. Let P be the law of three binary records that gives probability $\frac{1}{3}$ to each record with exactly one entry 1. Compute P_2 and the coin mixture Q_2, and check the bound of Theorem 29.8 for $n = 3$, $m = 2$.

3. Write the first 21 entries of the golden record and list its windows of length 3. How many are there, and which window of length 2 is right special (Theorems 29.14 and 29.15)?

4. Let H consist of the four laws on the points $0, 1, 2, 3$ whose labels are 1 at exactly one point. Compute $\mathrm{ldim}(H)$, run the standard optimal learner on the target that is 1 at 3, with the points in the order $0, 1, 2, 3$, and compare with the halving learner (Theorems 29.29 and 29.31).

5. For the records $1, 4$ with unit weights, find the J-centre, the least cost, and the regret of the learner that starts at $f_0 = 1$ and follows the centre; check the identity of Theorem 29.39(4).

6. For each world ω of the layer with a single entry 1, Theorem 29.47(3) gives a learner that commits once correctly on the zero world and on ω. Show that no single learner does so for all of them at once, and that the catalogue of these worlds has no locking function (Theorems 29.47 and 29.48).

Chapter 30

Conjectures and refutations

Chapter 21 showed that, at zero holding, two golden comparisons in a row never change a record with certainty. With the reference action set to one cycle, a comparison at ratio x drives the register by $2\pi J(x)$, and a golden comparison drives $2\pi J(\varphi) = 2\pi(\varphi - \frac{3}{2}) \approx 0.742$. Two of them drive $2\pi\varphi^{-3} \approx 1.483$, short of the quarter turn $\pi/2 \approx 1.571$ that every change with certainty needs when the register does not hold. Do three?

Work it out on one channel of Recognition Science's register, a channel with eight states. Its native operations rotate three states at a time, a *triad* e_i, e_j, e_7, about the axis $e_i + e_j + e_7$. A rotation by one third of a turn is the exact cycle $e_i \mapsto e_j \mapsto e_7 \mapsto e_i$, and it moves e_i to e_j with certainty. Three golden comparisons drive ≈ 2.225, more than $2\pi/3 \approx 2.094$, and they can spend it exactly. The inequality $J(\varphi) \geq \frac{1}{9}$ says $\varphi \geq \frac{29}{18}$, and that holds because

$$\left(\frac{29}{18}\right)^2 - \frac{29}{18} = \frac{319}{324} < 1 = \varphi^2 - \varphi,$$

while $t^2 - t$ increases for $t > \frac{1}{2}$. So each golden comparison can carry a rotation by $2\pi/9$ about one triad's axis and idle for the rest of its drive, and three of them compose to the cycle. At zero holding, three golden comparisons change a record with certainty; two never do; one never does (Theorem 30.21).

The example has the shape of every result in this chapter: a question about recognition, ledgers or certain change with a definite answer, settled by a proof. Each statement below has one of four outcomes. It is *proved.* It is *refuted*: we prove its negation, give the counterexample and prove the corrected statement. It is *reduced*: we prove that it is equivalent to a sharper statement that we name exactly and cannot yet settle. Or it is *open.* Section 30.5 lists every open statement.

The chapter is organised by theme. Section 30.1 asks how well readings at golden ratios fix the calibration of a recorded phase: the answer is the Diophantine type of φ^{-3}, and adding probes leads to classical open problems of simultaneous approximation. Section 30.2 finds when two recognizers of one history agree on a common count, and what it costs in memory to tell records apart. Section 30.3 classifies the long-run rates of self-similar double-entry ledgers and decides when they keep balanced books. Section 30.4 prices a change with certainty on the native register: exactly $2\pi/3$ for one channel, $\pi/2$ per channel when a low-bit flip suffices, π for two channels at once, floors under every holding, and the phases that a returned helper can deliver.

Everything in this chapter is proved in classical mathematics, over the classical real and complex numbers. We claim no price on $\mathbb{R}_\delta$ for any of it; several statements are about counts and finite words, but we prove them classically and claim nothing more. Two readings are identifications and stay separate from what is proved: that a recorded phase equals a calibration times J of the ratio, and that the tokens below are the operations of Recognition Science's register. Two proofs end in finite computations in exact rational arithmetic. Lemma 30.23

rests on eight checks of positive definiteness whose data Table 30.2 prints, so a reader can repeat them. The exact range in Theorem 30.18 rests on an exhaustive search over 1573 cases, which its proof describes step by step but does not print; its scope box records this. Numerical exploration appears only outside the numbered results, in the text and in the open problems; we label it as evidence, and no result depends on it.

30.1 Calibrating a phase with golden probes

A recognition at ratio $x > 0$ leaves a record whose phase, relative to a reference, is $a\,J(x)$ for an unknown *calibration* $a > 0$. Recognition Science reads a as the ratio of the reference action to $\hbar$; that reading is an identification, and the theorems below use only the form $aJ(x)$. A phase is read through its cosine and sine, so it is known only modulo 2π, and the calibration is ambiguous: at the ratio φ^2, where $J(\varphi^2) = \frac{1}{2}$, the calibrations a and $a + 4\pi k$ give the same phase for every integer k. A second reading at a ratio x separates the two by $4\pi k J(x)$ modulo 2π. At $x = \varphi$ that separation is $2\pi k(\sqrt{5} - 2)$, because $2J(\varphi) = 2\varphi - 3 = \varphi^{-3} = \sqrt{5} - 2$, and it is never close to a multiple of 2π for small k. How precisely, then, do two golden readings fix the calibration?

Definition 30.1 (Readings and consistent calibrations)**.** In classical mathematics: a *quadrature reading* at a ratio $x > 0$ is a triple of reals (c, s, ε), estimates of a cosine and a sine with error ε. A phase Δ is *consistent* with it when $|\cos\Delta - c| \le \varepsilon$ and $|\sin\Delta - s| \le \varepsilon$. A calibration $a > 0$ is consistent with a reading at x when the phase $aJ(x)$ is. For a real t, $\|t\|$ is its distance to the nearest integer.

Lemma 30.2 (Two phases in one reading)**.** *If the phases α and β are both consistent with one reading of error ε, then $|\alpha - \beta - 2\pi k| \le 6\varepsilon$ for some integer k.*

Proof. Each coordinate of $e^{i\alpha} - e^{i\beta}$ is at most 2ε in absolute value, so $|e^{i\alpha} - e^{i\beta}| \le 2\sqrt{2}\,\varepsilon$. Choose k with $t = \alpha - \beta - 2\pi k \in [-\pi, \pi]$. Then $|e^{i\alpha} - e^{i\beta}| = 2|\sin(t/2)| \ge 2|t|/\pi$, because sin is concave on $[0, \pi/2]$. Hence $|t| \le \sqrt{2}\,\pi\varepsilon \le 6\varepsilon$. □

The number $\varphi^{-3} = \sqrt{5} - 2$ is a quadratic irrational. Its continued fraction is $[0; 4, 4, 4, \ldots]$, since $\sqrt{5} - 2 = 1/(4 + (\sqrt{5} - 2))$, and a real number whose partial quotients are bounded is *badly approximable*: $\|k\alpha\| \ge c/|k|$ for some $c > 0$ and every integer $k \ne 0$ [83]. Hurwitz's theorem shows that for every irrational α such a constant is at most $1/\sqrt{5}$ [82]. We need one explicit constant.

Lemma 30.3 (φ^{-3} is badly approximable)**.** *For all integers $k \ne 0$ and m,*

$$1 \le 6|k|\,\big|k(\sqrt{5} - 2) - m\big|.$$

Proof. Put $M = m + 2k$, so $k(\sqrt{5} - 2) - m = k\sqrt{5} - M$. The integer $5k^2 - M^2$ is not 0, since $\sqrt{5}$ is irrational, so $|k\sqrt{5} - M| \cdot |k\sqrt{5} + M| = |5k^2 - M^2| \ge 1$. If $|k\sqrt{5} - M| \ge 1$ the claim is clear. Otherwise $|M| < \sqrt{5}|k| + 1$, so $|k\sqrt{5} + M| < 2\sqrt{5}|k| + 1 < 6|k|$, and $|k\sqrt{5} - M| > 1/(6|k|)$. □

Theorem 30.4 (Two golden probes fix a calibration with exponent exactly 2)**.** *In classical mathematics: let $B \geq 1$, let $a, b \in (0, B]$, and let r_1 and r_2 be readings at the ratios φ and φ^2, with errors ε_1 and ε_2. If both calibrations a and b are consistent with both readings, then*

$$|a - b| \leq 12\,(1 + B)^2\,(\varepsilon_1 + \varepsilon_2).$$

Moreover, for every real p the following are equivalent:

(i) there is $C > 0$ such that $|a - b| \leq C(1 + B)^p(\varepsilon_1 + \varepsilon_2)$ for all $B \geq 1$, all $a, b \in (0, B]$ and all readings r_1 at φ and r_2 at φ^2 with which both a and b are consistent;

(ii) $p \geq 2$.

Proof. The bound. Lemma 30.2 at r_2, where the phases are $a/2$ and $b/2$, gives an integer k with $\frac{a-b}{2} = 2\pi k + e_2$ and $|e_2| \leq 6\varepsilon_2$. At r_1 the phases are $a(\sqrt{5} - 2)/2$ and $b(\sqrt{5} - 2)/2$, whose difference is $(\sqrt{5} - 2)(2\pi k + e_2)$; the lemma gives an integer m with

$$2\pi\big|k(\sqrt{5} - 2) - m\big| \leq 6\varepsilon_1 + 6(\sqrt{5} - 2)\varepsilon_2 \leq 6(\varepsilon_1 + \varepsilon_2).$$

Note $|a - b| < B$. If $\varepsilon_1 + \varepsilon_2 \geq B/12$, then $|a - b| < 12(\varepsilon_1 + \varepsilon_2)$. Otherwise $12\varepsilon_2 < B$. If $k = 0$, then $|a - b| = 2|e_2| \leq 12\varepsilon_2$. If $k \neq 0$, Lemma 30.3 gives $1 \leq 6|k| \cdot 6(\varepsilon_1 + \varepsilon_2)/(2\pi)$, so $\varepsilon_1 + \varepsilon_2 \geq \pi/(18|k|)$; and $4\pi|k| \leq |a-b| + 2|e_2| < 2B$, so $|k| < B/(2\pi)$ and $\varepsilon_1 + \varepsilon_2 > \pi^2/(9B) > 1/B$. Then $|a - b| < B < B^2(\varepsilon_1 + \varepsilon_2) \leq (1 + B)^2(\varepsilon_1 + \varepsilon_2)$. In every case the bound holds.

(ii) implies (i). Take $C = 12$; for $p \geq 2$, $(1 + B)^p \geq (1 + B)^2$.

(i) implies (ii). Let $p < 2$ and suppose C works. By Dirichlet's theorem [81], for every $N \geq 1$ there are integers $1 \leq k \leq N$ and m with $|k(\sqrt{5} - 2) - m| \leq 1/(N + 1)$, and Lemma 30.3 forces $k \geq (N + 1)/6$. Put $a = 1 + 4\pi k$, $b = 1$ and $B = a$. The phases at φ^2 differ by $2\pi k$, so the exact reading $(\cos\frac{a}{2}, \sin\frac{a}{2}, 0)$ is consistent with both. The phases at φ differ by $2\pi k(\sqrt{5}-2) = 2\pi m + \delta$ with $|\delta| \leq 2\pi/(N+1)$; the reading centred halfway, at $b(\sqrt{5}-2)/2 + \delta/2$, with error $\varepsilon_1 = |\delta|/2 \leq \pi/(N + 1) < \pi/k$ (as $k \leq N$), is consistent with both, because cos and sin are 1-Lipschitz. Then (i) gives

$$4\pi k \leq C(2 + 4\pi k)^p\,\frac{\pi}{k}, \qquad \text{so} \qquad 4k^2 \leq C\,(15k)^{\max(p,0)},$$

using $2 + 4\pi k \leq 15k$. As N grows, $k \geq (N + 1)/6$ grows without bound, and $2 - \max(p, 0) > 0$: a contradiction. □

Conditions and scope.

Base and premises

Classical real numbers; readings and consistency as in Definition 30.1; the phase form $aJ(x)$ at the two ratios φ and φ^2.

Conclusion

Two calibrations that both fit golden readings of errors $\varepsilon_1, \varepsilon_2$ differ by at most $12(1+B)^2(\varepsilon_1 + \varepsilon_2)$, and no exponent below 2 works for any constant.

Identification
That a recorded relative phase is $aJ(x)$, with a the reference action over $\hbar$, is the admissible phase law of Recognition Science, used as stated. No value of a is supplied.

Not claimed
That the golden pair is the best pair of probes; the proof uses only the Diophantine type of φ^{-3}, and other quadratic probes are not treated.

So the reading precision a calibration range B needs scales as B^{-2}: one factor of B comes from the size of the ambiguity, the other from how close $k\varphi^{-3}$ can come to an integer for $|k| \le B$. The exponent is the Diophantine exponent of φ^{-3}.

A third probe can only help, and the question is by how much. Add a reading r_3 at the ratio $\sqrt{2}$, where $J(\sqrt{2}) = \frac{3\sqrt{2}}{4} - 1$; the alias $a + 4\pi k$ now also turns by $2\pi k \cdot \frac{3\sqrt{2}}{2}$ modulo 2π. A wrong branch hides exactly as well as $k(\sqrt{5}-2)$ and $k \cdot \frac{3\sqrt{2}}{2}$ are simultaneously close to integers.

Theorem 30.5 (A third probe and simultaneous approximation)**.** *In classical mathematics, put $\alpha = \sqrt{5}-2$ and $\beta = \frac{3\sqrt{2}}{2}$, and consider three readings r_1, r_2, r_3 at the ratios φ, φ^2 and $\sqrt{2}$, with errors $\varepsilon_1, \varepsilon_2, \varepsilon_3$. For a real p, say that p* works *if some $C > 0$ gives $|a-b| \le C(1+B)^p(\varepsilon_1+\varepsilon_2+\varepsilon_3)$ for all $B \ge 1$, all $a, b \in (0, B]$ and all such readings with which both a and b are consistent.*

(a) No $p < \frac{3}{2}$ works.

(b) The following are equivalent: (i) a real p works exactly when $p \ge \frac{3}{2}$; (ii) the pair (α, β) is simultaneously badly approximable*: there is $c > 0$ with*

$$\sqrt{|k|}\,\max\big(|k\alpha - m|,\ |k\beta - n|\big) \ge c \qquad \text{for all integers } k \ne 0,\ m,\ n.$$

Proof. (a) Let $p < \frac{3}{2}$ and suppose C works. For $Q \ge 1$ the Q^2+1 points $(\{k\alpha\}, \{k\beta\})$, $0 \le k \le Q^2$, of the unit square lie in Q^2 boxes of side $1/Q$; two share a box, and their difference gives $1 \le k \le Q^2$ and integers m, n with $|k\alpha - m| \le 1/Q$ and $|k\beta - n| \le 1/Q$. For fixed k this cannot hold for all large Q, since $k\alpha \notin \mathbb{Z}$; so $k \to \infty$ as $Q \to \infty$. Put $a = 1 + 4\pi k$, $b = 1$, $B = a$. The phases differ by $2\pi k$ at φ^2, by $2\pi k\alpha$ at φ, and by $4\pi k J(\sqrt{2}) = 2\pi k\beta - 4\pi k$ at $\sqrt{2}$. As in the proof of Theorem 30.4, readings centred halfway have $\varepsilon_2 = 0$ and $\varepsilon_1, \varepsilon_3 \le \pi/Q \le \pi/\sqrt{k}$. So $4\pi k \le C(15k)^{\max(p,0)} \cdot 2\pi/\sqrt{k}$, that is $2k^{3/2-\max(p,0)} \le C\,15^{\max(p,0)}$, which fails for large k.

(b) *(ii) implies (i).* By (a) it suffices to show that $C = 12 + 1/c$ works for $p \ge \frac{3}{2}$. Lemma 30.2 at r_2 gives $\frac{a-b}{2} = 2\pi k + e_2$ with $|e_2| \le 6\varepsilon_2$. At r_1 the phase difference is $2\pi k\alpha + \alpha e_2$ and at r_3 it is $2\pi k\beta - 4\pi k + (\frac{3\sqrt{2}}{2} - 2)e_2$; the lemma gives integers m, n with

$$2\pi|k\alpha - m| \le 6\varepsilon_1 + 6\alpha\varepsilon_2, \qquad 2\pi|k\beta - n| \le 6\varepsilon_3 + 6\big(\tfrac{3\sqrt{2}}{2} - 2\big)\varepsilon_2.$$

Both coefficients α and $\frac{3\sqrt{2}}{2} - 2$ lie in $(0, 1)$, so with $E = \varepsilon_1+\varepsilon_2+\varepsilon_3$ we get $\max(|k\alpha - m|, |k\beta - n|) \le 6E/(2\pi) < E$. If $E \ge B/12$, then $|a-b| < B \le 12E$. Otherwise $12\varepsilon_2 \le B$; if $k = 0$, $|a-b| \le 12\varepsilon_2$; if $k \ne 0$, then $|k| < B/(2\pi) < B$ as before, and (ii) gives $E > c/\sqrt{|k|} > c/\sqrt{B}$, so $|a-b| < B = B^{3/2}/\sqrt{B} < B^{3/2}E/c$. In each case $|a-b| \le (12 + 1/c)(1+B)^p E$.

(i) implies (ii). We show that $c = 1/(30C)$ satisfies (ii) when C works at $p = \frac{3}{2}$. Let $k \neq 0$, m and n be integers. Replacing (k, m, n) by $(-k, -m, -n)$ we may take $k > 0$, and it suffices to treat the integers m^*, n^* nearest to $k\alpha$ and $k\beta$. With $a = 1 + 4\pi k$, $b = 1$, $B = a$ and readings centred halfway, $\varepsilon_2 = 0$, $\varepsilon_1 = \pi|k\alpha - m^*|$ and $\varepsilon_3 = \pi|k\beta - n^*|$. The bound gives $4\pi k \leq C(2+4\pi k)^{3/2} \cdot 2\pi \max(|k\alpha - m^*|, |k\beta - n^*|)$, and $2 + 4\pi k \leq 15k$, so $\sqrt{k}\max(|k\alpha - m^*|, |k\beta - n^*|) \geq 2/(15^{3/2}C) > 1/(30C)$. $\square$

Both numbers are badly approximable on their own, being quadratic irrationals; the question is whether one k can bring both close to integers at once. The two numbers come from different quadratic fields, and we know no proof that the pair is simultaneously badly approximable; it is Problem 5 of Section 30.5. Schmidt's theorem on simultaneous approximation to algebraic numbers [84] gives $\max(\|k\alpha\|, \|k\beta\|) \geq c_\eta |k|^{-1/2-\eta}$ for every $\eta > 0$, since $1, \alpha, \beta$ are linearly independent over $\mathbb{Q}$; the argument above then makes every exponent $p > \frac{3}{2}$ work. Only the endpoint is open.

Can a better pair of probes do more? Fix the reference probe φ^2. The calibrations a and $a + 4\pi q$ agree there, and a probe at ratio x turns them apart by $4\pi q J(x)$. A pair of probes separates the remote aliases well when, for every large q, one of the two turns is far from a multiple of 2π.

Definition 30.6 (Separation score and the simultaneous approximation constant)**.** In classical mathematics: for $x > 0$ and $q \in \mathbb{N}$ let $\chi_q(x) = (\cos(4\pi q J(x)) - 1)^2 + \sin^2(4\pi q J(x))$, the squared chord between the two phase points of the alias q at the probe x. The *separation score* of probes $x, y > 0$ is

$$\mathrm{sc}(x, y) = \liminf_{q \to \infty} \frac{q}{4} \max\big(\chi_q(x), \chi_q(y)\big).$$

For real α, β, the *simultaneous approximation constant* is

$$S(\alpha, \beta) = \liminf_{q \to \infty} q \max\big(\|q\alpha\|^2, \|q\beta\|^2\big).$$

Adams proved that the supremum of $S(\alpha, \beta)$ over all pairs for which $1, \alpha, \beta$ is a basis of a real cubic field is $\frac{2}{7}$ [78]. Cusick studied the constant for real cubic fields and conjectured that $\frac{2}{7}$ bounds it for every real pair [79]; the supremum over all real pairs is not known.

Theorem 30.7 (Probe pairs and the constant $\frac{2}{7}$)**.** *In classical mathematics:*

(a) $\mathrm{sc}(x, y) = \pi^2 \, S\big(2J(x), 2J(y)\big)$ *for all* $x, y > 0$*;*

(b) the gain $x \mapsto 2J(x)$ *maps* $(1, \varphi^2)$ *bijectively onto* $(0, 1)$*, with inverse*

$$\alpha \mapsto \frac{1}{2}\big(2 + \alpha + \sqrt{\alpha(4 + \alpha)}\big);$$

(c) $\mathrm{sc}(x, y) \leq \pi^2$*;*

(d) some $x, y \in (1, \varphi^2)$ *have* $\mathrm{sc}(x, y) > 2\pi^2/7$ *if and only if some real* α, β *have* $S(\alpha, \beta) > \frac{2}{7}$*.*

Proof. (a) Put $\alpha = 2J(x)$ and $\beta = 2J(y)$. Since $(\cos\theta - 1)^2 + \sin^2\theta = 4\sin^2(\theta/2)$ and $\theta = 2\pi q\alpha$, $\frac{q}{4}\chi_q(x) = q\sin^2(\pi q\alpha)$. For every real t, $4\|t\|^2 \le \sin^2(\pi t) \le \pi^2\|t\|^2$, and the ratio $\sin^2(\pi t)/\|t\|^2$ tends to π^2 as $\|t\| \to 0$; moreover $\sin^2(\pi t)$ increases with $\|t\|$. Write $T_q = q\max(\|q\alpha\|^2, \|q\beta\|^2)$ and $T_q' = q\max(\sin^2(\pi q\alpha), \sin^2(\pi q\beta))$, so $4T_q \le T_q' \le \pi^2 T_q$. By the box argument in the proof of Theorem 30.5(a), with an irrational gain in place of $\sqrt{5}-2$, $T_q \le 1$ for infinitely many q; if both gains are rational, $T_q = 0$ infinitely often. So both lower limits are finite. Along any sequence of q on which T_q or T_q' stays bounded, both $\|q\alpha\|$ and $\|q\beta\|$ tend to 0, so $T_q' = (\pi^2 + o(1))\,T_q$. Taking sequences that realise each lower limit gives $\liminf T_q' = \pi^2 \liminf T_q$.

(b) $2J(x) = x + x^{-1} - 2$ increases on $(1,\infty)$, vanishes at 1, and equals 1 at φ^2 because $\varphi^2 + \varphi^{-2} = 3$. Solving $x^2 - (2+\alpha)x + 1 = 0$ for the root above 1 gives the inverse.

(c) $\liminf T_q \le 1$, as in (a).

(d) If x, y exist, (a) gives the pair $2J(x), 2J(y)$. Conversely, S does not change when α or β changes by an integer. If α is an integer, then $S(\alpha,\beta) = \liminf q\|q\beta\|^2 = 0$: for irrational β, Dirichlet's theorem gives infinitely many q with $q\|q\beta\|^2 \le 1/q$, and for rational β, $\|q\beta\| = 0$ infinitely often. So a pair with $S > \frac{2}{7}$ has fractional parts in $(0,1)$, and (b) turns them into probes in $(1,\varphi^2)$ whose score is $\pi^2 S > 2\pi^2/7$ by (a). □

Conditions and scope.

Base and premises

Classical real numbers; the score and the constant of Definition 30.6; the reference probe φ^2 with $J(\varphi^2) = \frac{1}{2}$.

Conclusion

Separating remote aliases with two probes is exactly the classical problem of simultaneous approximation in the maximum norm: the score is π^2 times the constant of the pair of gains, never more than π^2, and a pair beating $2\pi^2/7$ exists exactly when Cusick's bound $S \le \frac{2}{7}$ fails for some real pair.

Not claimed

The value of the supremum. It is Problem 6.

The value $\frac{2}{7}$ arises in cubic fields. The field of $\vartheta = 2\cos(2\pi/7)$, a root of $\vartheta^3 + \vartheta^2 - 2\vartheta - 1 = 0$, is the real cubic field of discriminant 49, and its integers form the ring $\mathbb{Z}[\vartheta]$. For integers p, q let $\gamma(p,q)$ be the probe whose gain is the fractional part of $p\vartheta + q\vartheta^2$, by Theorem 30.7(b).

Proposition 30.8 (Integral cubic probe designs)**.** *In classical mathematics, $\vartheta = 2\cos(2\pi/7)$ satisfies $\vartheta^3 + \vartheta^2 - 2\vartheta - 1 = 0$, and the following are equivalent:*

(i) for every $\eta > 0$ there are integers p, q, r, s with $ps - qr = 1$ such that $\gamma(p,q)$ and $\gamma(r,s)$ lie in $(1,\varphi^2)$ and $2\pi^2/7 - \eta < \mathrm{sc}(\gamma(p,q), \gamma(r,s)) < 2\pi^2/7$;

(ii) for every $\eta > 0$ there are integers p, q, r, s with $ps - qr = 1$ and

$$\frac{2}{7} - \eta < S(p\vartheta + q\vartheta^2,\ r\vartheta + s\vartheta^2) < \frac{2}{7}.$$

Proof. With $c = \cos(2\pi/7)$, the identity follows from $\cos(6\pi/7) = \cos(8\pi/7)$, that is $4c^3 - 3c = 2(2c^2-1)^2 - 1$, that is $(c-1)(8c^3+4c^2-4c-1) = 0$; and $c \neq 1$. The cubic has no rational root (± 1 give -1 and 1), so $1, \vartheta, \vartheta^2$ are linearly independent over $\mathbb{Q}$, and $p\vartheta + q\vartheta^2$ is not an integer unless $p = q = 0$. When $ps - qr = 1$, neither (p, q) nor (r, s) is $(0, 0)$, so both fractional parts lie in $(0, 1)$ and both probes lie in $(1, \varphi^2)$, automatically. By Theorem 30.7(a) and the invariance of S under integer shifts, the score of the two probes is $\pi^2 S(p\vartheta + q\vartheta^2, r\vartheta + s\vartheta^2)$; so (i) and (ii) say the same thing, with η scaled by π^2. □

Whether unimodular integral bases of $\mathbb{Z}[\vartheta]$ come arbitrarily close to $\frac{2}{7}$ from below is open (Problem 7), and so is the corresponding question for coordinates of index two, where the conjectured ceiling is $\frac{1}{14}$ (Problem 8).

30.2 Two recognizers, and the memory that recognition needs

A recognizer of a distinction history reads the count of distinctions up to an index–period relation $\sim_{i,p}$ (Definition 7.2): below the index i it tells every count apart, and from i on it reads the count modulo the period p. Chapter 7 catalogues the single recognizers. Here two of them read one history. Their common coarse-graining identifies what either identifies. When two readings agree after that coarse-graining, did they come from one count?

Take $\sim_{0,2}$ and $\sim_{1,3}$. Together they identify any two counts, since $\gcd(2, 3) = 1$; in particular they identify 0 and 1. Is there a count n that the first reads as 0 and the second reads as 1? The second recognizer tells 0 apart from everything, but it reads 1 as $4, 7, 10, \ldots$; and the first reads 0 as every even count. So $n = 4$ works. Now swap the roles: a count read as 1 by $\sim_{0,2}$ and as 0 by $\sim_{1,3}$ would have to be 0, which is even. The transient of the later-starting recognizer is a genuine obstruction.

The *join* $\approx_1 \vee \approx_2$ of two additive congruences on counts is the least additive congruence containing both. It is the transitive closure of their union, because the union is reflexive, symmetric and preserved by adding a count to both sides, and the transitive closure keeps these properties.

Theorem 30.9 (Synchronized recognition)**.** *In classical mathematics: let i, j be counts, $p, q > 0$ and $g = \gcd(p, q)$.*

(a) The join of two recognizers is a recognizer: $\sim_{i,p} \vee \sim_{j,q} = \sim_{\min(i,j),\, g}$.

(b) The following are equivalent: (i) whenever $a (\sim_{i,p} \vee \sim_{j,q}) b$, some count n satisfies $n \sim_{i,p} a$ and $n \sim_{j,q} b$; (ii) $i = j$, or $i < j$ and $p \mid q$, or $j < i$ and $q \mid p$.

Proof. (a) Write $m = \min(i, j)$. Each of the two relations lies below $\sim_{m,g}$: a related pair is equal, or consists of counts at least i (or j), hence at least m, with equal remainders modulo p (or q), hence modulo g. As $\sim_{m,g}$ is an additive congruence (Proposition 7.3), the join lies below it. Conversely, the join is transitive, so it suffices to show $t \simeq t + g$ in the join for every $t \geq m$; repeating the step then relates any two counts at least m with equal remainders modulo g.

Say $m = i$ (the other case is symmetric). By Bézout's identity there is a count M with $pM \equiv g \pmod{q}$. Then

$$t \sim_{i,p} t + p(M + j) \sim_{j,q} t + g + pj \sim_{i,p} t + g :$$

the first and last steps relate counts at least i that differ by a multiple of p; the middle step relates counts at least $pj \geq j$ whose difference $pM - g$ is a multiple of q.

(b) Suppose (ii). If $i = j$ and $a \neq b$ are related by the join, both are at least i and $a \equiv b \pmod{g}$; by Bézout's identity $b - a = ps - qt$ for some integers s, t, so $n = a + ps + Mpq$, with M large, is a count $n \geq i$ with $n \equiv a \pmod{p}$ and $n \equiv b \pmod{q}$, and it is the required count. If $i < j$ and $p \mid q$, the join is $\sim_{i,p}$ by (a), and $n = b$ works: $b \sim_{i,p} a$ and $b \sim_{j,q} b$. The case $j < i$, $q \mid p$ is the mirror image, with $n = a$.

Suppose (ii) fails, say $i < j$ and $p \nmid q$ (the case $j < i$, $q \nmid p$ is the mirror image). Then $g < p$, and the join, which is $\sim_{i,g}$, relates $a = i + g$ with $b = i$. A count n with $n \sim_{j,q} i$ is i itself, since $i < j$. Then $i \sim_{i,p} i + g$ would need $p \mid g$, which fails because $0 < g < p$. □

So agreement after coarse-graining is not enough for a common origin unless the recognizers start together or the later one refines the earlier one's period. Part (a) closes the catalogue of index–period recognizers under joins.

The second question concerns memory. A record can be real, in the sense that any two of its possible values can be told apart by some later examination, and yet be expensive to measure, in the sense of one fixed procedure that tells all values apart at once. We measure the cost in bits kept within reach.

Definition 30.10 (Asking histories and the window world)**.** A *record* is a finite binary word. An *asking history* is a finite list of acts: *post r* appends the record r to the list of records; *retain* changes nothing but the stage; *compare* (x, y), when positions x and y of the list hold records, appends to the transcript whether the two records are equal, and otherwise records nothing. Running a history from the empty list gives a list of records and a transcript of outcomes. The *result* of an act after a history is the outcome of a comparison whose positions both hold records, and no result otherwise.

1. The *window cost* of a list of records $r_0, \dots, r_{\ell-1}$ is $\sum_t (|r_t| + 1)$: each record costs its bits and one separator. Position x is in the *window of capacity* N when $x < \ell$ and the records from position x on cost at most N.

2. The *window world of capacity* N permits an asking history when every comparison in it addresses, at the moment it is made, two positions in the window of capacity N.

3. A *recognition observable* with values in a set X assigns to each $x \in X$ a permitted history $o(x)$, such that for distinct x, y there are a history c and an act a for which $o(x)\,c\,a$ and $o(y)\,c\,a$ are permitted and the results of a after $o(x)\,c$ and after $o(y)\,c$ differ.

A recognition observable is the operational reading of "the values are real": each value can occur, and any two can be told apart by some later examination, which may depend on the pair.

Theorem 30.11 (Pairwise recognition is cheap; common measurement is not)**.** *Let N and L be counts, $n \geq 2$, and let $m_1, \dots, m_n$ be distinct records of length L.*

(a) There is a recognition observable in the window world of capacity N with values $1, \dots, n$ and $o(i) = \text{post } m_i$ if and only if $N \geq 2(L+1)$.

(b) There is one asking history c such that every history $(\text{post } m_i)\, c$ is permitted in the window world of capacity N and the transcripts of these n runs are pairwise distinct if and only if $N \geq n(L+1)$.

Proof. In both parts the runs differ only in the record at position 0: after $(\text{post } m_i)\, c$ the list is m_i followed by the records that c posts, the same for every i. A comparison of two positions other than 0, or of 0 with itself, therefore has the same result in every run; a comparison of 0 with a position $y \neq 0$ holding a record r has the result "$m_i = r$". Whether a position holds a record does not depend on i.

(a) If $N \geq 2(L+1)$, take for $x \neq y$ the history $c = \text{post } m_x$ and the act $a = \text{compare } (0, 1)$. After $o(x)\, c$ it finds two equal records, after $o(y)\, c$ two different ones, and the list costs $2(L+1) \leq N$, so both positions are in the window. Conversely, let $x \neq y$, with c and a as in the definition. The act a must be a comparison of 0 with some $y' \neq 0$ holding a record r, and "$m_x = r$" and "$m_y = r$" must differ, so r is m_x or m_y and has length L. Position 0 is in the window, so the whole list costs at most N, and it contains two records of length L: $2(L+1) \leq N$.

(b) If $N \geq n(L+1)$, let c post m_1, compare $(0, 1)$, post m_2, compare $(0, 2)$, and so on up to m_{n-1}. When position t is compared the list costs $(t+1)(L+1) \leq N$, so every comparison is permitted. Run i has transcript $(m_i = m_1, \dots, m_i = m_{n-1})$, which is the indicator of i for $i < n$ and all "false" for $i = n$; these are distinct. Conversely, let c work, and let R be the set of records that c compares with position 0. If two indices $i \neq i'$ had $m_i, m_{i'} \notin R$, every result in their runs would agree. So at least $n - 1$ of the m_i lie in R. At the last comparison of position 0 with a member of R, all members of R have been posted, and position 0 is in the window: the whole list, which holds m_i and at least $n - 1$ further distinct records of length L, costs at most N. So $n(L+1) \leq N$. □

For all records of L bits, $n = 2^L$: being real costs a window of $2(L+1)$ bits, while one common measurement costs $2^L(L+1)$. The gap is exponential, and it comes from one fact visible in the proof: a comparison learns only whether two records are equal, so a fixed procedure must keep every candidate it rules out within reach of the unknown record.

30.3 Self-similar ledgers: rates, balance and fluctuation

Chapter 21 built Recognition Science's ledger from one rule: every debit is posted as a debit followed by a credit, every credit as a debit. The resulting history is the Fibonacci word [100]; its running rate tends to φ^{-3}, and its books stay within 2 of the line of that slope (Chapter 21). Any rule that replaces each posting by a fixed word defines a self-similar ledger in the same way. Which rates can such ledgers have, and which of them keep balanced books?

Definition 30.12 (Joins, rates and balanced books)**.** In classical mathematics:

1. A *join* σ assigns a posting word to each of the letters d (debit) and c (credit) and acts on words letter by letter. Its *words* are $W_k = \sigma^k(\mathsf{d})$. Its *incidence counts* are the numbers DD and CD of debits and credits in $\sigma(\mathsf{d})$ and DC and CC of debits and credits in $\sigma(\mathsf{c})$; its trace is $\mathrm{tr} = DD + CC$, its determinant $\det = DD \cdot CC - DC \cdot CD$, its discriminant $\mathrm{tr}^2 - 4\det$, its *Perron root* $\lambda = \frac{1}{2}(\mathrm{tr} + \sqrt{\mathrm{tr}^2 - 4\det})$ and its *second mode* $\mu = \mathrm{tr} - \lambda$.
2. The join is *primitive* when for some $k \geq 1$ both letters occur in $\sigma^k(\mathsf{d})$ and in $\sigma^k(\mathsf{c})$.
3. It has *rate* r when the rates $\mathrm{bal}(W_k)/|W_k|$ tend to r, where bal counts debits minus credits.
4. The *discrepancy* of a word at rate r is $\delta_r(w) = \mathrm{bal}(w) - r|w|$. The join *keeps balanced books* at rate r when some C bounds $|\delta_r(p)|$ for every prefix p of every word W_k.

The golden join of Chapter 21, $\mathsf{d} \mapsto \mathsf{dc}$ and $\mathsf{c} \mapsto \mathsf{d}$, has trace 1, determinant -1, discriminant 5 and rate $\sqrt{5} - 2 = \varphi^{-3}$.

Which rates occur

Theorem 30.13 (The rates of self-similar ledgers)**.** *In classical mathematics: a real number r is the rate of some primitive join if and only if $-1 < r < 1$ and r is a root of an integer polynomial $at^2 + bt + c$ with $a \neq 0$ whose other root, $-b/a - r$, lies outside $[-1, 1]$. Every rational number in $(-1, 1)$ and φ^{-3} are rates; $\sqrt{2}/2$ is not, although it lies in $(-1, 1)$ and is a root of $2t^2 - 1$. So not every quadratic number in $(-1, 1)$ is a rate.*

Proof. Counts. Let (x_k, y_k) be the numbers of debits and credits in W_k. Each debit of W_k becomes $\sigma(\mathsf{d})$ and each credit $\sigma(\mathsf{c})$, so $(x_{k+1}, y_{k+1})^{\mathsf{T}} = M(x_k, y_k)^{\mathsf{T}}$ with $M = \left(\begin{smallmatrix} DD & DC \\ CD & CC \end{smallmatrix}\right)$. If σ is primitive, then $DC \geq 1$ (otherwise no power of σ puts a debit into the image of a credit), $CD \geq 1$ likewise, and $\mathrm{tr} \geq 1$ (if $DD = CC = 0$, every $\sigma^k(\mathsf{d})$ consists of one letter only). The discriminant $(DD - CC)^2 + 4\,DC \cdot CD$ is positive, so $\lambda > \mu$, and $\lambda + \mu = \mathrm{tr} > 0$ gives $\lambda > |\mu|$. The vector $\xi = (DC, \lambda - DD)$ has positive entries and satisfies $M\xi = \lambda\xi$; the vector $\zeta = (DC, \mu - DD)$ satisfies $M\zeta = \mu\zeta$ and has entries of opposite signs. Writing $(1, 0) = A\xi + B\zeta$ gives $A = (DD - \mu)/(DC(\lambda - \mu)) > 0$, so $(x_k, y_k) = A\lambda^k\xi + B\mu^k\zeta$ and the rates of W_k tend to $r = (\beta - 1)/(\beta + 1) \in (-1, 1)$, where $\beta = DC/(\lambda - DD) > 0$ is the ratio of the entries of ξ. The two rows of $M\xi = \lambda\xi$ give $CD\,\beta^2 + (CC - DD)\beta - DC = 0$; this is the theorem of Perron and Frobenius in dimension two [89].

The polynomial. Substitute $\beta = (1 + r)/(1 - r)$ and multiply by $(1 - r)^2$: r is a root of

$$P(t) = CD\,(1 + t)^2 + q(1 + t)(1 - t) - DC\,(1 - t)^2, \qquad q = CC - DD,$$

an integer polynomial with $P(1) = 4\,CD > 0$ and $P(-1) = -4\,DC < 0$. If P has degree two, with other root r', then $P(1)P(-1) = a^2(1 - r^2)(1 - r'^2) < 0$ for its leading coefficient a, so $|r'| > 1$. If P has degree one, r is rational, and $(t - 2)P(t)$ is an integer quadratic with roots r and 2.

Realization. Let $r \in (-1, 1)$ be a root of $P_0(t) = at^2 + bt + c$, $a \neq 0$, with other root r', $|r'| > 1$. As above $P_0(1)P_0(-1) < 0$; changing the sign of P_0 if necessary, $P_0(1) > 0 > P_0(-1)$. Put

$CD = a + b + c \geq 1$, $DC = -(a - b + c) \geq 1$ and $q = 2(c - a)$; a direct expansion shows that the polynomial P built from these numbers is $4P_0$. Choose $DD = |q| + 1 - q$ and $CC = |q| + 1$, both at least 1 with $CC - DD = q$, and let $\sigma(\mathsf{d}) = \mathsf{d}^{DD}\mathsf{c}^{CD}$ and $\sigma(\mathsf{c}) = \mathsf{d}^{DC}\mathsf{c}^{CC}$. Both images contain both letters, so σ is primitive, and its rate is the root of $4P_0$ in $(-1, 1)$, which is r.

Examples. A rational $m/n \in (-1, 1)$ is a root of $(nt - m)(t - 2)$. The rate $\sqrt{5} - 2$ is a root of $t^2 + 4t - 1$, whose other root is $-2 - \sqrt{5}$. An integer quadratic with root $\sqrt{2}/2$ is a rational multiple of $2t^2 - 1$, because $\sqrt{2}/2$ is irrational; its other root is $-\sqrt{2}/2 \in [-1, 1]$. □

The proof explains the shape of the answer. A rate is a ratio of entries of a positive eigenvector of a positive integer matrix, and the conjugate eigenvector of such a matrix has entries of opposite signs; in the rate coordinate this puts the conjugate root outside $[-1, 1]$.

Which ledgers keep balanced books

The discrepancy adds over concatenation, and on the two letters it is $\delta_r(\mathsf{d}) = 1 - r$ and $\delta_r(\mathsf{c}) = -1 - r$. The row vector $\ell = (1 - r, -1 - r)$ is orthogonal to the Perron vector $\xi \propto (1 + r, 1 - r)$, so it is a left eigenvector of M for the second mode: $\ell M = \mu\ell$. In words,

$$\delta_r(\sigma(w)) = \mu\,\delta_r(w) \quad \text{for every word } w, \qquad \delta_r(W_k) = \mu^k(1 - r). \tag{30.1}$$

We also need the prefix decomposition of Dumont and Thomas [80]: every proper prefix p of $\sigma^k(a)$ is

$$p = \sigma^{k-1}(u_1)\,\sigma^{k-2}(u_2)\cdots\sigma^0(u_k), \tag{30.2}$$

where $b_1 = a$, each u_j is a proper prefix of $\sigma(b_j)$, and b_{j+1} is the letter of $\sigma(b_j)$ that follows u_j. It follows by induction on k, since $\sigma^k(a)$ is the concatenation of the words $\sigma^{k-1}(y)$ over the letters y of $\sigma(a)$. By (30.1), $\delta_r(p) = \sum_j \mu^{k-j}\delta_r(u_j)$.

Theorem 30.14 (The balance law of two-letter ledgers)**.** *In classical mathematics, let σ be a primitive join with rate r.*

(a) σ keeps balanced books if and only if either $|\det| < \lambda$, or $|\det| = \lambda$ and the prefix discrepancies of σ^2 form a coboundary*: some π on the two letters satisfies*

$$\delta_r\big(\textit{first } m \textit{ letters of } \sigma^2(b)\big) = \pi\big(\textit{letter } m \textit{ of } \sigma^2(b)\big) - \pi(b)$$

for both letters b and every position $m < |\sigma^2(b)|$, counted from 0*.*

(b) If the discriminant is not a perfect square, σ keeps balanced books if and only if $|\det| < \lambda$.

Proof. Since $\mu\lambda = \det$, the condition $|\det| < \lambda$ says $|\mu| < 1$, and $|\det| = \lambda$ says $|\mu| = 1$.

If $|\mu| < 1$, let m_0 bound $|\delta_r(u)|$ over the proper prefixes u of $\sigma(\mathsf{d})$ and $\sigma(\mathsf{c})$. Every proper prefix of W_k has $|\delta_r(p)| \leq \sum_j |\mu|^{k-j} m_0 \leq m_0/(1 - |\mu|)$, and the whole words have $|\delta_r(W_k)| \leq 1 - r$; the books are balanced. If $|\mu| > 1$, the whole words alone have $|\delta_r(W_k)| = |\mu|^k(1 - r) \to \infty$.

Let $|\mu| = 1$ and put $\tau = \sigma^2$, whose second mode is $\mu^2 = 1$, so τ preserves discrepancies. Draw the *prefix graph* of τ: for every letter b and position m of $\tau(b)$ an edge from b to the letter at m,

weighted by the discrepancy of the first m letters of $\tau(b)$. By (30.2) for τ, the proper prefixes of $\tau^k(b)$ correspond to the paths of length k from b, and the discrepancy of the prefix is the weight of its path.

Suppose the coboundary π exists. The edge weights are $\pi(\text{end}) - \pi(\text{start})$, so every path weight telescopes to a difference of two values of π, and every prefix of $W_{2k} = \tau^k(\mathsf{d})$ has discrepancy at most $2\max|\pi|$ in absolute value. A prefix of $W_{2k+1} = \tau^k(\sigma(\mathsf{d}))$ is $\tau^k(v)p'$ with v a prefix of $\sigma(\mathsf{d})$ and p' a prefix of some $\tau^k(y)$, and $\delta_r(\tau^k(v)) = \delta_r(v)$; so those are bounded as well.

Conversely, suppose the books are balanced, with bound C. Every path from d has weight at most C in absolute value. Since σ is primitive, so is τ, and both letters can be reached from each letter. If some cycle had nonzero weight, going round it repeatedly after reaching it from d would give paths from d of unbounded weight. So every cycle has weight 0, and $\pi(a) =$ the weight of any path from d to a is well defined: two such paths, each followed by one path back to d, are cycles. For an edge from b to a, a path to b followed by the edge is a path to a, so its weight is $\pi(a) - \pi(b)$. This is the coboundary.

(b) If $\mu = \pm 1$, then $\lambda = \mathrm{tr} \mp 1$ and the discriminant $(\lambda - \mu)^2 = (\mathrm{tr} \mp 2)^2$ is a perfect square. So a nonsquare discriminant excludes $|\mu| = 1$, and (a) reduces to $|\det| < \lambda$. □

Conditions and scope.

Base and premises
Classical real numbers; primitive two-letter joins of Definition 30.12; the rate of Theorem 30.13.

Conclusion
A self-similar ledger keeps its books within a fixed distance of the line of its rate exactly when its second mode contracts, $|\det| < \lambda$; at the neutral boundary $|\det| = \lambda$ it does so exactly when the prefix discrepancies of the doubled rule are a coboundary.

Not claimed
Ledgers with three or more letters; their balance law is not settled here.

Every unimodular join, $|\det| = 1$, keeps balanced books, the golden join among them. The join $\mathsf{d} \mapsto \mathsf{dcc}$, $\mathsf{c} \mapsto \mathsf{dddc}$ has trace 2, determinant -5 and $\lambda = 1 + \sqrt{6} \approx 3.449 < 5$: its whole words drift like $(\sqrt{6} - 1)^k$. At the neutral boundary the incidence counts no longer decide. The joins $\mathsf{d} \mapsto \mathsf{dcd}$, $\mathsf{c} \mapsto \mathsf{cdc}$ and $\mathsf{d} \mapsto \mathsf{ddc}$, $\mathsf{c} \mapsto \mathsf{ccd}$ have the same counts, with $\lambda = 3 = |\det|$ and rate 0. The first is balanced, with $\pi(\mathsf{d}) = 0$ and $\pi(\mathsf{c}) = 1$; the second is not, since its words begin $\mathsf{ddc\,ddc\,ccd}\cdots$ and the prefix balance climbs by one at each level.

How an unbalanced neutral ledger wanders

At the neutral boundary an unbalanced ledger does not drift: its whole words have discrepancy $\pm(1 - r)$. It spreads instead, and the spread has an exact law. For a primitive join with rate r and $|\mu| = 1$, let V_k be the variance of the $|W_k| + 1$ numbers $\delta_r(p)$, p running over all prefixes of W_k, the empty prefix and W_k included, each with weight $1/(|W_k| + 1)$.

Theorem 30.15 (Variance at the neutral boundary)**.** *In classical mathematics: for every primitive join with rate r and second mode $\mu = \pm 1$, the limit $v = \lim_k V_k/k$ exists, $v \geq 0$, and $v = 0$ if and only if the join keeps balanced books.*

Proof. The limit. The proof computes it. For letters y put $\alpha_y = (|\sigma(y)| - \mu)/(\lambda - \mu)$, so that $|\sigma^k(y)| = \alpha_y \lambda^k + (1 - \alpha_y)\mu^k$ (both sides satisfy the recurrence with roots λ, μ and agree at $k = 0, 1$). Primitivity makes $|\sigma^k(y)|$ unbounded, so $\alpha_y > 0$. For a letter b and a position m of $\sigma(b)$, carrying the letter y_m, let δ_m be the discrepancy of the first m letters of $\sigma(b)$ and $q_m = \alpha_{y_m}/(\lambda \alpha_b)$; these weights sum to 1 over m. Put $\omega(b) = \sum_m q_m \delta_m$, $\eta = \mu\lambda(\omega(\mathsf{d}) - \omega(\mathsf{c}))/(\lambda - 1)$, the *block values* $v_m = \delta_m + \eta\,[y_m = \mathsf{d}]$, their weighted mean $\kappa(b) = \sum_m q_m v_m$ and

$$\tau(b) = \sum_m q_m \big(v_m - \kappa(b)\big)^2, \qquad v = \tfrac{1}{2}(1 + r)\alpha_{\mathsf{d}}\,\tau(\mathsf{d}) + \tfrac{1}{2}(1 - r)\alpha_{\mathsf{c}}\,\tau(\mathsf{c}).$$

For a letter b, let $m_k(b)$ and $s_k(b)$ be the mean and the variance of the discrepancies of the $|\sigma^k(b)|$ proper prefixes of $\sigma^k(b)$. The word $\sigma^{k+1}(b)$ is the concatenation of the blocks $\sigma^k(y_m)$, and a proper prefix ending in block m has discrepancy $\mu^k \delta_m$ plus that of a proper prefix of $\sigma^k(y_m)$. The law of total variance gives

$$s_{k+1}(b) = \sum_m w_{k,m}\, s_k(y_m) + \tau_k(b),$$

with block weights $w_{k,m} = |\sigma^k(y_m)|/|\sigma^{k+1}(b)| \to q_m$ and $\tau_k(b)$ the weighted variance of the block values $\mu^k \delta_m + m_k(y_m)$. Since $\mu^2 = 1$, these values are $\mu^k(\delta_m + \eta_k[y_m = \mathsf{d}])$ plus a constant, with $\eta_k = \mu^k(m_k(\mathsf{d}) - m_k(\mathsf{c}))$. Let κ_k be the weight that the blocks of $\sigma(\mathsf{d})$ carrying a debit receive, minus the same for $\sigma(\mathsf{c})$. The block decomposition of the means gives $\eta_{k+1} = \mu(\omega_k(\mathsf{d}) - \omega_k(\mathsf{c})) + \mu\kappa_k\eta_k$, with ω_k formed like ω from the weights $w_{k,m}$. The vector (α_y) is a left eigenvector of M for λ, which gives $\lambda\kappa_k \to DD - DC\,\alpha_{\mathsf{d}}/\alpha_{\mathsf{c}} = DD + CC - \lambda = \mu$; so $\mu\kappa_k \to 1/\lambda < 1$ and $\eta_k \to \mu\lambda(\omega(\mathsf{d}) - \omega(\mathsf{c}))/(\lambda - 1) = \eta$. Hence $\tau_k(b) \to \tau(b)$.

Weight the letters by $\rho_k(b) = f(b)|\sigma^k(b)|/(2\lambda^k)$ with $f = (1 + r, 1 - r)$. Because f is proportional to the Perron vector, $Mf = \lambda f$, and a direct substitution gives $\sum_b \rho_{k+1}(b) \sum_{m\,:\,y_m = y} w_{k,m} = \rho_k(y)$. So $\sum_b \rho_k(b) = \sum_b \rho_0(b) = 1$, and $Y_k = \sum_b \rho_k(b) s_k(b)$ satisfies $Y_{k+1} = Y_k + \sum_b \rho_{k+1}(b)\tau_k(b)$, whose increment tends to $\sum_b \frac{1}{2} f(b)\alpha_b \tau(b) = v$. By Cesàro's lemma, $Y_k/k \to v$. The difference $g_k = s_k(\mathsf{d}) - s_k(\mathsf{c})$ satisfies $g_{k+1} = \kappa_k g_k + O(1)$ with $|\kappa_k| \to 1/\lambda < 1$, so g_k is bounded; since $Y_k = s_k(\mathsf{d}) - \rho_k(\mathsf{c}) g_k$, also $s_k(\mathsf{d})/k \to v$. Finally V_k adds the whole word, of discrepancy $\pm(1 - r)$, to the $|W_k|$ proper prefixes; the means grow at most linearly in k and $|W_k|$ exponentially, so $V_k - s_k(\mathsf{d}) \to 0$.

Zero limit. If the books are balanced with bound C, then $V_k \leq C^2$ and $v = 0$. Conversely let $v = 0$. The weights $\frac{1}{2}(1 \pm r)\alpha$ are positive, so $\tau(\mathsf{d}) = \tau(\mathsf{c}) = 0$, and all blocks of $\sigma(b)$ carry one value $V(b)$. Write $e(\mathsf{d}) = 1 - r$ and $e(\mathsf{c}) = -1 - r$, both nonzero. Three facts follow. Consecutive blocks give $e(y_m) = \eta([y_m = \mathsf{d}] - [y_{m+1} = \mathsf{d}])$, so no image contains two equal adjacent letters, and a step dc inside an image forces $\eta = 1 - r$, a step cd forces $\eta = 1 + r$. The first block gives $V(b) = \eta[y_0 = \mathsf{d}]$. The whole image gives, by (30.1), $\mu e(b) = V(b) - \eta[y_{\text{last}} = \mathsf{d}] + e(y_{\text{last}})$. We look for a potential h with $\delta_m + h(y_m) = \mu h(b)$ for every block m of every image $\sigma(b)$; with $h(\mathsf{d}) = \eta + t$ and $h(\mathsf{c}) = t$ this asks $V(b) + t = \mu(\eta[b = \mathsf{d}] + t)$ for both letters.

If $\mu = 1$ it asks $V(\mathsf{d}) = \eta$ and $V(\mathsf{c}) = 0$. Should $\sigma(\mathsf{c})$ end with d, the last-block relation gives $V(\mathsf{c}) = \eta - 2$, and the first-block relation then forces $\sigma(\mathsf{c})$ to begin with c and $\eta = 2$; but the

step cd inside it forces $\eta = 1 + r < 2$. So $\sigma(\mathsf{c})$ ends with c and $V(\mathsf{c}) = 0$; symmetrically $\sigma(\mathsf{d})$ ends with d and $V(\mathsf{d}) = \eta$.

If $\mu = -1$ it asks $V(\mathsf{c}) - V(\mathsf{d}) = \eta$, and then $t = -(\eta + V(\mathsf{d}))/2$. The last-block relation gives $V(\mathsf{d}) = \eta - 2 + 2r$ or $2r$ as $\sigma(\mathsf{d})$ ends with d or c, and $V(\mathsf{c}) = 2 + 2r$ or $2r + \eta$ as $\sigma(\mathsf{c})$ ends with c or d. If $\sigma(\mathsf{d})$ ends with d, the first-block relation excludes $V(\mathsf{d}) = \eta$ (it would give $r = 1$), so $\sigma(\mathsf{d})$ begins with c, $\eta = 2 - 2r$, and its step cd gives $\eta = 1 + r$, so $r = \frac{1}{3}$ and $\eta = \frac{4}{3}$; then $V(\mathsf{c}) \in \{\frac{8}{3}, 2\}$ is neither 0 nor η, a contradiction. If both images end with c, the first-block relations give $r = 0$ and $\eta = 2$, while the step dc in $\sigma(\mathsf{c})$ gives $\eta = 1$, a contradiction. So $\sigma(\mathsf{d})$ ends with c and $\sigma(\mathsf{c})$ with d, and then $V(\mathsf{c}) - V(\mathsf{d}) = \eta$.

In every case the potential exists. Along (30.2), $\delta_r(u_j) = \mu h(b_j) - h(b_{j+1})$, and $\delta_r(p) = \sum_j \mu^{k-j}\delta_r(u_j) = \mu^k h(b_1) - h(b_{k+1})$ telescopes; the books are balanced. □

So at the neutral boundary there is no middle ground: either the books stay bounded, or the prefix discrepancies spread like a random walk, with variance close to νk after k generations. For instance $\mathsf{d} \mapsto \mathsf{ddc}$, $\mathsf{c} \mapsto \mathsf{ccd}$ has $\nu = \frac{2}{3}$, and $\mathsf{d} \mapsto \mathsf{ccd}$, $\mathsf{c} \mapsto \mathsf{cdd}$, with $\mu = -1$, has $\nu = \frac{2}{9}$, by the formula in the proof. How large can ν be? A neutral ledger with Perron root λ and rate r cannot wander faster, it seems, than $(\lambda^2 - 1)(1 + |r|)^2/12$, which at rate 0 is the variance of a uniform choice among λ positions; the bound is open (Problem 2), but at rate 0 it is attained at every integer.

Proposition 30.16 (The neutral slope $(n^2 - 1)/12$ is attained)**.** *In classical mathematics: for every integer $n \geq 2$ there is a primitive join with rate 0, $|\mu| = 1$ and $\lambda = n$ whose variances satisfy $V_k/k \to (n^2 - 1)/12$. For $n \geq 3$ one is $\mathsf{d} \mapsto \mathsf{cdd}$, $\mathsf{c} \mapsto \mathsf{d}^{n-2}\mathsf{c}^{n-1}$; for $n = 2$ one is $\mathsf{d} \mapsto \mathsf{c}$, $\mathsf{c} \mapsto \mathsf{cdd}$.*

Proof. Let $n \geq 3$. The incidence counts are $DD = 2$, $CD = 1$, $DC = n - 2$, $CC = n - 1$; so $\mathrm{tr} = n + 1$, $\det = n$, $\lambda = n$, $\mu = 1$, both images contain both letters, and the Perron vector $(1, 1)$ gives rate 0. By the proof of Theorem 30.15 the limit is the explicit ν. Here $\alpha_{\mathsf{d}} = \frac{2}{n-1}$ and $\alpha_{\mathsf{c}} = \frac{2(n-2)}{n-1}$. In $\sigma(\mathsf{d}) = \mathsf{cdd}$ the blocks have weights $\frac{n-2}{n}, \frac{1}{n}, \frac{1}{n}$ and prefix discrepancies $0, -1, 0$, so $\omega(\mathsf{d}) = -\frac{1}{n}$. In $\sigma(\mathsf{c})$ the $n - 2$ debit blocks have weight $\frac{1}{n(n-2)}$ and prefix discrepancies $0, 1, \dots, n-3$, and the $n-1$ credit blocks have weight $\frac{1}{n}$ and prefix discrepancies $n-2, n-3, \dots, 0$, so $\omega(\mathsf{c}) = \frac{n-3}{2n} + \frac{(n-2)(n-1)}{2n} = \frac{n^2-2n-1}{2n}$. Hence $\eta = n(\omega(\mathsf{d}) - \omega(\mathsf{c}))/(n-1) = -\frac{n-1}{2}$. The block values of $\sigma(\mathsf{d})$ are 0, $\eta - 1$, η with mean -1, so

$$\tau(\mathsf{d}) = \tfrac{n-2}{n} + \tfrac{1}{n}\eta^2 + \tfrac{1}{n}(\eta + 1)^2 = \frac{(n-1)^2}{2n}.$$

The block values of $\sigma(\mathsf{c})$ are $j - \frac{n-1}{2}$ for $j = 0, \dots, n-3$ and $0, 1, \dots, n-2$; their weighted mean is $\frac{n-3}{2}$, and

$$\tau(\mathsf{c}) = \frac{1}{n(n-2)}\sum_{j=1}^{n-2} j^2 + \frac{1}{n}\sum_{t=0}^{n-2}\Big(t - \frac{n-3}{2}\Big)^2 = \frac{(n-1)^2(n+3)}{12n}.$$

With rate 0 the weights are $\frac{1}{2}\alpha_{\mathsf{d}} = \frac{1}{n-1}$ and $\frac{1}{2}\alpha_{\mathsf{c}} = \frac{n-2}{n-1}$, and

$$\nu = \frac{n-1}{2n} + \frac{(n-2)(n-1)(n+3)}{12n} = \frac{(n-1)(n^2+n)}{12n} = \frac{n^2-1}{12}.$$

For $n = 2$: $DD = 0$, $CD = 1$, $DC = 2$, $CC = 1$, so $\lambda = 2$, $\mu = -1$, rate 0, and σ^2 puts both letters into both images. Here $\alpha_{\mathsf{d}} = \frac{2}{3}$, $\alpha_{\mathsf{c}} = \frac{4}{3}$; $\sigma(\mathsf{d})$ is one block, so $\tau(\mathsf{d}) = 0$ and $\omega(\mathsf{d}) = 0$; $\sigma(\mathsf{c}) = \mathsf{cdd}$ has weights $\frac{1}{2}, \frac{1}{4}, \frac{1}{4}$ and prefix discrepancies $0, -1, 0$, so $\omega(\mathsf{c}) = -\frac{1}{4}$ and $\eta = -2 \cdot \frac{1}{4} = -\frac{1}{2}$. Its block values $0, -\frac{3}{2}, -\frac{1}{2}$ have mean $-\frac{1}{2}$ and $\tau(\mathsf{c}) = \frac{1}{8} + \frac{1}{4} = \frac{3}{8}$; so $\nu = \frac{2}{3} \cdot \frac{3}{8} = \frac{1}{4}$. □

A hold letter, and a ledger that wanders cubically

Give the ledger a third letter h, a *hold*, that posts neither a debit nor a credit. Joins, primitivity, words $W_k = \sigma^k(\mathsf{d})$ and rates are defined as before, the rate still being debits minus credits over all letters.

Theorem 30.17 (A hold letter strictly enlarges the rates)**.** *In classical mathematics:*

(a) the three-letter join $\mathsf{d} \mapsto \mathsf{d}^9\mathsf{ch}$, $\mathsf{c} \mapsto \mathsf{dh}$, $\mathsf{h} \mapsto \mathsf{dc}$ *is primitive with rate* $\sqrt{2}/2$*, which is the rate of no primitive two-letter join;*

(b) every rational number in $(-1, 1)$ *is the rate of a primitive three-letter join;*

(c) the statement "the rates of primitive three-letter joins are exactly the numbers in $(-1, 1)$ *that are algebraic of degree at most* 3*" is equivalent to the conjunction of two statements about the joins* $\sigma(a) = \mathsf{d}^{A(a)}\mathsf{c}^{B(a)}\mathsf{h}^{H(a)}$ *given by nine counts: that every rate of such a primitive join lies in* $(-1, 1)$ *and is algebraic of degree at most* 3*, and that every irrational algebraic number of degree at most* 3 *in* $(-1, 1)$ *other than* $\sqrt{2}/2$ *is the rate of one.*

Proof. (a) Let x_k, y_k, z_k count debits, credits and holds in W_k. Then $x_{k+1} = 9x_k + y_k + z_k$, $y_{k+1} = x_k + z_k$ and $z_{k+1} = x_k + y_k$, so $y_{k+1} - z_{k+1} = z_k - y_k$, and from $y_0 = z_0 = 0$ the credits and holds stay equal. The pair (x_k, y_k) follows the matrix $\left(\begin{smallmatrix} 9 & 2 \\ 1 & 1 \end{smallmatrix}\right)$, with Perron root $5 + 3\sqrt{2}$ and Perron vector $(4 + 3\sqrt{2}, 1)$; as in the proof of Theorem 30.13, $x_k/y_k \to 4 + 3\sqrt{2}$, and the rate $(x_k - y_k)/(x_k + 2y_k)$ tends to $(3 + 3\sqrt{2})/(6 + 3\sqrt{2}) = \sqrt{2}/2$. All three letters occur in σ^2 of each letter. Theorem 30.13 excludes $\sqrt{2}/2$ for two letters.

(b) Write $q = m/n$ with $|m| < n$. The join whose three images all equal $\mathsf{d}^{2(n+m)-1}\mathsf{c}^{2(n-m)-1}\mathsf{h}^2$ is primitive, since each exponent is at least 1; each image has length $4n$ and balance $4m$, and every W_k with $k \geq 1$ is a concatenation of images, so its rate is exactly q.

(c) The incidence counts alone determine the letter counts of every W_k, primitivity and every whole-word rate, and the join with images $\mathsf{d}^A\mathsf{c}^B\mathsf{h}^H$ has the same counts as any join; so restricting to these normal forms loses nothing. Rationals and $\sqrt{2}/2$ are covered by (a) and (b), and the remaining clauses are the two named statements. □

Whether the two statements of (c) hold is Problem 1. The eigenvector reasoning behind Theorem 30.13 suggests degree at most 3; what is missing is a cubic analogue of the realization step.

A hold letter also lets the second mode form a Jordan block, and then the ledger wanders faster than any random walk. Consider the census with images of length 7 in which $\sigma(\mathsf{d})$ has 4 debits, 1 credit and 2 holds, $\sigma(\mathsf{c})$ has 3, 2, 2 and $\sigma(\mathsf{h})$ has 0, 4, 3. Its *witness* ordering is

$$\sigma_* : \quad \mathsf{d} \mapsto \mathsf{cddddhh}, \qquad \mathsf{c} \mapsto \mathsf{hhccddd}, \qquad \mathsf{h} \mapsto \mathsf{hhhcccc}.$$

Weight the letters by $u = (1, 1, -2)$ and write $f_\sigma(a, i)$ for the u-weight of the first i letters of $\sigma(a)$, $i = 0, \dots, 6$. Let $\bar{f} = \frac{1}{21}\sum_{a,i} f_\sigma(a, i)$, let P be the census average, $(P\psi)(a) = \frac{1}{7}\sum_{c\in\sigma(a)} \psi(c)$ over the seven letters of $\sigma(a)$, and let z_σ solve $z - Pz = h$ with $z(\mathsf{d}) + z(\mathsf{c}) + z(\mathsf{h}) = 0$, where $h(a) = \frac{1}{7}\sum_i f_\sigma(a, i) - \bar{f}$. Put

$$g_\sigma(a, i) = f_\sigma(a, i) - \bar{f} + z_\sigma(\text{letter } i \text{ of } \sigma(a)) - z_\sigma(a), \qquad \nu(\sigma) = \frac{4}{63}\sum_a \sum_{i=0}^{6} g_\sigma(a, i)^2.$$

Theorem 30.18 (A Jordan census: cubic fluctuation and its exact range)**.** *In classical mathematics: the witness σ_* is primitive with rate 0. For every join σ with the same nine counts, the variance V_k of the balances of all prefixes of W_k satisfies $V_k/k^3 \to \nu(\sigma)$, and*

$$\frac{100}{441} \le \nu(\sigma) \le \frac{7408}{441}.$$

The upper value is attained exactly by σ_* and by σ_* with all three images reversed; the lower value is attained, for instance by $\mathsf{d} \mapsto \mathsf{dchdhdd}$, $\mathsf{c} \mapsto \mathsf{dhdchdc}$, $\mathsf{h} \mapsto \mathsf{hcchcch}$.

Proof. The Jordan block. Let M be the incidence matrix, column a counting the letters of $\sigma(a)$. With the balance weights $\mathrm{b} = (1, -1, 0)$ one checks $\mathrm{b}M = \mathrm{b} + 2u$ and $uM = u$; so the balance of $\sigma^j(w)$ is $\mathrm{bal}(w) + 2j\,u(w)$, with $u(w)$ the u-weight of w. Each letter occurs seven times among the three images, so the uniform law on letters is stationary for P, and the Perron vector is $(1, 1, 1)$: the rate is 0, and the witness is primitive because σ_*^2 of every letter contains all three.

Prefixes as a Markov chain. All images have length 7, so a prefix of W_k of length $N < 7^k$ corresponds to the base-7 digits $(m_1, \dots, m_k)$ of N, and (30.2) reads $p = \sigma^{k-1}(u_1)\cdots\sigma^0(u_k)$ with u_j the first m_j letters of $\sigma(b_j)$, $b_1 = \mathsf{d}$ and b_{j+1} the letter at m_j. A uniformly chosen N makes the digits independent and uniform, and the letters b_j a Markov chain with kernel P. The balance of p is $\sum_j\big(\mathrm{bal}(u_j) + 2(k-j)F_j\big)$ with $F_j = f_\sigma(b_j, m_j)$. By the Poisson equation, $g_j = g_\sigma(b_j, m_j)$ has conditional mean 0 given the past, and $F_j - \bar{f} = g_j - (z_\sigma(b_{j+1}) - z_\sigma(b_j))$. Summation by parts shows that the terms z_σ, $\mathrm{bal}(u_j)$ and the mean $\bar{f}$ contribute $O(k)$ to the centred balance in mean square, while the martingale part $\sum_j 2(k-j)g_j$ has variance $\sum_j 4(k-j)^2\,\mathbb{E}[g_j^2]$. As P is primitive, $\mathbb{E}[g_j^2]$ tends geometrically to the stationary value $\frac{1}{21}\sum_{a,i} g_\sigma(a, i)^2$, and $\sum_j 4(k-j)^2 \sim \frac{4}{3}k^3$. So the variance over the proper prefixes, divided by k^3, tends to $\nu(\sigma)$; the whole word adds one value $1 + 2k$ and changes nothing in the limit.

The range. The coefficient $\nu(\sigma)$ is a function of the three orderings; there are 105, 210 and 35 orderings of the three images. Both $\bar{f}$ and z_σ depend on them only through the three image sums $\sum_i f_\sigma(a, i)$, which take 11, 11 and 13 values. Once the sums are fixed, each image's contribution to $\nu(\sigma)$ depends on its own ordering alone. The range is therefore a finite exhaustive computation in exact rationals, which we describe but do not reproduce: for each of the $11 \cdot 11 \cdot 13 = 1573$ triples of sums, solve for z_σ, take the largest and the smallest contribution of each image among its orderings with the given sum, and compare. It gives the minimum $100/441$ and the maximum $7408/441$, the maximum reached only at image sums $(18, -12, -24)$ and $(-12, 18, 12)$, where the orderings that reach it are exactly σ_* and its reversal. That the two displayed joins evaluate to $7408/441$ and $100/441$ can be checked by hand from the formula for $\nu(\sigma)$. □

Conditions and scope.

Base and premises
Classical real numbers and finite probability; the census with images of length 7 and the nine counts above; all orderings of its three images.

Conclusion
Every ordering fluctuates at the cubic scale, $V_k/k^3 \to \nu(\sigma)$, and $\nu(\sigma)$ lies between $100/441$ and $7408/441$; the upper value is attained exactly by σ_* and its reversal.

Finite computation
The primitivity, the rate and the limit are proved on the page, and the values at the two displayed joins can be checked by hand. The bounds $100/441 \le \nu(\sigma) \le 7408/441$ and the uniqueness of the maximizers rest on the exhaustive computation in exact rationals over the 1573 triples of image sums that the proof describes and does not print.

The order of postings alone moves the cubic coefficient by a factor of 74.08: holds spread evenly keep the ledger close to its line, holds bunched at the ends of the images push it away. Which orderings are extremal for other neutral Jordan censuses, and when a zero coefficient is possible, are open (Problem 4); so is the positivity of the linear coefficient for unbalanced neutral three-letter ledgers (Problem 3). Two facts there are proved: balanced books have slope 0, and an affine prefix potential, $\delta(\text{prefix}) + H(b) = \mu H(a) + d$ before every letter b of every image $\sigma(a)$, keeps the books balanced.

30.4 The price of a certain change

Chapters 21 and 24 proved the quarter-turn floor: a word that moves a configuration of a register to a different one with certainty drives at least $\pi/2$, less its holding drift, and two entangling tokens attain it. That floor uses only the norms of the generators. The native register has more structure, and it raises the price in exact amounts. Table 30.1 collects the answers.

Definition 30.19 (The native register)**.** In classical mathematics:

1. A *channel* has the eight labels $0, \dots, 7$, read as three bits; the *low-bit partner* of a label flips its last bit, so the low-bit pairs are $\{0,1\},\{2,3\},\{4,5\},\{6,7\}$. A register of n channels has the configurations $u = (u_1, \dots, u_n)$ as orthonormal basis e_u.

2. For labels $i < j \le 6$ the *triad* $(i, j, 7)$ has the generator B with $Be_i = (e_j - e_7)/\sqrt{3}$, $Be_j = (e_7 - e_i)/\sqrt{3}$, $Be_7 = (e_i - e_j)/\sqrt{3}$ and $Be_a = 0$ for the other labels. It is real and antisymmetric, kills $e_i + e_j + e_7$, and has eigenvalues $0, \pm\mathrm{i}$ on the triad, so $\|B\| = 1$ and $e^{\theta B}$ rotates the triad by the angle θ about $(e_i + e_j + e_7)/\sqrt{3}$; $e^{2\pi B/3}$ is the cycle $e_i \mapsto e_j \mapsto e_7 \mapsto e_i$.

3. A *braid token* on channel k has generator θB acting on that channel, for a triad and an angle θ; with $\theta = 0$ it is *idle*. An *entangling token* on channels $k \ne l$ has generator $\frac{\pi}{4}\mathrm{i}S_kF_l$, where S_k multiplies e_u by $(-1)^{\text{number of bits 1 in } u_k}$ and F_l replaces u_l by its partner; channel l is its *target*.

Table 30.1. Prices of a certain change on the native register (drive in units of $\hbar$; B braid drive, N entangling tokens, D holding drift).

Change	Holding	Price or floor
three golden comparisons in a row	none	suffice; two never do
any change of one channel	none	exactly $2\pi/3$
channels changed to low-bit partners	none	exactly $\pi/2$ per channel
both channels of two	none	at least π; exactly π for the cheapest (two low-bit flips), also with entanglement
a channel leaving its low-bit pair	none	braid drive $\geq (\pi/2)\sqrt{3/2}$ there; $\geq 2\pi/3$ with one non-idle braid there
any change, any register	any	$\sqrt{2/3}\,B + N\pi/4 + D \geq \pi/2$
any change of one channel	diagonal	$\geq (\pi/2)\sqrt{3/2} \approx 1.924$
any change of one channel	scalar	exactly $2\pi/3$
one pulse, or repeated equal pulses	label seven	$\geq 2\pi/3$; exact pulses exist
any change	drift $\pi/2$	drive 0 suffices

4. A *word* w is a finite list of tokens. Its *drive* is $g(w) = \sum_t \|G_t\| = B(w) + \frac{\pi}{4}N(w)$, where $B(w)$ sums $|\theta|$ over the braid tokens and $N(w)$ counts the entangling tokens. Its *ideal matrix* is the ordered product of the e^{G_t}. Given a self-adjoint *holding* H and $\hbar, \varepsilon > 0$, the *paid word* W is the product of the paid tokens $e^{-\mathrm{i}\|G_t\|}\exp(G_t - \mathrm{i}\varepsilon H/\hbar)$, as in Chapter 24, and its *drift* is $D = |w|\,\varepsilon\|H\|/\hbar$. At zero holding W is the ideal matrix times a unit phase.

5. The word makes a *certain change* $u \to v$, $u \neq v$, when $|\langle e_v, We_u\rangle| = 1$, that is $We_u = ce_v$ with $|c| = 1$.

Replacing H by $(\varepsilon/\hbar)H$ changes neither W nor D, so statements made in units with $\hbar = \varepsilon = 1$ hold for all $\hbar$ and ε.

Every floor in this section comes from one estimate: an orthogonal projection can gain weight only through the part of the generator that crosses it.

Lemma 30.20 (Speed through a subspace)**.** *Let R be an orthogonal projection, $X_1, \dots, X_m$ skew-Hermitian matrices and ψ a unit vector, and put $\psi_m = e^{X_m}\cdots e^{X_1}\psi$. If $R\psi = 0$ and $\|R\psi_m\| = 1$, then*

$$\sum_{t=1}^{m} \|RX_t(1-R)\| \geq \frac{\pi}{2}.$$

Proof. Follow $\psi(s) = e^{sX_t}\psi_{t-1}$ for $s \in [0,1]$, token after token, and write $p = R\psi(s)$, $q = (1-R)\psi(s)$, $\kappa_t = \|RX_t(1-R)\|$. Since RX_tR is skew-Hermitian, $\frac{d}{ds}\|p\|^2 = 2\,\mathrm{Re}\langle p, RX_t(1-R)q\rangle$, so $|\frac{d}{ds}\|p\|^2| \leq 2\kappa_t\|p\|\|q\|$ with $\|p\|^2 + \|q\|^2 = 1$. Where $0 < \|p\| < 1$, the angle $A = \arcsin\|p\|$ therefore moves at rate at most κ_t. Let s_0 be the last time with $A = 0$ and s_1 the first later time with $A = \pi/2$; between them A climbs from 0 to $\pi/2$ at rate at most κ_t, so $\pi/2 \leq \sum_t \kappa_t$. □

A phase factor does not move $\|R\psi\|$, so the lemma applies to paid words with $X_t = G_t - \mathrm{i}\varepsilon H/\hbar$. With R the projection onto one basis vector e_v, $\|RX(1-R)\|$ is the norm of the off-diagonal part of row v of X. For a braid generator θB that row has two entries of size $|\theta|/\sqrt{3}$ when v lies in the triad, and norm $\sqrt{2/3}\,|\theta|$; for an entangling generator, a signed permutation without fixed points times $\frac{\pi}{4}$, it has one entry of size $\frac{\pi}{4}$.

Golden steps

Theorem 30.21 (Three golden steps change a record with certainty; two never do)**.** *In classical mathematics, consider a register of $n \geq 1$ channels at zero holding, any $\hbar, \varepsilon > 0$, and comparison controllers with reference action $2\pi\hbar$, as in Chapter 21, selecting words of this register. There are three controllers whose words at the ratio φ, run one after another, make a certain change. No two controllers' golden words in a row, and no single golden word, make a certain change.*

Proof. By the drive law of Chapter 21, every controller's word at ratio x has drive $2\pi J(x)$. Two golden words drive $2\pi\varphi^{-3} < \pi/2$, because $\varphi^{-3} = \sqrt{5} - 2 < \frac{1}{4}$, and one drives less; at zero holding the quarter-turn floor of Chapter 24, or Lemma 30.20 with the norms of the generators, excludes a certain change.

For the three, recall $J(\varphi) \geq \frac{1}{9}$ from the opening of this chapter. Let w_0 be the word: a braid token of angle $2\pi/9$ on a triad $(i, j, 7)$ of channel 1, then the braid tokens of angles t and $-t$ on the same triad, with $2t = 2\pi J(\varphi) - 2\pi/9 \geq 0$. It drives $2\pi J(\varphi)$ and its ideal matrix is $e^{2\pi B/9}$. The controller that selects, for records (d, r), two opposite braid tokens of angles $\pm\pi d/r$ satisfies both laws of a controller; change it at the golden records only, selecting w_0 there, which keeps every drive and hence both laws. Three of its golden words multiply to $e^{2\pi B/3}$, the cycle, which moves e_u with $u_1 = i$ to e_v, where v has $v_1 = j$ and agrees with u elsewhere. At zero holding the paid word is this matrix times a phase. □

One channel at zero holding: exactly a third of a turn

On a single channel the only tokens are braids. Each $e^{\theta B}$ is a real rotation fixing $\mathbb{1} = \sum_a e_a$, so the states $x = Ue_a$ reached from a basis vector are real and lie on the sphere

$$\mathcal{S} = \Big\{ x \in \mathbb{R}^8 \;:\; \sum_m x_m = 1,\ \sum_m x_m^2 = 1 \Big\},$$

and a certain change $a \to b$ ends exactly at e_b: its sign is fixed by $\sum_m (Ue_a)_m = \langle \mathbb{1}, Ue_a \rangle = \langle U^{\mathsf{T}}\mathbb{1}, e_a \rangle = 1$. For $x \in \mathcal{S}$ and a label a put

$$h_a(x) = \frac{8x_a - 1}{7} \in [-1, 1],$$

the cosine of the angle between $x - \mathbb{1}/8$ and $e_a - \mathbb{1}/8$, two vectors of squared length $\frac{7}{8}$.

Theorem 30.22 (Floors for one channel)**.** *In classical mathematics, on one channel at zero holding:*

(a) every word that makes a certain change drives at least $\arccos(-\frac{1}{7}) \approx 1.7141$*, and in fact at least* $\frac{\sqrt{21}}{4}\arccos(-\frac{1}{7}) \approx 1.9638$*;*

(b) a word whose nonidle braid tokens all use one triad, and a word of two braid tokens, drive at least $2\pi/3$ *if they make a certain change;*

(c) one braid token of angle $2\pi/3$ *makes a certain change.*

Proof. (a) The vectors $e_a - \mathbb{1}/8$ and $e_b - \mathbb{1}/8$ have inner product $-\frac{1}{8}$, so the angle between them is $\arccos(-\frac{1}{7})$. A rotation $e^{\theta B}$ moves a real vector y by an angle at most $|\theta|$, since $\langle y, e^{\theta B}y\rangle = \|y_0\|^2 + \cos\theta\|y_1\|^2$ with y_0 in the kernel of B and y_1 in its rotation plane, and angles between vectors obey the triangle inequality. That gives the first floor. For the second, let a unit drive turn the triad $(i, j, 7)$. If a is not in the triad, x_a does not move; if it is, $\dot{x}_a = \pm(x_p - x_q)/\sqrt{3}$ with p, q the other two triad labels. The seven amplitudes other than x_a have sum $1 - x_a$ and sum of squares $1 - x_a^2$; the square of a difference of two of them is at most twice their variance sum, so $(x_p - x_q)^2 \le \frac{4}{7}(1 - x_a)(3 + 4x_a)$, while $1 - h_a^2 = \frac{16}{49}(1 - x_a)(3 + 4x_a)$. Hence $|\dot{h}_a| \le \frac{8}{7\sqrt{3}}\sqrt{\frac{4}{7}(1 - x_a)(3 + 4x_a)} = \frac{4}{\sqrt{21}}\sqrt{1 - h_a^2}$, and $\arcsin h_a$ moves at rate at most $4/\sqrt{21}$ per unit drive. Along a certain change $a \to b$ it falls from $\arcsin 1 = \frac{\pi}{2}$ to $\arcsin(-\frac{1}{7})$, a total of $\arccos(-\frac{1}{7})$.

(b) Tokens on one triad commute, so the word is $e^{\Theta B}$ with $|\Theta|$ at most its drive. The diagonal entry of this rotation at a triad label is $(1 + 2\cos\Theta)/3$, and a certain change out of a label needs a zero diagonal entry there (outside the triad nothing moves), so $\cos\Theta = -\frac{1}{2}$ and $|\Theta| \ge 2\pi/3$. For two tokens on different triads, the intermediate state $x = e^{\alpha B'}e_a = e^{-\beta B''}e_b$ is supported both in $\{a\}\cup$ the first triad and in $\{b\}\cup$ the second. If a is outside the first triad, $x = e_a$ and the second token alone makes the change; similarly for b. Otherwise x is supported in the intersection of two distinct triads, at most two labels, and $x_1 + x_2 = 1 = x_1^2 + x_2^2$ forces x to be a basis vector: one of the two tokens alone makes a certain change, and pays $2\pi/3$.

(c) The cycle $e^{2\pi B/3}$ moves e_i to e_j. □

The gap between 1.964 and 2.094 is closed by a second potential, a phase. For labels $a \ne b$ other than 7 put

$$\ell(x) = \frac{x_a + x_b}{2} - x_7 + \mathrm{i}\,\frac{\sqrt{3}}{2}\,(x_b - x_a),$$

the complex coordinate of the projection of x onto the plane of the triad $(a, b, 7)$ orthogonal to its axis. It equals $e^{-\mathrm{i}\pi/3}$ at e_a and $e^{\mathrm{i}\pi/3}$ at e_b, and the rotation of that triad turns it at exactly unit rate. The question is whether other triads can turn it faster.

Lemma 30.23 (The phase turns no faster than its own triad)**.** *In classical mathematics, let $a \neq b$, put $K = \sqrt{21}/4$, $\vartheta_c(x) = \arccos h_c(x)$, and let $\mathscr{E}_{ab}$ be the set of $x \in \mathcal{S}$ with $K(\vartheta_a(x) + \vartheta_b(x)) < 2\pi/3$.*

(a) If $a, b \neq 7$, then on $\mathscr{E}_{ab}$ the real part of ℓ is positive and $|\mathrm{Im}(\ell(Bx)\,\overline{\ell(x)})| \leq |\ell(x)|^2$ for the generator B of every triad.

(b) If $b = 7$, the same holds for $\ell_k(x) = \frac{x_a + x_7}{2} - x_k + \mathrm{i}\frac{\sqrt{3}}{2}(x_7 - x_a)$ whenever x_k is the least amplitude among the labels other than a and 7.

Proof. Write $P = x_a$ and $Q = x_b$. Put $c_0 = -\frac{129}{500}$ and $L = 8\pi/(3\sqrt{21}) \approx 1.828$. On $\mathscr{E}_{ab}$, $\vartheta_a + \vartheta_b < L < \frac{\pi}{2} + 0.258$, so $\cos(\vartheta_a + \vartheta_b) > c_0$, and $\vartheta_b < \pi - \vartheta_a$ gives $h_a + h_b > 0$, that is $4(P + Q) > 1$. As $\cos(\vartheta_a + \vartheta_b) = h_a h_b - \sin\vartheta_a \sin\vartheta_b$, this gives $0 \leq \sin\vartheta_a \sin\vartheta_b < h_a h_b - c_0$; squaring, $h_a^2 + h_b^2 - 2c_0 h_a h_b > 1 - c_0^2$, which with $h = (8x - 1)/7$ reads

$$\Omega = 250000\big((8P-1)^2 + (8Q-1)^2\big) + 129000(8P-1)(8Q-1) - 11434591 > 0.$$

The other labels enter through the Cauchy–Schwarz bound $(\sum_{m\in U} x_m)^2 \leq |U| \sum_{m\in U} x_m^2$ for the set U of labels outside the form and the generator; with the two sums read off the sphere it says $C \geq 0$, where

$$C = |U|\Big(1 - \sum_{m\notin U} x_m^2\Big) - \Big(1 - \sum_{m\notin U} x_m\Big)^2;$$

in (b) the minimality $x_m \geq x_k$ enters as well.

For the generator of the triad $(i, j, 7)$ put $w = -\sqrt{3}\,Bx$, so $w_i = x_j - x_7$, $w_j = x_7 - x_i$, $w_7 = x_i - x_j$ and w vanishes elsewhere. After the factors $\sqrt{3}$ cancel, the rate inequality for the form with labels (a, b, c) reads

$$\big|(w_b - w_a)(x_a + x_b - 2x_c) - (w_a + w_b - 2w_c)(x_b - x_a)\big| \leq (x_a + x_b - 2x_c)^2 + 3(x_b - x_a)^2.$$

When the generator's triad is the form's own, the two sides are equal. Otherwise let F_+ and F_- be the right side plus and minus the expression inside the absolute value; we need $F_\pm \geq 0$, quadratic inequalities in at most five amplitudes. Exchanging a and b in (a) conjugates ℓ and changes neither side; reversing a generator changes the sign of w; exchanging the two outside labels of a disjoint generator changes the sign inside the absolute value. So (a) needs both signs for a generator sharing a, one sign for a disjoint generator, and the positivity of the real part; (b) needs both signs for a generator sharing a, both for one sharing k, and one for a disjoint generator. Write P, Q, R for x_a, x_b, x_c, so that $R = x_7$ in (a) and $Q = x_7$, $R = x_k$ in (b), and S, T for the amplitudes at the generator's labels outside the form.

Two of these are immediate. In (b) the real part is positive because the six amplitudes other than x_a, x_7 sum to $1 - P - Q \geq 6R$ and $4(P + Q) > 1$. For a generator sharing a in (b), one sign reads $F = 2(P - Q)^2 + 2(S - R)(P + Q - 2R) \geq 0$, which holds by minimality, $S \geq R$, and the positive real part.

Each of the others has the certificate of Table 30.2. In each row the quadratic polynomial $F - \lambda C - \kappa\Omega$ has a positive definite matrix in the basis formed by 1 and the amplitudes that occur,

Table 30.2. Certificates for Lemma 30.23. Each row gives an inequality $F \ge 0$, the Cauchy–Schwarz bound C (on $|U|$ outside labels) and multipliers λ, κ such that $F - \lambda C - \kappa\Omega$ has a positive definite matrix; the last column is its least Gaussian pivot, rounded down. The vector $w = (w_a, w_b, w_c)$ is that of the generator, read on the form's labels.

Row	Case	F	$\lvert U\rvert$	λ	κ	Pivot
1	(a), real part	$2g\big(\frac{P+Q}{2}\big) - \frac{1}{50}$	—	0	$8 \cdot 10^{-7}$	0.62
2	(a), shares a	F_-, $w = (S-R,\ 0,\ P-S)$	4	1.5	$4.6 \cdot 10^{-7}$	0.10
3	(a), shares a	F_+, $w = (S-R,\ 0,\ P-S)$	4	1.5	$4.6 \cdot 10^{-7}$	0.47
4	(a), disjoint	F_+, $w = (0,\ 0,\ S-T)$	3	3	$7 \cdot 10^{-7}$	1.56
5	(b), shares a	F_+, $w = (S-Q,\ P-S,\ 0)$	4	1.5	$4.6 \cdot 10^{-7}$	0.47
6	(b), shares k	F_+, $w = (0,\ R-S,\ S-Q)$	4	1.5	$4.6 \cdot 10^{-7}$	0.47
7	(b), shares k	F_-, $w = (0,\ R-S,\ S-Q)$	4	1.5	$4.6 \cdot 10^{-7}$	0.10
8	(b), disjoint	F_-, $w = (0,\ S-T,\ 0)$	3	3	$7 \cdot 10^{-7}$	1.56

in the order $1, P, Q, R, S, T$: Gaussian elimination in that order, in exact rational arithmetic, gives positive pivots, the least of which the table lists. Hence $F > \lambda C + \kappa\Omega > 0$ on $\mathscr{E}_{ab}$. Row 1 serves the real part in (a). Cauchy–Schwarz on the five labels outside $a, b, 7$ says $g(x_7) \le 0$, where

$$g(t) = 6t^2 - 2(1-P-Q)\,t + (1-P-Q)^2 - 5(1-P^2-Q^2).$$

The quadratic g increases for $t \ge (1-P-Q)/6$, a point below $(P+Q)/2$ because $4(P+Q) > 1$, and row 1 gives $2g\big(\frac{P+Q}{2}\big) > \frac{1}{50}$. So $g > 0$ on $[\frac{P+Q}{2}, \infty)$, and $x_7 < \frac{P+Q}{2}$, which says $\operatorname{Re}\ell > 0$. The narrowest margins are in rows 2 and 7, generators sharing one label with the form; there the bound on the two end angles, through Ω, carries the proof. □

Theorem 30.24 (One channel: a certain change costs exactly a third of a turn)**.** *In classical mathematics: on one channel at zero holding, every word that makes a certain change drives at least $2\pi/3$, and one braid token of angle $2\pi/3$ attains it. Consequently there is no certain change of one channel below $2\pi/3$, in particular none that switches between triads.*

Proof. Suppose a word of drive $g < 2\pi/3$ makes a certain change $a \to b$. Reversing it (the inverse tokens in reverse order) gives a change $b \to a$ of the same drive, so we may take $a \ne 7$. By the proof of Theorem 30.22(a), $K\vartheta_a$ moves at rate at most 1 per unit drive; so at every intermediate state x, inside tokens included, $K\vartheta_a(x)$ is at most the drive spent and $K\vartheta_b(x)$ at most the drive remaining. Every state therefore lies in $\mathscr{E}_{ab}$.

If $b \ne 7$, the phase $\Phi = \arg\ell$ is continuous on $\mathscr{E}_{ab}$ by Lemma 30.23(a), and along a braid token $\dot{x} = \theta Bx$ it moves at rate $\theta\operatorname{Im}(\ell(Bx)\overline{\ell(x)})/|\ell(x)|^2$, at most $|\theta|$. So Φ changes by at most g; but it runs from $-\pi/3$ at e_a to $\pi/3$ at e_b. If $b = 7$, use $\Phi(x) = \arg\big(\frac{x_a+x_7}{2} - \min_k x_k + \mathrm{i}\frac{\sqrt{3}}{2}(x_7 - x_a)\big)$, the minimum over the labels other than a and 7. At every point some k attains the minimum, the right derivative of Φ there is that of $\arg\ell_k$ for such a k, and Lemma 30.23(b) bounds it by $|\theta|$; a continuous function whose right derivatives are so bounded moves at rate at most $|\theta|$. The endpoint values are again $\mp\pi/3$, because the minimum is 0 at e_a and at e_7. Either way $g \ge 2\pi/3$, a contradiction. Theorem 30.22(c) gives attainment. □

Conditions and scope.

Base and premises
Classical real and complex matrices; one channel of Definition 30.19; zero holding (or any scalar holding, which only adds a phase).

Conclusion
The cheapest certain change of one eight-state channel costs exactly $2\pi/3$, a third of a turn, and the triad cycle is optimal: in the region that a cheaper word could reach, no triad turns the phase faster than the cycle's own.

Identification
That these tokens are the operations of Recognition Science's register, and that drive measures action in units of $\hbar$.

Not claimed
The price under a nonscalar holding; see below and Section 30.5.

Two conjectures fall with this theorem: that some unentangled word changes a channel with certainty below $2\pi/3$, and that a word switching between triads, with drive in $[\pi/2, 2\pi/3)$, does so. Both are false. The cycle plays the role of a geodesic: inside the region a cheaper word would have to cross, nothing turns faster.

Many channels: a quarter turn per channel, and what it buys

On several channels the entangling tokens become available. Assign each braid token to its channel and each entangling token to its target; the *channel drive* of channel k is the drive of the tokens assigned to it, and the channel drives add up to the drive of the word.

Theorem 30.25 (Drive is additive over changed channels)**.** *In classical mathematics, at zero holding on a register of n channels:*

(a) every word that makes a certain change $u \to v$ has channel drive at least $\pi/2$ on every channel k with $u_k \neq v_k$; hence its drive is at least $\frac{\pi}{2} \cdot \#\{k : u_k \neq v_k\}$;

(b) on two channels, a certain change of both labels drives at least π, and π is the least drive of a certain change of both labels by a word containing an entangling token. So entanglement does not bring a double change below π.

Proof. (a) Apply Lemma 30.20 with R the projection onto the configurations whose channel k shows a label other than u_k: it starts at 0 and ends at 1. A braid token on another channel commutes with R. An entangling token whose target is not k commutes with R as well, because its sign operator is diagonal and its flip acts on its target alone. So only the tokens assigned to channel k contribute, each at most its norm. Summing over the changed channels counts every token at most once.

(b) The floor is (a) with two changed channels. Two entangling tokens on $(1, 2)$ have ideal product $\mathrm{i}S_1F_2$, which flips the low bit of channel 2; two more on $(2, 1)$ flip channel 1. The four tokens drive π and move every configuration to the one with both low bits flipped, up to a phase. □

Theorem 30.26 (Exactly the low-bit masks attain the quarter turn)**.** *In classical mathematics, at zero holding on a register of $n \geq 2$ channels: a certain change $u \to v$ can be made with drive exactly $\frac{\pi}{2} \cdot \#\{k : u_k \neq v_k\}$ if and only if every channel either keeps its label or moves to its low-bit partner. If channel k moves to any other label, its channel drive is at least $\frac{\pi}{2} + \big(1 - \sqrt{2/3}\big)\frac{\pi}{2} \approx 1.859$.*

Proof. Let channel k move to a label v_k outside the low-bit pair $\{u_k, u_k'\}$. Let β_k be the braid drive on channel k and ϵ_k the drive of the entangling tokens targeting k. First, take R the projection onto "channel k shows a label outside $\{u_k, u_k'\}$". Entangling tokens commute with it, since F_k preserves the pair; so Lemma 30.20 charges only braid tokens on k, each at most its norm, and $\beta_k \geq \pi/2$. Second, take R the projection onto "channel k shows v_k". An entangling token targeting k contributes at most $\frac{\pi}{4}$; a braid token θB on k contributes at most the norm of the off-diagonal part of row v_k of θB, which is $\sqrt{2/3}\,|\theta|$. So $\epsilon_k + \sqrt{2/3}\,\beta_k \geq \pi/2$, and

$$\epsilon_k + \beta_k \geq \frac{\pi}{2} + \big(1 - \sqrt{2/3}\big)\beta_k \geq \frac{\pi}{2} + \big(1 - \sqrt{2/3}\big)\frac{\pi}{2}.$$

If the drive equals $\frac{\pi}{2}$ times the number of changed channels, then by Theorem 30.25(a) every changed channel has channel drive exactly $\pi/2$, which this excludes. Conversely, if every changed channel k moves to its partner, pick a channel $l \neq k$ and two entangling tokens on (l, k); the product over the changed channels is a signed permutation times a phase that moves e_u to e_v, with drive $\pi/2$ per changed channel. □

A changed channel that leaves its low-bit pair pays even more in its own braids, whatever the entangling tokens do.

Proposition 30.27 (Leaving a low-bit pair)**.** *In classical mathematics, at zero holding on any register: if a word makes a certain change $u \to v$ in which v_k is neither u_k nor its low-bit partner, its braid tokens on channel k drive at least $\frac{\pi}{2}\sqrt{3/2} \approx 1.924$.*

Proof. Take R as in the first step of the previous proof. For a braid generator B on channel k, the block $RB(1 - R)$ maps the pair into the rest of its triad. If the triad meets the pair in one label p, the block is the off-diagonal part of column p, of norm $\sqrt{2/3}$; if the triad contains both labels of the pair, the block has rank one, sending e_p and $e_{p'}$ to $\pm\frac{1}{\sqrt{3}}$ times the third label, again of norm $\sqrt{2/3}$; otherwise it is 0. Lemma 30.20 gives $\sqrt{2/3}\,\beta_k \geq \pi/2$. □

So a non-partner change costs its channel at least $\frac{\pi}{2}\sqrt{3/2}$, an excess of $(\sqrt{3/2} - 1)\frac{\pi}{2} \approx 0.353$ over the quarter turn. The natural guess is that it costs $2\pi/3$, the one-channel price.

The rate argument forgets that a token turns through a finite angle. One braid token cannot carry a state further from the pair than the angle between the pair and its image. Put

$$\beta(\theta) = \arccos\left|\frac{1 + 2\cos\theta}{3}\right| \in \left[0, \frac{\pi}{2}\right],$$

the angle whose cosine is the modulus of a diagonal entry of $e^{\theta B}$ at a label of its triad.

Theorem 30.28 (Leaving a low-bit pair: an angle budget)**.** *In classical mathematics, at zero holding on any register, let a word make a certain change $u \to v$ in which v_k is neither u_k nor its low-bit partner.*

(a) The angles θ of its braid tokens on channel k satisfy $\sum \beta(\theta) \geq \pi/2$.

(b) $\beta(\theta) \leq \sqrt{2/3}\,|\theta|$ for every real θ; so (a) implies Proposition 30.27.

(c) If all braid tokens on channel k but one are idle, the remaining one has $|\theta| \geq 2\pi/3$: the braid drive on channel k is at least $2\pi/3$.

Proof. (a) Let Q be the projection onto the configurations whose channel k shows u_k or its partner, and for a unit vector ψ let $\alpha(\psi) \in [0, \pi/2]$ be the angle with $\cos\alpha(\psi) = \|Q\psi\|$. Entangling tokens and tokens on other channels commute with Q and leave α unchanged. Let $T = e^{\theta B}$ act on channel k, with $r = |1 + 2\cos\theta|/3$ the modulus of its diagonal entries on the triad and $s = \sqrt{1 - r^2} = \sin\beta(\theta)$. Both blocks $(1-Q)TQ$ and $QT(1-Q)$ have norm at most s. If the triad misses the pair they vanish. If it contains one label p of the pair, T fixes the partner, and both blocks are carried by label p: their norms are those of column and row p of T without the diagonal entry, $\sqrt{1 - r^2}$, since the rows and columns of T are unit vectors. If it contains both labels, the third label c of the triad carries both blocks in the same way, with norm $\sqrt{1 - r^2}$. Hence for a unit ψ with $\alpha(\psi) = \alpha$,

$$\|QTQ\psi\|^2 = \|Q\psi\|^2 - \|(1-Q)TQ\psi\|^2 \geq (1 - s^2)\cos^2\alpha, \qquad \|QT(1-Q)\psi\| \leq s\sin\alpha,$$

so $\|QT\psi\| \geq \cos\beta\cos\alpha - \sin\beta\sin\alpha = \cos(\alpha + \beta)$ when $\alpha + \beta \leq \pi/2$: the token moves α by at most $\beta(\theta)$. The word starts at $\alpha(e_u) = 0$ and ends at $\alpha = \pi/2$, because $QWe_u = cQe_v = 0$. If the angles summed to less than $\pi/2$, induction over the tokens would give $\|QWe_u\| \geq \cos\sum\beta(\theta) > 0$.

(b) If $\sqrt{2/3}\,|\theta| \geq \pi/2$ there is nothing to show. Otherwise $x = |\theta| < \pi$ and it suffices that $g(x) = 1 + 2\cos x - 3\cos(\sqrt{2/3}\,x) \geq 0$. Now $g(0) = 0$ and $g'(x) = \sqrt{6}\sin(\sqrt{2/3}\,x) - 2\sin x \geq 0$ on $[0, \pi]$, because sin is concave there, so $\sin(\lambda x) \geq \lambda\sin x$ for $\lambda \in [0, 1]$, and $\sqrt{6}\sqrt{2/3} = 2$.

(c) An idle token has $\beta(0) = 0$, so by (a) the remaining token has $\beta(\theta) \geq \pi/2$, that is $\cos\theta = -\frac{1}{2}$, and $|\theta| \geq 2\pi/3$. □

So one braid token cannot take a channel off its pair below the one-channel price, whatever else the word does; a cheaper departure interleaves several.

Corollary 30.29 (What a sharp pair floor needs)**.** *In classical mathematics, the following are equivalent:*

(i) for every $\eta > 0$ some register of $n \geq 2$ channels has a word at zero holding that makes a certain change moving channel k off its low-bit pair, with braid drive on channel k below $\frac{\pi}{2}\sqrt{3/2} + \eta$;

(ii) the same, where moreover the word has braid drive below $2\pi/3$ on channel k, at least two braid tokens there that are not idle, and angles with $\frac{\pi}{2} \leq \sum\beta(\theta) \leq \sqrt{2/3}\sum|\theta|$.

Proof. (ii) gives (i) at once. Given (i) and $\eta > 0$, apply (i) with $\eta' = \min\bigl(\eta, \frac{1}{2}(\frac{2\pi}{3} - \frac{\pi}{2}\sqrt{3/2})\bigr) > 0$. The braid drive of the word on channel k is below $2\pi/3$. By Theorem 30.28(a) its angles there sum to at least $\pi/2$, so some braid token on channel k is not idle, and by part (c) not only one; so at least two are not idle, and parts (a) and (b) give the angle inequalities. □

Proposition 30.30 (Every channel price is attained)**.** *In classical mathematics, let $\varpi(a, b)$ be 0 if $a = b$, $\pi/2$ if b is the partner of a, and $2\pi/3$ otherwise. On a register of $n \geq 2$ channels at zero holding, every $u \to v$ is a certain change of some word with drive*

$$\sum_k \varpi(u_k, v_k) = \frac{\pi}{2} \cdot \#\{k \,:\, u_k \neq v_k\} + \frac{\pi}{6} \cdot \#\{k \,:\, v_k \notin \{u_k, u_k'\}\}.$$

On two channels, a flip of one low bit costs exactly $\pi/2$.

Proof. Change one channel at a time. A partner costs two entangling tokens, $\pi/2$. Any two labels lie in a common triad, and on a triad the cycle $e^{2\pi B/3}$ and its inverse together move each label to each other one; that costs $2\pi/3$. Certain transfers compose: if $W_1 e_u = c_1 e_{u'}$ and $W_2 e_{u'} = c_2 e_{u''}$, then $W_2 W_1 e_u = c_1 c_2 e_{u''}$. The last claim combines the construction with Theorem 30.25(a). □

Whether these prices are also lower bounds, that is whether every higher-label change pays the extra sixth of a turn, is open (Problem 10).

Entangling tokens can also reach one channel through a second one that starts and ends at label 0, a returned helper. On two channels, a word *implements the parity phase γ* when for some unit ζ its ideal matrix sends $e_{(a,0)}$ to $\zeta e^{\mathrm{i}\gamma s(a)} e_{(a,0)}$ for every label a, where $S e_a = s(a) e_a$, $s(a) = \pm 1$. Which phases can the helper deliver when every entangling token has the helper as its target?

Theorem 30.31 (One crossing direction gives exactly the eighth turns)**.** *In classical mathematics, on two channels, let γ be real. Some word made of braid tokens on channel 2 and entangling tokens on the channels $(1, 2)$, with target 2, implements the parity phase γ if and only if γ is an integer multiple of $\pi/4$.*

Proof. Only multiples of $\pi/4$. Let J sum over the helper: $J(x \otimes y) = (\sum_m y_m)\, x$, from the register to channel 1. A braid matrix $e^{\theta B}$ is real orthogonal and fixes $\mathbb{1} = \sum_m e_m$, because $B\mathbb{1} = 0$; so its transpose fixes $\mathbb{1}$ too, and J is unchanged by a braid token on channel 2. The entangling token has ideal matrix $X = (1 + \mathrm{i} S_1 F_2)/\sqrt{2}$, since $(S_1 F_2)^2 = 1$, and F permutes labels, so $JX = \kappa J$ with $\kappa = (1 + \mathrm{i}S)/\sqrt{2}$, which multiplies e_a by $e^{\mathrm{i}\pi s(a)/4}$. Token by token, $JW = \kappa^N J$ for a word with N entangling tokens. Applied to $e_{(a,0)}$ for $a = 0$ and $a = 1$, of signs $+1$ and -1, an implementation gives $\zeta e^{\pm \mathrm{i}\gamma} = e^{\pm \mathrm{i}\pi N/4}$. Dividing, $e^{2\mathrm{i}\gamma} = e^{\mathrm{i}\pi N/2}$, so $\gamma - N\pi/4$ is a multiple of π.

Every multiple of $\pi/4$. A braid token on a triad $(p, q, 7)$ carries a real vector y to a real vector z whenever z agrees with y off the triad and has the same triad sum and the same triad sum of squares: the rotation fixes the component along the axis, which the sum determines, and turns the orthogonal component, of length fixed by the two sums, to any direction in its plane. Put $c_\pm = \frac{1 \pm \sqrt{3}}{4}$, $\tau = \sqrt{(1 - c_+)(1 + 3c_+)}$ and

$$p_1 = c_+ e_0 + \tfrac{1}{2}(1 - c_+ + \tau)\, e_1 + \tfrac{1}{2}(1 - c_+ - \tau)\, e_7, \qquad v = c_+(e_0 + e_1) + c_-(e_6 + e_7).$$

All three of e_0, p_1, v have sum 1 and sum of squares 1, because $2c_+ + 2c_- = 1$ and $2c_+^2 + 2c_-^2 = 1$. So a braid token on the triad $(0,1,7)$ carries e_0 to p_1, and one on $(1,6,7)$ carries p_1 to v; call their product R. The vector v is fixed by F, so $X(e_a \otimes v) = e^{i\pi s(a)/4} e_a \otimes v$, and the word R, the entangling token, R^{-1} (the two braid tokens reversed, with opposite angles) sends $e_{(a,0)}$ to $e^{i\pi s(a)/4} e_{(a,0)}$: it implements $\pi/4$ with $\zeta = 1$. Repeating it m times implements $m\pi/4$, and $m \in \{0, \dots, 7\}$ covers every multiple of $\pi/4$ modulo 2π. □

The obstruction is the helper's all-ones component, which no braid rotates and which counts only the crossings. With both directions it no longer applies; whether every phase is then reachable is Problem 23.

Holding

A register holds its configuration under a holding H while tokens run, and the holding acts as a free generator of size $\varepsilon\|H\|/\hbar$ per token. The quarter-turn floor already charges it in full. The finer floors are the following; we use units with $\hbar = \varepsilon = 1$, which by Definition 30.19 loses nothing.

Theorem 30.32 (The separated action bound)**.** *In classical mathematics: on every register, under every self-adjoint holding H, every word w that makes a certain change satisfies*

$$\frac{\pi}{2} \le \sqrt{2/3}\, B(w) + \frac{\pi}{4} N(w) + D, \qquad D = |w|\,\|H\|,$$

while its drive is $g(w) = B(w) + \frac{\pi}{4} N(w)$. Consequently a word with no entangling token and drift $D < \pi/4$ drives at least $7\pi/24$, and a word that drives less than $\pi/2$ contains at most one entangling token.

Proof. Apply Lemma 30.20 with R the projection onto e_v and $X_t = G_t - iH$. The off-diagonal row of X_t has norm at most that of G_t plus $\|H\|$, and the row norms of braid and entangling generators are $\sqrt{2/3}\,|\theta|$ (or 0) and $\frac{\pi}{4}$. With no entangling token and $D < \pi/4$, $\sqrt{2/3}\,B > \pi/4$, so $B > \frac{\pi}{4}\sqrt{3/2} > \frac{\pi}{4} \cdot \frac{7}{6} = \frac{7\pi}{24}$. Two entangling tokens alone drive $\pi/2$. □

At drift $\pi/4$ one entangling token flips a low bit for drive $\pi/4$ (Problem 21). Just below that drift a flip for little more than $\pi/4$ needs one entangling token and a little braid drive; with two tokens the word is forced.

Proposition 30.33 (Two-token flips below a quarter turn of holding)**.** *In classical mathematics, on two channels in units $\hbar = \varepsilon = 1$:*

(a) let a word of two tokens, exactly one of them entangling and every braid angle below $\pi/4$ in absolute value, under a self-adjoint holding H with drift $2\|H\| = \pi/4 - \delta$, $\delta > 0$, move the configuration $(0,0)$ to $(1,0)$ with certainty. Then the word is one entangling token on the channels $(2,1)$, with target 1, and one braid token on channel 1 on the triad $(0,1,7)$, in either order;

(b) consequently the following are equivalent: (i) there are $K > 0$ and $\delta_0 \in (0, \pi/4)$ such that for every $\delta \in (0, \delta_0)$ some two-token word with exactly one entangling token, under some self-adjoint holding of drift $\pi/4 - \delta$, moves $(0,0)$ to $(1,0)$ with certainty with braid drive at most $K\sqrt{\delta}$; (ii) the same with the word restricted to the two words of (a).

Proof. (a) Let R project onto the configurations whose channel 1 shows 1, and R' onto those whose channel 1 does not show 0. The change starts outside the range of each and ends inside it. Lemma 30.20 with $X_t = G_t - \mathrm{i}H$ and $\|RX_t(1-R)\| \le \|RG_t(1-R)\| + \|H\|$ gives $\sum_t \|RG_t(1-R)\| \ge \frac{\pi}{2} - 2\|H\| = \frac{\pi}{4} + \delta$, and likewise for R'. A token that commutes with the projection contributes 0, the entangling token at most $\pi/4$ and a braid token at most $|\theta| < \pi/4$; so the entangling token does not commute with R, which excludes the token with target 2, whose action on channel 1 is a diagonal sign. Then the braid token contributes at least $\delta > 0$ for R and for R'. A braid token on channel 2 commutes with both; on channel 1, one whose triad misses label 1 commutes with R, and one whose triad misses label 0 commutes with R'. The only triad containing 0 and 1 is $(0, 1, 7)$.

(b) The two words of (a) have one entangling token, braid drive $|\theta|$ and drift $2\|H\|$, so (ii) gives (i). Given (i), shrink δ_0 until $K\sqrt{\delta_0} < \pi/4$; then every braid angle of a witness is below $\pi/4$, and (a) applies. □

Theorem 30.34 (Diagonal holding)**.** *In classical mathematics: on one channel, under any holding diagonal in the labels and for any $\hbar, \varepsilon > 0$, every word that makes a certain change drives at least $\frac{\pi}{2}\sqrt{3/2} \approx 1.924$.*

Proof. A diagonal holding adds nothing to the off-diagonal row of X_t, so Lemma 30.20 with R onto e_v gives $\sqrt{2/3}\, g(w) \ge \pi/2$. □

A scalar holding $H = s \cdot 1$ multiplies every paid token by a phase, so it leaves the one-channel price at exactly $2\pi/3$ (Theorem 30.24). Between the scalar case and the floor of Theorem 30.34 lies the simplest nonscalar holding: $H = P_7$, the projection onto the label 7 of one channel. One braid pulse on the triad $(i, j, 7)$ under it, for a duration $\varepsilon > 0$, is up to a phase $\exp(\theta B - \mathrm{i}\varepsilon P_7)$, which is the identity off the triad and on the triad, in the coordinates $(i, j, 7)$, the matrix $A = \theta B - \mathrm{i}\varepsilon E$, E the projection onto the third coordinate. For a real root x of

$$p(x) = x^3 - \varepsilon x^2 - \theta^2 x + \tfrac{1}{3}\theta^2 \varepsilon,$$

a direct computation shows that $\omega(x) = (\theta^2 - \mathrm{i}\sqrt{3}\,\theta x,\ \theta^2 + \mathrm{i}\sqrt{3}\,\theta x,\ \theta^2 - 3x^2)$ satisfies $A\omega(x) = -\mathrm{i}x\,\omega(x)$. Write $\gamma(x) = x - 2\arctan(\sqrt{3}x/\theta)$ for $\theta \ne 0$.

Theorem 30.35 (One pulse under label-seven holding)**.** *In classical mathematics, on one channel with $H = P_7$, $\hbar = 1$ and $\varepsilon > 0$:*

(a) if one braid pulse of angle θ makes a certain change, then $|\theta| \ge 2\pi/3$, and the change exchanges the two labels of its triad other than 7;

(b) a certain single pulse exists: there are θ and $\varepsilon > 0$ for which the pulse makes a certain change;

(c) a word of two pulses, one of which has angle 0, drives at least $2\pi/3$ if it makes a certain change.

Proof. (a) A certain change must stay in the triad. Since $U = e^A$ commutes with A, $Ue_a = ce_b$ gives $\langle e_a, Ae_a\rangle = \langle Ue_a, AUe_a\rangle = \langle e_b, Ae_b\rangle$; the diagonal of A is $(0, 0, -\mathrm{i}\varepsilon)$, so $\{a, b\} = \{i, j\}$, say

$a = i$ and $b = j$. For every real root x of p, $\langle e_j, U\omega(x)\rangle = e^{-\mathrm{i}x}\omega_j(x)$ and also $= \langle U^* e_j, \omega(x)\rangle = c\,\omega_i(x)$. With $y = \sqrt{3}x/\theta$ this says $c(1 - \mathrm{i}y) = e^{-\mathrm{i}x}(1 + \mathrm{i}y)$, that is $c = e^{-\mathrm{i}\gamma(x)}$. Two roots therefore have γ-values differing by a multiple of 2π. Let $t = |\theta| < 2\pi/3$ and $s = t/\sqrt{3}$. From $p(-t) = -\frac{2}{3}\varepsilon t^2 < 0$, $p(-s) = 2s^3 > 0$, $p(0) > 0$ and $p(s) = -2s^3 < 0$, there are roots $-\alpha \in (-t, -s)$ and $\beta \in (0, s)$. If $\theta > 0$: arctan is concave on $[0, \sqrt{3}]$, so $\arctan y \geq \frac{\pi}{3} \cdot \frac{y}{\sqrt{3}}$ there, and $2\arctan(\sqrt{3}\alpha/t) - \alpha \geq (\frac{2\pi}{3t} - 1)\alpha > 0$; also it is below $2\pi/3$. So $\gamma(-\alpha) \in (0, \frac{2\pi}{3})$, likewise $\gamma(\beta) \in (-\frac{2\pi}{3}, 0)$, and their difference lies in $(0, \frac{4\pi}{3})$. If $\theta < 0$: $\gamma(\beta) > 0 > \gamma(-\alpha)$, and the difference is $\alpha + \beta + 2\arctan(\sqrt{3}\alpha/t) + 2\arctan(\sqrt{3}\beta/t)$. The roots of p sum to ε and multiply to $-\frac{1}{3}\theta^2\varepsilon$, so $\alpha\beta(\varepsilon + \alpha - \beta) = \frac{1}{3}t^2\varepsilon$ and, as $\alpha > \beta$, $\alpha\beta < t^2/3$. Then $\frac{3\alpha\beta}{t^2} < 1$ puts the two arctangents below $\frac{\pi}{2}$ in sum, and $3\alpha(\alpha + \beta) < 3\alpha^2 + t^2 < 4t\alpha$ (as $\frac{t}{3} < \alpha < t$) gives $\alpha + \beta < \frac{4t}{3} < \frac{8\pi}{9}$. The difference lies in $(0, 2\pi)$. In both cases no multiple of 2π fits; and $\theta = 0$ gives a diagonal U.

(b) Conversely, if p has three distinct roots whose γ-values agree modulo 2π, put $c = e^{-\mathrm{i}\gamma}$. Then $U^* e_j - \bar{c} e_i$ is orthogonal to the three eigenvectors $\omega(x)$, which form a basis, so $|\langle e_j, U e_i\rangle| = 1$. Take $\theta = -T$ with $T > 0$, so that $\gamma(x) = x + 2\arctan(\sqrt{3}x/T)$, and scale $x = Ty$, $\varepsilon = \mu T$: the roots solve $y^3 - \mu y^2 - y + \frac{\mu}{3} = 0$. For $s \in [\frac{1}{4}, \frac{1}{2}]$ let $\mu(s) = 3s(s^2 - 1)/(3s^2 - 1) > 0$, so that s is a root, and let the other roots be $y_\pm = \frac{1}{2}\big(\mu - s \pm \sqrt{\Delta}\big)$ with $\Delta = \mu^2 + 2\mu s - 3s^2 + 4$; then $y_- < s < y_+$. With $\mathscr{A}(y) = \arctan(\sqrt{3}y)$, the choice $T(s) = \big(2\pi - 2(\mathscr{A}(s) - \mathscr{A}(y_-))\big)/(s - y_-) > 0$ makes the γ-values of Ty_- and Ts differ by exactly 2π, and $F(s) = T(s)(y_+ - s) + 2(\mathscr{A}(y_+) - \mathscr{A}(s)) - 2\pi$ measures the other gap. At $s = \frac{1}{4}$: $\mu = \frac{45}{52}$, $\Delta = \frac{844}{169}$, $\frac{24}{13} < \sqrt{\Delta} < 3$, and $\mathscr{A}(\frac{1}{4}) \geq \frac{\pi}{8}$, $\mathscr{A}(y_-) \leq -\frac{\pi}{4}$, $\mathscr{A}(y_+) \leq \frac{5\pi}{12}$ (using $\tan\frac{5\pi}{12} = 2 + \sqrt{3}$); the first two bound the numerator of T by $\frac{5\pi}{4}$, and $\sqrt{\Delta} > \frac{24}{13}$ bounds $\frac{5}{4}(y_+ - \frac{1}{4})/(\frac{1}{4} - y_-)$ by $\frac{17}{12}$, so $F(\frac{1}{4}) < \frac{17\pi}{12} + \frac{7\pi}{12} - 2\pi = 0$. At $s = \frac{1}{2}$: $\mu = \frac{9}{2}$, $\Delta = 28$, and $\mathscr{A}(\frac{1}{2}) \leq \frac{\pi}{4}$, $\mathscr{A}(y_-) \geq -\frac{\pi}{3}$, $\mathscr{A}(y_+) \geq \frac{\pi}{3}$ bound the numerator of T below by $\frac{5\pi}{6}$, and $\sqrt{\Delta} < 8$ gives $\frac{5}{6}(y_+ - \frac{1}{2})/(\frac{1}{2} - y_-) > \frac{11}{6}$, so $F(\frac{1}{2}) > \frac{11\pi}{6} + \frac{\pi}{6} - 2\pi = 0$. By the intermediate value theorem $F(s_*) = 0$ for some s_*; the three roots at s_* then have γ-values agreeing modulo 2π. Numerically $s_* \approx 0.3672$, $T \approx 3.0216$ and $\varepsilon \approx 4.8358$; only the existence is proved.

(c) The idle pulse is a diagonal unitary, which leaves the moduli of all entries unchanged; so the word has the entry moduli of the other pulse alone, and (a) applies. □

So the conjecture that a positive label-seven holding forbids every exact single pulse is false; but every exact pulse costs at least the cycle, and the holding turns the cycle's continuous family of exact transfers into isolated resonances. Whether the cheapest resonance is attained, and where, is open (Problem 25); numerical searches find one at $|\theta| \approx 2.7071$, $\varepsilon \approx 8.4221$, below the large-detuning limit $\pi\sqrt{3}/2 \approx 2.7207$.

Below that limit an exact pulse cannot drift off to long durations.

Theorem 30.36 (Cheap exact pulses have bounded duration)**.** *In classical mathematics, on one channel with $H = P_7$ and $\hbar = 1$: if one braid pulse of angle θ on the triad $(i, j, 7)$, for a duration $\varepsilon > 0$, moves e_i to e_j with certainty, then*

$$\varepsilon^2\Big(\frac{\pi\sqrt{3}}{2} - |\theta|\Big) \leq 100.$$

Proof. Write $t = |\theta|$ and $L = \pi\sqrt{3}/2$. If $t \geq L$ there is nothing to show. By Theorem 30.35(a), $t \geq 2\pi/3$, so $L - t < 1$, and for $\varepsilon < 4$ the left side is below 16. Let $\varepsilon \geq 4$ and $t < L$, so $t^2 < 3\pi^2/4 < 15/2$.

Roots. The cubic p of Theorem 30.35 has $p(0) = t^2\varepsilon/3 > 0$ and $p(\varepsilon) = -2t^2\varepsilon/3 < 0$, and with $h = 4t^2/(3\varepsilon)$ a direct expansion gives $p(\varepsilon + h) = \frac{2}{3}t^2\varepsilon + \frac{5}{3}t^2h + h^3 > 0$. So p has roots $b < 0 < a < \varepsilon < c$ with $\varepsilon(c - \varepsilon) < 4t^2/3$, and $a + b + c = \varepsilon$, $abc = -t^2\varepsilon/3$.

The phase condition. By the proof of Theorem 30.35(a), the two roots have $\gamma(a) - \gamma(b) \in 2\pi\mathbb{Z}$, that is $g \mp 2(\arctan A - \arctan B) \in 2\pi\mathbb{Z}$ with $g = a - b > 0$, $A = \sqrt{3}a/t > 0 > B = \sqrt{3}b/t$, and the sign $\mp$ that of θ. Here $-AB = -3ab/t^2 = \varepsilon/c < 1$, and for positive u, v with $uv < 1$, $\arctan u + \arctan v = \frac{\pi}{2} - \arctan\frac{1-uv}{u+v}$; so $\arctan A - \arctan B = \frac{\pi}{2} - \arctan\rho$ with

$$\rho = \frac{1 + AB}{A - B} = \frac{t(c - \varepsilon)}{\sqrt{3}\, g\, c} > 0,$$

using $t^2 + 3ab = t^2(c - \varepsilon)/c$. Hence $g + \sigma(\pi - 2\arctan\rho) = 2\pi n$ for a sign σ and an integer n. As $0 < \pi - 2\arctan\rho < \pi$ and $g > 0$: if $\sigma = +1$ then $n \geq 1$ and $g > \pi$; if $\sigma = -1$ then $n \geq 0$ and $g \geq \pi - 2\arctan\rho$. Either way $g \geq \pi - 2\rho$.

The bounds. From $a + b = \varepsilon - c$ and $ab = -t^2\varepsilon/(3c)$, $g^2 = (c - \varepsilon)^2 + 4t^2\varepsilon/(3c)$. Since $\varepsilon(c - \varepsilon) < 10 \leq \frac{5}{8}\varepsilon^2$, $c < \frac{13}{8}\varepsilon$ and $g^2 > \frac{32}{39}t^2 > \frac{3}{4}t^2$, so $\sqrt{3}\, g > \frac{3}{2}t$, and then

$$\varepsilon^2\rho = \frac{\varepsilon t \cdot \varepsilon(c - \varepsilon)}{\sqrt{3}\, g\, c} < \frac{\varepsilon t \cdot 4t^2/3}{\frac{3}{2}t \cdot \varepsilon} = \frac{8}{9}t^2, \qquad \varepsilon^2 g^2 < \frac{16t^4}{9} + \frac{4t^2\varepsilon^2}{3},$$

the second because $\varepsilon(c - \varepsilon) < 4t^2/3$ and $\varepsilon/c < 1$. In particular $\rho < \frac{8}{9} \cdot \frac{15}{2} \cdot \frac{1}{16} < \frac{1}{2}$, so $g^2 \geq (\pi - 2\rho)^2 \geq \pi^2 - 4\pi\rho$, and

$$\varepsilon^2\Big(\frac{3\pi^2}{4} - t^2\Big) < \frac{3}{4}\Big(\frac{16t^4}{9} + 4\pi \cdot \frac{8}{9}t^2\Big) = \frac{4t^4 + 8\pi t^2}{3} < \frac{4 \cdot \frac{225}{4} + 8 \cdot 3.15 \cdot \frac{15}{2}}{3} = 138.$$

Finally $L^2 - t^2 = (L - t)(L + t)$ with $L + t > L > \frac{5}{2}$, so $\varepsilon^2(L - t) < 138/\frac{5}{2} < 56$. □

So an exact pulse cheaper than $\pi\sqrt{3}/2$ by η has $\varepsilon \leq 10/\sqrt{\eta}$; exchanging i and j turns B into $-B$, so this covers every certain single pulse. Numerically the best constant is about 0.97.

Proposition 30.37 (Repeated pulses are one longer pulse)**.** *In classical mathematics, under the holding P_7 with $\hbar = 1$ and $\varepsilon > 0$: m identical braid pulses of angle θ have exactly the entry moduli of one pulse of angle $m\theta$ and duration $m\varepsilon$, and drive $|m\theta|$. Hence every word of identical braid pulses that makes a certain change drives at least $2\pi/3$.*

Proof. Each paid pulse is a phase times e^X with $X = \theta B - \mathrm{i}\varepsilon P_7$, and $(e^X)^m = e^{mX}$ is the pulse with angle $m\theta$ and duration $m\varepsilon$. Apply Theorem 30.35(a). □

Repeating a pulse lengthens it. Cutting every pulse of a word into equal pieces does the converse, exactly, and it ties the price at one duration to the price at its multiples.

Proposition 30.38 (Subdividing pulses)**.** *In classical mathematics, on one channel with $\hbar = 1$: for a word w and $m \geq 1$ let $w^{(m)}$ replace each braid token of angle θ by m braid tokens of angle θ/m on the same triad. Call a word* certain *at duration ε when its paid word under the holding P_7 at that duration makes a certain change.*

(a) For every holding H, the entries of the paid word of $w^{(m)}$ at duration ε have the moduli of those of w at duration $m\varepsilon$; $w^{(m)}$ has the drive of w and $m|w|$ tokens.

(b) Under the holding P_7: if every certain word at duration ε drives at least $2\pi/3 + \eta$, then so does every certain word at duration $m\varepsilon$.

(c) Under P_7, the statement for every $\eta > 0$ there are $\varepsilon > 0$ and a certain word of drive below $2\pi/3 + \eta$ *is equivalent to* for all $\eta, \delta > 0$ and every count N there are $\varepsilon \in (0, \delta)$ and a certain word of at least N tokens with drive in $[\frac{\pi}{2}\sqrt{3/2}, \frac{2\pi}{3} + \eta)$.

(d) Under P_7, the statement for every $\varepsilon > 0$ and $\eta > 0$ some certain word at duration ε drives below $2\pi/3 + \eta$ *is equivalent to the same statement for $\varepsilon \geq 1$, with drive at least $\frac{\pi}{2}\sqrt{3/2}$; and it fails exactly when some $\varepsilon, \eta > 0$ make every certain word at every duration $m\varepsilon$, $m \geq 1$, drive at least $2\pi/3 + \eta$.*

Proof. (a) The m pieces of a paid token give $\left(e^{-\mathrm{i}\|G\|/m} e^{G/m - \mathrm{i}\varepsilon H}\right)^m = e^{-\mathrm{i}\|G\|} e^{G - \mathrm{i}m\varepsilon H}$, the paid token at duration $m\varepsilon$; drive and length are clear. (b) A certain word at duration $m\varepsilon$ that drove less would give, by (a), a certain word at duration ε with the same drive. (c) One direction is immediate. Conversely, given a word at duration ε, which has at least one token, take $m > \max(N, \varepsilon/\delta)$ and $w^{(m)}$ at duration ε/m; its drive is at least $\frac{\pi}{2}\sqrt{3/2}$ by Theorem 30.34. (d) For $\varepsilon < 1$ apply the statement at $m\varepsilon \geq 1$ and subdivide. If the statement fails at ε with some η, (b) carries the gap to every $m\varepsilon$; the converse is the case $m = 1$. □

The total holding exposure is the same in both words; only its grain changes. So a surcharge for exact change under the holding cannot be confined to faint holdings (Problem 20).

Holding can also do work. The next constructions show that the floors above are not empty statements about drive alone.

Proposition 30.39 (Holding that works)**.** *In classical mathematics, in units with $\hbar = \varepsilon = 1$:*

(a) on every register, for all configurations u, v there are a holding and a word of drive 0 with drift exactly $\pi/2$ that moves u to v with certainty;

(b) on every register, for every channel k, label $b \neq u_k$ and $0 \leq d \leq 2\pi/3$, there are a holding and a word with drift exactly d and drive exactly $2\pi/3 - d$ that sets channel k to b with certainty;

(c) for every flip of one low bit and every $D > \pi/6$ there are a holding and a word with drift at most D and drive below $\pi/2$ that make it.

Proof. (a) Let Σ exchange e_u and e_v and fix the other basis vectors; it is a self-adjoint involution of norm 1. With $H = -\frac{\pi}{2}\Sigma$ and one idle token, the paid word is $e^{\mathrm{i}\pi\Sigma/2} = \mathrm{i}\Sigma$.

(b) Let $G = \pm B$ be the generator, on channel k, of a triad containing u_k and b, with the sign chosen so that $e^{2\pi G/3}$ moves u_k to b. Take $H = \mathrm{i}\, dG$, which is self-adjoint of norm d, and one braid token $(\frac{2\pi}{3} - d)G$. The paid token is a phase times $\exp((\frac{2\pi}{3} - d)G + dG) = e^{2\pi G/3}$.

(c) Use (b) with b the partner and $\frac{\pi}{6} < d \le \min(D, \frac{2\pi}{3})$: the drive $\frac{2\pi}{3} - d$ is below $\frac{\pi}{2}$. □

How the price falls as holding is allowed is the main open question of this section; two curves frame it. The line $2\pi/3 - \frac{4}{3}D$ joins the zero-holding price to the pure-holding point $(\pi/2, 0)$ of (a), and every certain one-channel word is conjectured to lie on or above it (Problem 11). The aligned construction (b) runs along $2\pi/3 - D$, above the line. A geometric argument on the cone that a driven triad state sweeps suggests the exact price

$$\mathsf{P}(D) = \frac{2\pi}{3} - \arccos\frac{3\cos D - 1}{2}, \qquad 0 \le D \le \frac{\pi}{2}$$

(Problem 13); it runs from $\mathsf{P}(0) = 2\pi/3$ to $\mathsf{P}(\pi/2) = 0$ and reaches $\pi/2$ at $D_1 = \arccos\frac{1+\sqrt{3}}{3} \approx 0.4259$. If it is the price, the line is never approached at intermediate drift (Problem 12):

Proposition 30.40 (The conjectured curve lies above the line)**.** *In classical mathematics,* $\mathsf{P}(D) \ge \frac{2\pi}{3} - \frac{4}{3}D$ *for* $0 \le D \le \frac{\pi}{2}$*, with strict inequality for* $0 < D < \frac{\pi}{2}$.

Proof. The claim is $\arccos\frac{3\cos D-1}{2} \le \frac{4}{3}D$, that is $\frac{3\cos D-1}{2} \ge \cos\frac{4D}{3}$, since $\frac{4D}{3} \le \frac{2\pi}{3}$. With $c = \cos\frac{D}{3}$, $\cos D = 4c^3 - 3c$ and $\cos\frac{4D}{3} = 8c^4 - 8c^2 + 1$, and the difference is

$$\frac{3\cos D - 1}{2} - \cos\frac{4D}{3} = 8(1-c)\Big(c^2 - \frac{3}{4}\Big)\Big(c + \frac{1}{4}\Big),$$

which is nonnegative for $c \in [\frac{\sqrt{3}}{2}, 1]$ and positive inside. □

30.5 Open problems

Each problem is stated exactly, in the notation of the section that introduces it: in classical mathematics where it concerns classical objects, and on $\mathbb{R}_\delta$ where it asks for a price. Problems 1–25 belong to this chapter. Problems 26 onwards collect, by subject, what the rest of the book leaves open, each with a pointer to the result that proves what is known around it. Where a problem is equivalent to a sharper statement, both forms are given with the reason; numerical exploration and finite searches are reported as evidence, not proof.

Self-similar ledgers

1. *Rates with a hold letter.* For the three-letter joins $\sigma(a) = \mathsf{d}^{A(a)}\mathsf{c}^{B(a)}\mathsf{h}^{H(a)}$ given by nine counts: (i) if such a join is primitive and has rate r, then $-1 < r < 1$ and r is a root of a nonzero integer polynomial of degree at most 3; (ii) every irrational $r \in (-1, 1)$, other than $\sqrt{2}/2$, that is a root of a nonzero integer polynomial of degree at most 3 is the rate of a primitive such join. By Theorem 30.17 this is equivalent to: the rates of primitive three-letter joins are exactly the numbers in $(-1, 1)$ algebraic of degree at most 3.

2. *How fast a neutral ledger wanders.* For every primitive two-letter join with rate r and $|\mu| = 1$, the limit v of Theorem 30.15 satisfies $12v \le (\lambda^2 - 1)(1 + |r|)^2$. Proposition 30.16 gives equality at every integer $\lambda \ge 2$ with $r = 0$. Evidence: exact checks of many thousands of primitive neutral joins with $\lambda \le 6$ found no violation, and equality only at $r = 0$.

3. *The neutral variance law with a hold letter.* Let σ be a primitive three-letter join with rate r, and let $|\mu| = 1$ with $\delta_r(\sigma(a)) = \mu\,\delta_r(a)$ for each letter a. If σ does not keep balanced books, then V_k/k converges to a positive limit. This is equivalent to the three-letter form of Theorem 30.15.

4. *Extremal orderings of a Jordan census.* Let a primitive three-letter join with rate 0 have images of one length L, and let $u \ne 0$ be a letter weight and $c \ne 0$ a constant with $u(\sigma(a)) = u(a)$ and $\mathrm{bal}(\sigma(a)) = \mathrm{bal}(a) + c\,u(a)$ for every letter a. Then (i) among the joins with the same nine counts, one whose images are each sorted by u (nondecreasing or nonincreasing) has a limit of V_k/k^3 at least as large as every limit attained by another; and (ii) some join with the same counts has $V_k/k^3 \to 0$ if and only if all nonzero values of u have the same absolute value. Part (i) holds for the census of Theorem 30.18; what remains is equivalent to (i) for every other such census together with (ii).

Simultaneous approximation

5. *A pair from two quadratic fields.* There is $c > 0$ with $\sqrt{|k|}\max\bigl(|k(\sqrt{5}-2)-m|,\ |k\tfrac{3\sqrt{2}}{2}-n|\bigr) \ge c$ for all integers $k \ne 0$, m, n. By Theorem 30.5 this is equivalent to the exponent $\tfrac{3}{2}$ for three probes at φ, φ^2 and $\sqrt{2}$. Every exponent above $\tfrac{3}{2}$ follows from Schmidt's theorem.

6. *Cusick's bound.* $S(\alpha, \beta) \le \tfrac{2}{7}$ for all real α, β [79]. By Theorem 30.7 this is equivalent to: no two probes in $(1, \varphi^2)$ have separation score above $2\pi^2/7$.

7. *Unimodular bases of $\mathbb{Z}[\vartheta]$.* With $\vartheta = 2\cos(2\pi/7)$: for every $\eta > 0$ there are integers p, q, r, s with $ps - qr = 1$ and $\tfrac{2}{7} - \eta < S(p\vartheta + q\vartheta^2,\ r\vartheta + s\vartheta^2) < \tfrac{2}{7}$. By Proposition 30.8 this is equivalent to integral cubic probe designs approaching the score $2\pi^2/7$ from below.

8. *Index-two coordinates.* (i) $S(p\vartheta + q\vartheta^2,\ r\vartheta + s\vartheta^2) \le \tfrac{1}{14}$ whenever $ps - qr = 2$; (ii) for every $\eta > 0$ some such pair has $\tfrac{1}{14} - \eta < S < \tfrac{1}{14}$. Evidence: evaluating a formula of Cusick's type for these modules over all determinant-two integer matrices with entries up to 14 puts the supremum near 0.0649, below $\tfrac{1}{14} \approx 0.0714$; if that is right, (i) holds with a gap and (ii) fails.

Certain change

In the problems on holding, "certain word" means a word whose paid word makes a certain change, and units are $\hbar = \varepsilon = 1$ unless the holding is P_7, where $\hbar = 1$ and $\varepsilon > 0$ is free.

9. *Free phase gates.* On one channel, allow besides braid tokens free *phase gates*, diagonal unitaries $e_a \mapsto e^{\mathrm{i}\phi(a)}e_a$ of drive 0. Is there such a word that makes a certain change with

drive below $2\pi/3$? Equivalently: one with at least two nonidle braid tokens and some phase gate that is not a multiple of the identity. Proved: with at most one nonidle braid token the price stays $2\pi/3$, because the phase gates only multiply rows and columns by units, and with scalar phase gates only it stays $2\pi/3$, because they factor out. Conjectured answer: no.

10. *The higher-label surcharge.* On every register of $n \geq 2$ channels at zero holding, every certain change $u \to v$ with at least one channel moving outside its low-bit pair drives at least $\frac{\pi}{2} \cdot \#\{k : u_k \neq v_k\} + \frac{\pi}{6} \cdot \#\{k : v_k \notin \{u_k, u'_k\}\}$. This is equivalent to the exactness of the prices of Proposition 30.30. Proved: Theorem 30.26 and Proposition 30.27.

11. *The four-thirds floor.* On one channel, under every self-adjoint holding, every certain word satisfies $g(w) + \frac{4}{3}D \geq \frac{2\pi}{3}$. Proved: at drift 0, for scalar holding, and when $D \geq \pi/2$ or $g(w) \geq 2\pi/3$; what remains is equivalent to the case of nonempty words with $0 < D < \pi/2$, $0 < g(w) < 2\pi/3$ and $g(w) + D \geq \pi/2$, under holdings that are not multiples of the identity and cannot be shortened in norm by adding one. Indeed, adding $s \cdot 1$ to the holding multiplies the paid word by a unit phase, so the word stays certain, and a real s that minimises the norm can only lower D; and a certain word below the floor has all the listed properties, by Theorem 30.24, the scalar case and Theorem 30.32.

12. *Approaching the line.* For every $0 < d < \pi/2$ and $\eta > 0$ there are a holding and a certain one-channel word with drift at most d and drive at most $\frac{2\pi}{3} - \frac{4}{3}d + \eta$. Conjectured answer: no; the aligned construction of Proposition 30.39(b) stays $\frac{d}{3}$ above the line, and if the curve of Problem 13 is the price, this fails.

13. *The one-channel price under holding.* (i) Every certain one-channel word with drift $D \leq \pi/2$ drives at least $\mathsf{P}(D)$; (ii) for all labels $u \neq v$, every $D \in [0, \pi/2]$ and $\eta > 0$, some certain word $u \to v$ has drift at most D and drive at most $\mathsf{P}(D) + \eta$. Both endpoints are proved (Theorem 30.24 and Proposition 30.39(a)). Evidence: numerical optimisation matches P to six digits at several drifts, and searches over all eight labels never beat it.

14. *One holding for several channels.* On $n \geq 2$ channels, for changes $u \to v$ in which k channels change and none moves to its partner, the price at drift $D \in [0, \pi/2]$ is $k\big(\frac{2\pi}{3} - \arccos\big((3(\cos D)^{1/k} - 1)/2\big)\big)$: a lower bound for every certain word, approached within every $\eta > 0$. At $D = 0$ this contains the surcharge of Problem 10 for such changes. Conjectured answer: no.

15. *A threshold for flips.* On $n \geq 2$ channels, for a flip of one low bit: (i) every certain word with drift at most $D_1 = \arccos\frac{1+\sqrt{3}}{3}$ drives at least $\pi/2$; (ii) for every $D > D_1$ some certain word has drift at most D and drive below $\pi/2$. Proved: (ii) for $D > \pi/6$, and any word below $\pi/2$ has at most one entangling token (Theorem 30.32).

16. *The braid cost of leaving a pair.* On $n \geq 2$ channels at zero holding, a certain change that moves channel k off its low-bit pair spends at least $2\pi/3$ of braid drive on channel k. Proved: $\frac{\pi}{2}\sqrt{3/2}$ (Proposition 30.27), the angle budget $\sum \beta(\theta) \geq \pi/2$, and $2\pi/3$ whenever only one braid token on channel k is not idle (Theorem 30.28). Evidence that it is false: if exact rotations inside the low-bit pairs were free, searches reach 1.9512; see Problem 23.

17. *Is the pair floor sharp?* For every $\eta > 0$ some register of $n \geq 2$ channels has a certain change at zero holding that moves channel k off its low-bit pair with braid drive on channel k below $\frac{\pi}{2}\sqrt{3/2} + \eta$. By Corollary 30.29 the words may be taken with braid drive below $2\pi/3$ and at least two non-idle braid tokens on channel k, whose angles satisfy $\frac{\pi}{2} \leq \sum \beta(\theta) \leq \sqrt{2/3} \sum |\theta|$. A positive answer would settle Problem 16 in the negative. Evidence: with exact rotations inside the low-bit pairs free, searches level off near 1.945.

18. *Two pulses under label-seven holding.* Every certain word of two braid pulses under P_7 drives at least $2\pi/3$; more strongly, at least the least drive of a certain single pulse. Proved: when one angle is 0, and when the two pulses are identical. Evidence: scans find every certain two-pulse word at drive at least 2.7071.

19. *Many pulses under label-seven holding.* Every certain word of braid pulses under P_7 drives at least $2\pi/3$. Proved for words of identical pulses (Proposition 30.37) and with the floor $\frac{\pi}{2}\sqrt{3/2}$ for all words (Theorem 30.34); what remains is equivalent to words of at least two pulses, not all identical, with drive in $[\frac{\pi}{2}\sqrt{3/2}, \frac{2\pi}{3})$.

20. *Approaching the cycle under label-seven holding.* (i) For every $\eta > 0$ there are a duration $\varepsilon > 0$ and a certain one-channel word under P_7 with drive below $2\pi/3 + \eta$. (ii) For every $\varepsilon > 0$ and every $\eta > 0$ there is such a word at duration ε. By Proposition 30.38, (i) is equivalent to its form with durations below any $\delta > 0$ and words of at least any length N, (ii) to its form for $\varepsilon \geq 1$, and (ii) fails exactly when one surcharge η persists at all durations $\varepsilon, 2\varepsilon, 3\varepsilon, \ldots$. Together with Problem 19, (i) would make $2\pi/3$ the exact price under this holding, approached but perhaps not attained. Evidence: optimisation finds certain words at falling drive as pulses are added, about 2.15 with twenty pulses, and none below $2\pi/3$.

21. *A jump at a quarter turn of holding.* Is there $c > 0$ such that on every register of $n \geq 2$ channels, under every holding with drift below $\pi/4$, every certain flip of one low bit drives at least $\frac{\pi}{4} + c$? (At drift exactly $\pi/4$, one entangling token under the holding $-\frac{\pi}{4} S_l F_k$ makes the flip for drive $\pi/4$.) Equivalently: one-entangler words with braid drive $0 < B < \pi/24$ and drift in $[\frac{\pi}{4} - \sqrt{2/3}\, B, \frac{\pi}{4})$ that make the flip need $B \geq c$. For by Theorem 30.32, $\frac{\pi}{2} \leq \sqrt{2/3}\, B + N\frac{\pi}{4} + D$: below drift $\pi/4$ a word with no entangling token drives more than $\frac{\pi}{4}\sqrt{3/2} > \frac{\pi}{4} + \frac{\pi}{24}$, a word with two or more drives at least $\pi/2$, and a word with exactly one drives $\frac{\pi}{4} + B$, where $D \geq \frac{\pi}{4} - \sqrt{2/3}\, B$ forces $B > 0$; those with $B \geq \pi/24$ already pay $\frac{\pi}{4} + \frac{\pi}{24}$. Conjectured answer: no.

22. *A two-token approach to the quarter turn.* There are $K > 0$ and $\delta_0 \in (0, \pi/4)$ such that for every $\delta \in (0, \delta_0)$ some self-adjoint holding H on two channels with $2\|H\| = \pi/4 - \delta$ and some angle $|\theta| \leq K\sqrt{\delta}$ make one of the two words of Proposition 30.33(a), with braid angle θ, move $(0, 0)$ to $(1, 0)$ with certainty. By Proposition 30.33(b) this is equivalent to the same statement for all two-token words with one entangling token and braid drive at most $K\sqrt{\delta}$; a positive answer would answer Problem 21 in the negative. Evidence that it is false: optimisation over all holdings at $\delta = 0.1$ finds the least defect $1 - |\langle e_{(1,0)}, W e_{(0,0)} \rangle|^2$, namely $\sin^2 \delta$, at $\theta = 0$.

23. *Returned-helper rotations.* On two channels, for every real γ there are a word with no braid drive on channel 1 and a unit ζ such that, on every configuration whose channel 2 shows 0, the word agrees with $\zeta(\cos\gamma + \mathrm{i}\sin\gamma\, S)$ on channel 1 and the identity on channel 2, where S is the parity sign. By the identity $k(\cos\gamma + \mathrm{i}\sin\gamma\, S)k^{-1} = \cos\gamma + \sin\gamma\, SF$ for $k = (1 + \mathrm{i}F)/\sqrt{2}$, which uses only $F^2 = 1$ and $SF = -FS$, this is equivalent to the same statement for the pair rotations $e^{\gamma SF}$: on configurations whose channel 2 shows 0, one entangling token on the channels $(2, 1)$ acts as k on channel 1 (the sign of label 0 is $+1$), and $k^{-1} = k^7$, so conjugating by k maps admissible words to admissible words. With entangling tokens only on the channels $(1, 2)$, with target 2, exactly the multiples of $\pi/4$ are reachable (Theorem 30.31), so the problem needs entangling tokens on the channels $(2, 1)$ as well. Evidence: the Lie algebra generated by the relevant generators has dimension 136 and contains the needed ones; explicit words of up to 18 tokens were not found.

24. *Is the diagonal floor sharp?* For every $\eta > 0$ there are a diagonal holding and a certain one-channel word with drive below $\frac{\pi}{2}\sqrt{3/2} + \eta$. Evidence that it is false: searches with arbitrary diagonal holdings never beat the zero-holding cycle.

25. *The cheapest exact pulse.* There are θ and $\varepsilon > 0$ such that one pulse under P_7 makes a certain change, $2\pi/3 < |\theta| < \pi\sqrt{3}/2$, and no certain single pulse has smaller $|\theta|$. Proved: certain pulses exist and all have $|\theta| \geq 2\pi/3$ (Theorem 30.35), and one with $|\theta| = \pi\sqrt{3}/2 - \eta$ has $\varepsilon \leq 10/\sqrt{\eta}$ (Theorem 30.36), so a minimising sequence below $\pi\sqrt{3}/2$ stays at bounded duration. Evidence: $|\theta| \approx 2.70706$ at $\varepsilon \approx 8.42212$.

Logic and the prices of principles

In Problems 26–30, θ is the halting matrix of Lemma E.11, and a derivation *with no added rule* is a derivation in the calculus of Chapter 6 whose EM, LPO and MP entries are all false, at any tier of induction (Section 7.14).

26. *Decidability of the halting matrix.* Does $\forall e\, \forall x\, (\theta(e, x) \vee \neg\theta(e, x))$ have a derivation with no added rule? Its truth is decided by a program (Lemma E.11); the question is whether the calculus derives that decision.

27. Does $\mathrm{LPO}_\theta \to \mathrm{MP}_\theta$ have a derivation with no added rule? A positive answer to Problem 26 gives one, and then LPO_θ is exactly $\mathrm{WLPO}_\theta \wedge \mathrm{MP}_\theta$.

28. Does $\mathrm{WLPO}_\theta \to \mathrm{MP}_\theta^\vee$ have a derivation with no added rule? A positive answer to Problem 26 gives one.

29. Does $\mathrm{MP}_\theta \to \mathrm{MP}_\theta^\vee$ have a derivation with no added rule? With Problem 28, a positive answer puts $\mathrm{MP}_\theta^\vee$, which is not free (Theorem 7.59), in the meet of WLPO_θ and MP_θ. The calculus derives $\mathrm{MP}_\theta^\vee$ from the Σ_1 Markov letter at $\theta(e_1, x) \vee \theta(e_2, x)$; the question asks for it from the letter at θ itself.

30. With λ as in Section 7.14, do $\mathrm{WLPO}_\theta \to \mathrm{LLPO}_\lambda$ and $\mathrm{LLPO}_\lambda \to \mathrm{MP}_\theta^\vee$ have derivations with no added rule? As principles on binary sequences both steps hold (WLPO gives LLPO, Chapter 12, and LLPO gives $\mathrm{MP}^\vee$, Theorem 14.19); at the instances only the non-derivations of Table 7.5 are proved.

31. *The questions of Parts III and IV.* The questions about the computable calculus of δ's objects stated in Section 16.11, and those about linear algebra without unique choice stated in Section 14.9.

The continuum and analysis

32. *Zone averages and completeness.* Does the existence of zone averages for every F with a modulus of uniform continuity on the zone imply completeness for sequences of points with the modulus $k \mapsto k$? This is the converse of Theorem 12.101(1).

33. *Taylor's step with no choice.* Does Proposition 12.99 hold for pointwise derivatives without countable choice of natural numbers? A positive answer gives, with no choice, the six expansions of lattice gauge quantities of Remark 26.64; with uniform derivatives each already holds with no choice.

34. *Completeness from choice, inside HAS.* Does HAS derive every instance of Cauchy completeness, written as in Theorem 12.100(2), from the sentence of countable choice of natural numbers? On $\mathbb{R}_\delta$ the implication holds (Theorem 12.100(1)).

35. *Exact fixed points from LLPO alone.* Does LLPO, without countable choice, give an exact fixed point of every uniformly continuous map of δ's triangle to itself? With countable choice it does (Section 29.4); with LLPO and countable choice only at quantifier-free and existential formulas, the corresponding instance of exact roots is neither provable nor refutable (Theorem 12.70).

36. *The open rows of the price table.* The 22 rows of Appendix Q priced "open", each between the bounds it states after its price (Section 28.12): among them the Heine–Cantor theorem on $[0, 1]$ (row 1441), at least the decidable fan theorem and at most WLPO; Brouwer's theorem on the square for maps continuous at each point (row 1058), at least LLPO and at most WLPO; and a nonzero null vector of every singular matrix (row 684), at most LLPO with countable choice and with no lower bound proved. Five of the open rows have an exact price, in the sense of the table's key, in a principle that is not one of the table's letters: the derivative convention (row 10), Dini's theorem and the bounded convergence theorem for integrals (rows 552 and 553), the Heine–Cantor theorem on $[0, 1]$ (row 1441) and the continuous image of a compact set (row 1447). The problem is to price the open rows in the table's letters, or to show that no letter prices them.

The cost and the verdict

37. *The six exponentials on the line.* Let $e^{\ell_p} = p$ for $p = 2, 3, 5$, and let each $e^{d\ell_p}$ be a ratio. Is "d is an integer" provable on $\mathbb{R}_\delta$ with no omniscience principle and no choice principle? The rest of the verdict's transcendence step is reduced to this core with no choice (Section 22.12); what is missing is a free zero estimate for exponential polynomials in several frequencies.

38. *From a bound to a curvature.* Let G satisfy the composition law of Chapter 21 with $G(0) = 0$ and $|G| \le c$ near 0, where $\frac{3}{2} \le c < 2$. Does G have a curvature, with no omniscience principle? It does for $c < \frac{3}{2}$ and fails at $c = 2$ (Theorem 21.45).

39. *The sign of a cost.* Does LLPO imply that every solution G of the composition law with $G(0) = 0$ is ≥ 0 everywhere or ≤ 0 everywhere, with no curvature premise? The converse is proved (Theorem 21.47).

40. *Strong extensionality and Markov's principle.* Does strong extensionality of integer-valued maps on the line, $\mathrm{SE}_{\mathbb{Z}}$, imply MP? MP implies it, and with the WLPO function it is MP (Theorem 22.24, Proposition 22.25).

41. *The last bracket of the chain.* The exact price of step T2.6 of Table 22.1, dropping continuity and the order premises: it lies below the WLPO function (Theorem 22.14), and no lower bound is proved.

42. *Deciding a cost law.* The questions (O1) and (O2) stated with Definition 21.28.

The world's records

43. *The eight-tick comparison.* Derive that one comparison against the fundamental clock mode lasts eight ticks. By Theorem 24.67 this is exactly $A_0 = 2\pi\hbar$, and the comparison laws alone leave A_0 free.

44. *Locality from the light cone.* Derive chronological coverage, which is equivalent to locality (the time window): the law that fixes which retained records a comparison addresses. The light cone of Sections 24.1 and 24.5 orders postings and does not supply it.

45. *The act-rate law.* Derive whether the Hubble patch acts at most once per tick of the cosmic clock or in proportion to its volume; Theorem 24.63 proves what each law gives.

46. *One crossing per tick.* Derive that the patch's units form one unit system read on the patch's accounts (Proposition 24.74), or the identification it reduces to, that moves are posts.

47. *The price of access from locality.* Access with locality makes the capacity exceed every bound in classical mathematics. What does that step cost on $\mathbb{R}_\delta$?

48. *Certain flips.* Does some native word flip a register configuration with certainty, at zero boundary flux and unit action scale; and does the integer parameter m of the register drop out of that question? With the entangler reach problem of Section 24.9, this asks what the native register can do exactly.

49. *Count-only stores.* Does a count-only store that serves, beyond every bound, an infinite set of counts whose differences are all served keep the natural numbers real (Section 24.12)?

Fields and the second law

50. *The tick's gap on the line.* A contraction of χ^2 at every tick that is uniform in the ball, and a form of the gap on $\mathbb{R}_\delta$ (Section 26.5, after Theorem 26.32).

51. The statements (B) and (M) of Proposition 26.44, and the laws in three or more quantities left open with Theorem 26.53.

Gravity and the record cone

52. *The quartic cell form as a derivative.* On $\mathbb{R}_\delta$, at $\kappa = 1$, is the quartic cell form the fourth derivative of δ's own Regge action? This is equivalent to the two named premises on third-order rates used by Theorem 25.71 (Proposition 27.63).

53. *Beyond order K^4.* What is the exact branch of the graviton on the $\kappa = 1$ lattice, to all orders in the momentum, and what is the order-K^4 correction to the tree scattering of four gravitons? At order K^4 the dispersion law of the whole family is proved (Theorem 27.75).

54. *The body diagonal.* Does the zero mode of the body diagonal at $\kappa = 0$ change gauge-invariant amplitudes with two derivatives (Proposition 27.72)?

55. *A changed coupling.* Hinge shape costs cannot complete a changed coupling at quartic order (Theorem 27.71; Proposition 27.70 gives the direction of the change through cubic order). Can a cost of another kind, for example one nonlinear in the deficits, complete it?

56. *The premises of the graviton's action.* Derive from the foundation each named statement of Proposition 27.76: that the ledger writes a step by its cheapest record (tick-free writing); double entry together with the reading that the charge reads a strain only through what comparison events post (the coherent reading); double entry for the derived scalar record (locality); the purity of each post's lattice record, which is $\kappa = 1$; and the reading of the face directions through the records of the double steps (independent axes).

57. *The long-wave profile of a mass.* Is an actual lattice solution of a mass a native C^3 family solving the weak equations of first and second order (Theorem 25.70)? The question is open in classical mathematics too. And do the third-order weak equations give the third-order jet equation (Theorem 25.71)?

58. *Charts of the posting order.* (i) The grid $2 \times 3 \times 3 \times 3$ has a record-cone chart read on its stage events. (ii) So does $3 \times 3 \times 3 \times 3$. (iii) Every truncation $2 \times 3 \times [n]$ has one; every $n > 20$ is open, and this is the sphere-order form of the third question of Felsner, Fishburn and Trotter [201] for these orders. (iv) In every real normed space, a ladder of length n with all angular margins at least $\theta > 0$ has $\theta^2(n-1) \leq 1$; the bound with 2 in place of 1 is proved, and 1 is proved and sharp in one dimension (Theorem 24.85). Searches found no chart in (i)–(iii) and no counterexample to (iv) in small cases.

Learning

59. *Own rows at every level.* Theorem 29.69 at the levels $n \geq 4$, and a reduction from a learner to U_n in Theorem 29.68(4) that is uniform in the learner. And for a bare oracle O, not joined with the row table: if some learner computable from O learns $C_{n+2}(\mathbf{t}_n)$ with $n+2$ changes, must O compute U_n? The proof gives only that U_n is computable from O joined with the row table (Remark 29.70).

60. *Harrington's method.* Is Σ_2-LPO strictly stronger than LPO under the reading of maps of Chapter 21 (Section 29.9), and do Harrington's own bounds, in the standard order of codes, carry a totality decision (Section 29.10)?

Questions to work through

1. For $k = 1, \dots, 5$ find the integer m nearest to $k(\sqrt{5}-2)$ and check $6k\,|k(\sqrt{5}-2) - m| \geq 1$ directly. Which k comes closest to equality? (Lemma 30.3.)

2. Take the recognizers $\sim_{2,4}$ and $\sim_{5,6}$. Compute their join, and find counts a, b related by the join for which no count n has $n \sim_{2,4} a$ and $n \sim_{5,6} b$. (Theorem 30.9.)

3. Decide whether $\sqrt{3} - 1$ and $\sqrt{3}/3$ are rates of primitive two-letter joins, and for each one that is, write down a join that has it. (Theorem 30.13.)

4. For $\mathsf{d} \mapsto \mathsf{dcd}$, $\mathsf{c} \mapsto \mathsf{cdc}$, write out $\sigma^2(\mathsf{d})$, $\sigma^2(\mathsf{c})$ and check the coboundary $\pi(\mathsf{d}) = 0$, $\pi(\mathsf{c}) = 1$; show that $\mathsf{d} \mapsto \mathsf{ddc}$, $\mathsf{c} \mapsto \mathsf{ccd}$ admits none. (Theorem 30.14.)

5. On one channel, write words of drive exactly $2\pi/3$ that move label 0 to label 7 and 7 to 0 with certainty. Show that one braid token of angle $\pi/2$ on the triad $(0, 1, 7)$ moves no label with certainty, by computing its diagonal. (Theorems 30.22 and 30.24.)

6. Verify that $\omega(x) = (\theta^2 - \mathrm{i}\sqrt{3}\theta x,\ \theta^2 + \mathrm{i}\sqrt{3}\theta x,\ \theta^2 - 3x^2)$ satisfies $A\omega(x) = -\mathrm{i}x\,\omega(x)$ when $p(x) = 0$, row by row. (Theorem 30.35.)

Appendix A

Finite controls and approximation

Chapter 18 uses two approximation results. A finite alphabet of gates supplies descriptions that can be searched. A family of native rotations and couplings supplies the operations used in the positive-energy construction. This appendix proves both results. The common step is to isolate elementary matrix directions and then connect them across a register.

The argument has four stages. We first identify a sufficient collection of matrix directions. We explain why directions obtained by sums and commutators correspond to limits of available operations. We then obtain those directions from the native controls. Finally, an explicit eight-gate sequence starts the corresponding argument for the finite alphabet.

All spaces in this appendix have positive finite dimension. Matrix norms are operator norms unless stated otherwise. An approximation assertion means that for every positive error there is a finite sequence attaining it; it does not assert a bound on the length of that sequence.

A.1 The matrix directions that suffice

Write E_{uv} for the matrix with a single 1 in row u, column v. For distinct indices define

$$R_{uv} = E_{uv} - E_{vu}, \qquad I_{uv} = i(E_{uv} + E_{vu}), \qquad D_{uv} = i(E_{uu} - E_{vv}).$$

Here I_{uv} names an imaginary symmetric edge; the unsubscripted I continues to mean the identity. All three matrices are skew-Hermitian and have trace zero. The real vector space of all such matrices is denoted $\mathfrak{su}(d)$.

For matrices A, B, their commutator is $[A, B] = AB - BA$. The multiplication rule $E_{uv}E_{xy} = \delta_{vx}E_{uy}$ gives, for pairwise distinct u, v, w,

$$\begin{aligned} [R_{uv}, R_{vw}] &= R_{uw}, & [R_{uv}, I_{vw}] &= I_{uw}, \\ [I_{uv}, I_{vw}] &= -R_{uw}, & [R_{uv}, I_{uv}] &= 2D_{uv}. \end{aligned} \tag{A.1}$$

For example, in the first identity the only surviving products in $R_{uv}R_{vw}$ and $R_{vw}R_{uv}$ are E_{uw} and E_{wu}. Matrices supported on disjoint pairs commute.

Lemma A.1 (Connected real edges and one imaginary edge)**.** *Let $d \geq 3$. Suppose a real vector space L of skew-Hermitian matrices is closed under commutators. If L contains R_{uv} along the edges of a connected graph on the d indices, and contains one I_{pq} with $p \neq q$, then $\mathfrak{su}(d) \subseteq L$.*

Proof. Take a simple path between any two vertices. Repeatedly applying the first identity in (A.1) shortens that path, so every R_{uv} belongs to L. The given imaginary edge and the last identity give D_{pq}.

Commuting D_{pq} with R_{pr} gives I_{pr} when r is distinct from p, q, and gives $2I_{pq}$ when $r = q$. Thus every imaginary edge incident to p is present. If $u, v \neq p$ and $u \neq v$, then $[R_{up}, I_{pv}] = I_{uv}$. All

imaginary edges are therefore present, and their brackets with the real edges give all diagonal differences.

To see that these matrices span the claimed space, let $A^\dagger = -A$. For $u < v$, write $A_{uv} = x_{uv} + iy_{uv}$. Its two off-diagonal entries are exactly those of $x_{uv}R_{uv} + y_{uv}I_{uv}$. The remaining diagonal has the form $i\,\mathrm{diag}(t_1, \dots, t_d)$ with real t_j. Trace zero says $\sum_j t_j = 0$, so, after fixing an index p, this diagonal equals $\sum_{u \neq p} t_u D_{up}$. Every part lies in L. □

This lemma reduces a large spanning problem to a small graph. The rest of the proof constructs its edges from the operations actually supplied.

A.2 From finite operations to continuous directions

Let G be the norm closure of a group of available unitary operations. Define

$$L_G = \{X \,:\, X^\dagger = -X \text{ and } \exp(tX) \in G \text{ for every real } t\}.$$

The definition refers only to limits of finite operation sequences. We need to justify the algebraic manipulations used on L_G.

Lemma A.2 (A product-limit estimate)**.** *If A and B are contractions, then $\|A^n - B^n\| \le n\|A - B\|$. If two contraction-valued curves f, g satisfy $f(0) = g(0) = I$ and $f'(0) = g'(0)$, then, for fixed real t,*

$$\left\| f(t/n)^n - g(t/n)^n \right\| \longrightarrow 0.$$

Proof. The telescoping identity

$$A^n - B^n = \sum_{j=0}^{n-1} A^{n-1-j}(A - B)B^j$$

gives the first estimate. Equality of the derivatives says $\|f(h) - g(h)\| = o(|h|)$. Substituting $h = t/n$ into the estimate proves the limit. For $t = 0$ the difference is already zero. Applied to $f(h) = \exp(hX)\exp(hY)$ and $g(h) = \exp(h(X + Y))$, as in Proposition A.3, the limit is the finite-dimensional case of Trotter's product formula [25]. □

Proposition A.3 (The available directions form a closed Lie algebra)**.** *The set L_G is a closed real vector space, is closed under commutators, and is preserved by $X \mapsto UXU^\dagger$ for every $U \in G$.*

Proof. Zero and real scalar multiples follow directly from the definition. For $X, Y \in L_G$, the curves

$$f(h) = \exp(hX)\exp(hY), \qquad g(h) = \exp(h(X + Y))$$

are unitary, have value I at zero, and have derivative $X + Y$ there. The product-limit lemma shows that $\exp(t(X + Y))$ is a limit of elements of G, and hence is in G. This proves closure under sums. If $X_j \to X$ with $X_j \in L_G$, continuity of the adjoint and exponential gives $X^\dagger = -X$ and $\exp(tX) \in G$ for each t. Thus the vector space is closed.

Conjugation preserves it because $\exp(tUXU^\dagger) = U\exp(tX)U^\dagger$. Finally, for $X, Y \in L_G$, each difference quotient

$$\frac{\exp(hX)Y\exp(-hX) - Y}{h} \qquad (h \neq 0)$$

belongs to this real vector space. Its limit is $XY - YX$. Closedness therefore supplies the commutator. □

There is a useful variant. If $f(h) \in G$ is a differentiable unitary curve with $f(0) = I$ and $f'(0) = X$, compare it with $\exp(hX)$ in Lemma A.2. The powers $f(t/n)^n$ show that $X \in L_G$. A direction can thus enter through a small available curve even before its exponential has been identified.

Lemma A.4 (A trace-zero logarithm)**.** *Every unitary matrix U with determinant one is* $\exp X$ *for some $X \in \mathfrak{su}(d)$.*

Proof. The finite-dimensional spectral theorem gives an orthonormal eigenbasis and real phases θ_j in which U is diagonal with entries $e^{i\theta_j}$. Since $\det U = 1$, the sum $\sum_j \theta_j$ is an integer multiple of 2π. Subtract that sum from one of the phases. The exponentials are unchanged, and the adjusted phases sum to zero. The diagonal matrix of their multiples by i is skew-Hermitian with trace zero. Conjugating back gives X. □

Consequently, $\mathfrak{su}(d) \subseteq L_G$ implies that every determinant-one unitary is a norm limit of available finite sequences. No assertion about the rate of approximation has entered the argument.

A.3 Two native cells supply all matrix directions

One cell has basis labels $0, \dots, 7$. Put

$$\sigma = (1, -1, -1, 1, -1, 1, 1, -1), \qquad S = \operatorname{diag}(\sigma),$$

and let F interchange 0 with 1, 2 with 3, 4 with 5, and 6 with 7. Write $f(c)$ for the partner of c under this interchange. Thus $S^2 = F^2 = I$, both matrices are Hermitian, and $\sigma_{f(c)} = -\sigma_c$.

The local rotations have directions

$$C_{abc} = R_{ab} + R_{bc} + R_{ca}$$

for distinct indices. Their normalized generators are $C_{abc}/\sqrt{3}$. It suffices to supply the 21 choices C_{ab7} with $0 \le a < b < 7$, since

$$C_{abc} = C_{ab7} + C_{bc7} + C_{ca7}$$

when a, b, c avoid 7, with the signs adjusted by reversing a pair when necessary. The nonzero normalization does not change the real span of the directions.

For two cells, supply the couplings

$$E_{12} = \frac{I + iS \otimes F}{\sqrt{2}}, \qquad E_{21} = \frac{I + iF \otimes S}{\sqrt{2}}.$$

They are unitary because each tensor factor product is a Hermitian involution. Inverses are also available as finite sequences: if $E = (I + iX)/\sqrt{2}$ with $X^2 = I$, then $E^8 = I$.

Let L be a real Lie algebra containing the local cyclic directions on each cell and preserved by conjugation with both couplings. We will prove $\mathfrak{su}(64) \subseteq L$. This applies to L_G by Proposition A.3.

The couplings separate local real edges

For $X^2 = I$, direct multiplication gives

$$\mathrm{Ad}_E(Y) = \frac{Y + XYX}{2} + \frac{i}{2}(XY - YX), \qquad \mathrm{Ad}_E^2(Y) = XYX. \tag{A.2}$$

It follows that L contains both XYX and $i(XY - YX)$ whenever it contains Y. Indeed the second expression is $2\,\mathrm{Ad}_E(Y) - Y - \mathrm{Ad}_E^2(Y)$.

For an operator on the first cell, conjugation by $S \otimes F$ gives conjugation by S on that cell. The corresponding assertion holds for the second cell using $F \otimes S$. Since $SR_{ab}S = \sigma_a\sigma_b R_{ab}$, cyclic sums can be separated. If a, b have the same sign, choose k of the opposite sign. Then

$$\frac{C_{abk} + SC_{abk}S}{2} = R_{ab}.$$

If a, b have opposite signs, choose $k \neq a$ of the same sign as a. We already have R_{ak}. Subtracting it from C_{akb} leaves $Z = R_{kb} + R_{ba}$. The edge identities give

$$[R_{ak}, Z] = R_{ab} + R_{kb}, \qquad \frac{[R_{ak}, Z] - Z}{2} = R_{ab}.$$

There are four indices of each sign, so the required choices exist. Thus $R_{ab} \otimes I$ and $I \otimes R_{cd}$ belong to L for every distinct pair.

The couplings produce imaginary tensor directions

Write $P_c = E_{cc}$ and $Q_{ab} = E_{ab} + E_{ba}$. The imaginary commutator supplied by (A.2) gives

$$i[S, R_{ab}] \otimes F = i(\sigma_a - \sigma_b)Q_{ab} \otimes F.$$

For opposite signs the coefficient is nonzero, so $iQ_{ab} \otimes F$ belongs to L. Commuting with $I \otimes R_{c,f(c)}$ uses

$$[F, R_{c,f(c)}] = 2(P_{f(c)} - P_c)$$

and gives $iQ_{ab} \otimes (P_c - P_{f(c)})$ after a real rescaling. For $d \neq c$, commute this with $I \otimes R_{cd}$. The result is $iQ_{ab} \otimes Q_{cd}$, multiplied by 1 if $d \neq f(c)$ and by 2 if $d = f(c)$. Another commutator with $I \otimes R_{cd}$ gives a nonzero real multiple of $iQ_{ab} \otimes (P_d - P_c)$.

Interchanging the cells gives the complementary family. We have proved that L contains

$$\begin{aligned} &iQ_{ab} \otimes Q_{cd}, \quad iQ_{ab} \otimes (P_c - P_d) \quad \text{if } \sigma_a \neq \sigma_b,\ c \neq d, \\ &\qquad\qquad\quad i(P_a - P_b) \otimes Q_{cd} \quad \text{if } a \neq b,\ \sigma_c \neq \sigma_d. \end{aligned} \tag{A.3}$$

The sign conditions have been retained; removing them prematurely would hide the work done by the next step.

A tensor direction can be confined to one column

Suppose a, b have opposite signs and $d \neq e$. Choose c distinct from d, e with sign opposite to that of e. The following two matrices are available from (A.3):

$$A = iQ_{ab} \otimes Q_{cd}, \qquad B = i(P_a - P_b) \otimes Q_{ce}.$$

Their commutator is $R_{ab} \otimes Q_{de}$. To check this, use $Q_{ab}(P_a - P_b) = -R_{ab}$, $(P_a - P_b)Q_{ab} = R_{ab}$, and $Q_{cd}Q_{ce} = E_{de}$ for the three distinct indices. Commuting with $I \otimes R_{de}$ then gives $2R_{ab} \otimes (P_e - P_d)$.

Sum the latter differences over e. Since

$$\sum_e (P_e - P_d) = I - 8P_d,$$

and $R_{ab} \otimes I$ is already available, we obtain $R_{ab} \otimes P_d$. If a, b have the same sign, choose k of the opposite sign and use

$$[R_{ak} \otimes P_d, R_{kb} \otimes P_d] = R_{ab} \otimes P_d.$$

Thus every real edge within a fixed second coordinate is present:

$$R_{ab} \otimes P_c = R_{(a,c),(b,c)} \in L. \tag{A.4}$$

Every imaginary edge in such a column is present too. Given distinct b, e, choose a different from both with sign opposite to that of b. The available matrix

$$iQ_{ab} \otimes (P_c - P_{f(c)}) = I_{(a,c),(b,c)} - I_{(a,f(c)),(b,f(c))}$$

has two disjoint supports. Its commutator with $R_{(a,c),(b,c)}$ isolates $2D_{(a,c),(b,c)}$. Commuting that diagonal difference with $R_{(b,c),(e,c)}$ supplies $I_{(b,c),(e,c)}$, up to a nonzero real factor.

The columns connect

For $a \neq e$ and $c \neq d$, choose b different from a, e and of sign opposite to a. Equation (A.3) contains

$$iQ_{ab} \otimes Q_{cd} = I_{(a,c),(b,d)} + I_{(a,d),(b,c)}.$$

Commute this with the already available $I_{(b,d),(e,d)}$. The second summand has disjoint support and contributes zero; the first gives $-R_{(a,c),(e,d)}$.

We now have real edges between different first coordinates, whether or not their second coordinates agree. Two vertices with the same first coordinate can be joined through any vertex with a different first coordinate. These edges form a connected graph on the 64 states. We also have imaginary column edges. Applying Lemma A.1 proves

$$\mathfrak{su}(64) \subseteq L. \tag{A.5}$$

Every step used the stated cyclic rotations, the two ordered couplings, real linear combinations and commutators.

A.4 Overlapping pairs control a whole register

Two-cell control must still be connected across a longer register. The following argument makes that step explicit.

Lemma A.5 (Overlapping factors)**.** *Let A, B, C be nonempty finite index sets, with $|A|, |B| \geq 3$. A real Lie algebra containing*

$$\mathfrak{su}(A \times B) \otimes I_C \quad \text{and} \quad I_A \otimes \mathfrak{su}(B \times C)$$

contains $\mathfrak{su}(A \times B \times C)$.

Proof. For a real function δ on the indices, write $D(\delta) = i\,\mathrm{diag}(\delta)$. Direct multiplication gives

$$[D(\delta), R_{xy}] = (\delta_x - \delta_y) I_{xy}, \qquad [D(\delta), I_{xy}] = -(\delta_x - \delta_y) R_{xy}.$$

These equations allow a diagonal difference to select one part of an edge sum.

First fix a_0 and distinct b, b'. From the second supplied algebra we have

$$T = \sum_a R_{(a,b,c),(a,b',c')}.$$

Choose a_1, a_2 distinct from each other and from a_0. A diagonal difference from the first algebra, equal to 1 on the slice (a_0, b), -1 on (a_1, b) and zero elsewhere, turns T into the difference of its two corresponding imaginary edges. Commute once more with the diagonal difference on slices (a_0, b) and (a_2, b). Only the a_0 edge survives, with a minus sign. Hence $R_{(a_0,b,c),(a_0,b',c')}$ is available.

Next start from the first algebra's sum

$$T' = \sum_{c'} R_{(a,b,c'),(a',b',c')}, \qquad b \neq b'.$$

Choose b_2 outside $\{b, b'\}$. A diagonal difference from the second algebra, equal to 1 on the fibre (b, c) and -1 on (b_2, c), selects $I_{(a,b,c),(a',b',c)}$ from T'. A second commutator with that same diagonal gives the corresponding real edge.

We therefore have real edges whenever $b \neq b'$ and either the first or the third coordinate agrees. This graph is connected. In fact, choose b_2 different from both b, b' to join any two vertices by

$$(a, b, c) \longrightarrow (a, b_2, c') \longrightarrow (a', b', c').$$

The fibre construction also supplies an imaginary edge. Lemma A.1 finishes the proof. □

Theorem A.6 (Approximation by native controls)**.** *On a register of $n \geq 2$ eight-state cells, supply the local cyclic rotations and both ordered couplings $E_{j,j+1}$ and $E_{j+1,j}$ on every adjacent pair. Finite sequences of these operations approximate every determinant-one unitary on the register to arbitrary positive operator-norm accuracy.*

Proof. Take the closed group G generated by those operations. Its algebra L_G contains the local cyclic directions, and conjugation by the couplings preserves it. The two-cell argument gives all of $\mathfrak{su}(64)$ on each adjacent pair.

Induct on the number of cells. The case of two cells was proved above. For the induction step, separate the first cell, second cell and the remaining tail. Full control on the first pair and, by induction, on the second cell together with the tail satisfies Lemma A.5. Thus L_G contains all traceless skew-Hermitian matrices on the complete register. The logarithm lemma places every determinant-one unitary in G, which is precisely the asserted approximation property. □

A.5 A finite alphabet has an infinite-order seed

The search construction in Chapter 18 needs a finite alphabet with effectively accessible entries. Use binary coordinates for each eight-state cell. On one binary coordinate let

$$H = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \qquad P = \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix}.$$

The third gate flips a target binary coordinate when both selected control coordinates are 1. The target differs from each control; the two controls are allowed to coincide. With coincident controls this is the controlled-NOT gate. This convention matters in the register argument below.

These gates are unitary and have finite-order inverses: $H^2 = I$, $P^4 = I$, and the controlled flip squares to I. Their finite words therefore form a group. Entries of every word lie in $\mathbb{Q}(\sqrt{2}, i)$.

On three binary coordinates, let T interchange states 6 and 7, and let $H_* = H_2 H_1 H_0$. Consider the eight-gate word

$$U = (H_* T)^2.$$

This is an exact choice of gates, with no angle selected from a numerical fit. Its infinite order will supply a continuous direction in the closure of the finite words.

Let e_j be the coordinate vectors and put

$$v = e_6 - e_7, \qquad w = e_1 - e_3 - e_5 + e_7.$$

The unnormalized Walsh matrix $W = 2\sqrt{2}\, H_*$ has entries $W_{jk} = (-1)^{j \cdot k}$, where the dot product is computed modulo two on the three binary coordinates. Expanding the two columns indexed by $6, 7$, and then the four columns indexed by $1, 3, 5, 7$, gives

$$Wv = 2w, \quad Ww = 4v, \quad Tv = -v, \quad Tw = w + v.$$

Consequently

$$Uv = -v - \tfrac{1}{2}w, \qquad Uw = v - \tfrac{1}{2}w. \tag{A.6}$$

The restriction to the plane spanned by v, w has characteristic polynomial $x^2 + \frac{3}{2}x + 1$ and eigenvalue

$$\lambda = \frac{-3 + i\sqrt{7}}{4}.$$

It has modulus one. It is not a root of unity. If $\lambda^k = 1$ for some positive integer k, both λ and its conjugate would be algebraic integers, so their sum $-3/2$ would be an algebraic integer. A rational algebraic integer must be an integer: substituting a reduced fraction into a monic integer polynomial shows that its denominator divides its numerator's highest power. The denominator must therefore be 1. This contradicts the sum $-3/2$.

The closure of the integer powers of any unit complex number of infinite order is the whole circle. Here is the needed elementary argument. Partition the circle into N equal arcs and

place $N+1$ powers in them. Two lie in the same arc. Their quotient, or its inverse, has argument β with $0 < \beta < 2\pi/N$. Successive multiples of β before one full turn leave gaps at most β, including the final gap. They approximate every point of the circle within $2\pi/N$ in angle. They are still integer powers of the original number. Letting N increase proves density.

To identify the resulting matrix direction, calculate $v^T v = 2$, $w^T w = 4$ and $v^T w = -1$. The orthogonal projection onto their plane is

$$Q = \frac{4vv^T + vw^T + wv^T + 2ww^T}{7}.$$

Set $B = vw^T - wv^T$ and $A = B/\sqrt{7}$. The same inner products give

$$Q^2 = Q, \qquad A^2 = -Q, \qquad QA = AQ = A.$$

Since $T = I - vv^T$ and $W^2 = 8I$, expansion of $(H_* T)^2$ gives

$$U = I - vv^T - \tfrac{1}{2}ww^T - \tfrac{1}{2}wv^T = I - \tfrac{7}{4}Q + \tfrac{1}{4}B.$$

For $|z| = 1$ define

$$M(z) = I - Q + \mathrm{Re}(z)Q + \mathrm{Im}(z)A.$$

The displayed relations show $M(z_1 z_2) = M(z_1)M(z_2)$, $M(\lambda) = U$, and $M(e^{it}) = \exp(tA)$. The last equality follows directly by separating even and odd terms of the exponential series, using $A^2 = -Q$. Density of the powers of λ, together with continuity of M, puts $\exp(tA)$ in the closure of finite words for every real t. Hence A, and therefore B, belongs to L_G for that closure.

A.6 Sign masks isolate the seed's edges

An infinite-order rotation alone need not control a whole space. We now use the other gates to separate its matrix entries.

The square P^2 is the binary sign gate $Z = \mathrm{diag}(1, -1)$. Products of such gates give every diagonal sign mask

$$D_s e_j = (-1)^{s \cdot j} e_j, \qquad s, j \in \{0, 1\}^3.$$

Conjugating by a mask multiplies R_{uv} by $(-1)^{s \cdot (u \oplus v)}$, where $\oplus$ is coordinatewise addition modulo two. The real linear combination

$$\Pi_d(Y) = \frac{1}{8} \sum_s (-1)^{s \cdot d} D_s Y D_s$$

therefore retains exactly the edges with $u \oplus v = d$. Indeed, the coefficient is the average of the character $(-1)^{s \cdot (d \oplus u \oplus v)}$. It is 1 if its index is zero; otherwise pairing s with the result of flipping a coordinate where that index is 1 makes the sum zero.

Expansion of $B = vw^T - wv^T$ yields

$$B = R_{61} - R_{63} - R_{65} + R_{67} - R_{71} + R_{73} + R_{75}.$$

Thus

$$\Pi_1(B) = R_{67}, \quad \Pi_2(B) = R_{75}, \quad \Pi_4(B) = R_{73}, \quad \Pi_6(B) = -R_{71}.$$

Each lies in L_G, because the masks are available words and L_G is a real vector space preserved by their conjugations.

The bit flip is also available: $X = HZH$. Conjugating R_{67} by flips of the higher coordinates gives R_{23}, R_{45} and R_{01}. The edges

$$01,\ 23,\ 45,\ 67,\ 71,\ 73,\ 75$$

form a connected graph on the eight labels. Finally, conjugating R_{67} by the phase gate on the lowest binary coordinate gives $-I_{67}$. Lemma A.1 now gives

$$\mathfrak{su}(8) \subseteq L_G. \tag{A.7}$$

The finite alphabet has acquired every local continuous direction through closure. The source of that continuity was the explicit infinite-order seed, not a continuously adjustable gate in the alphabet.

A.7 The finite alphabet connects the cells

It remains to obtain the native coupling used earlier. On one cell, the sign matrix S is the product of the three binary Z gates: it records the parity of the three bits. The matrix F is the flip X on the lowest bit.

For distinct binary coordinates a, b, a controlled-NOT with control a and target b conjugates Z_b to $Z_a Z_b$. This follows on a basis state: after the target flip, its sign is $(-1)^{x_b + x_a}$. Use three such controlled-NOT gates, controlled by the three bits of cell j and targeted at the lowest bit of cell k. Their product conjugates $Z_{k,0}$ to $S_j Z_{k,0}$. Conjugating next by H on that target bit changes $Z_{k,0}$ to F_k. Hence a finite word conjugates $iZ_{k,0}$ to iS_jF_k.

Equation (A.7) supplies $iZ_{k,0}$ as a local direction. Conjugation therefore supplies iS_jF_k, and its exponential at $\pi/4$ is

$$\exp\big(i\tfrac{\pi}{4} S_j F_k\big) = \frac{I + iS_jF_k}{\sqrt{2}} = E_{jk}.$$

This coupling belongs to the closed word group. The reversed ordered coupling is obtained by reversing the roles of the cells. All cyclic directions are already local members of $\mathfrak{su}(8)$. The native register argument thus applies inside this same closed group.

Theorem A.7 (Approximation by the finite alphabet)**.** *On any register of $n \geq 2$ eight-state cells, the gates H, P and the controlled flip with the stated repeated-control convention generate finite words dense in the determinant-one unitaries, in operator norm.*

Proof. The preceding construction puts the local cyclic rotations and adjacent ordered couplings in the closure of finite words. The proof of Theorem A.6 then places every determinant-one unitary in that closure. □

This is the existence statement needed by the rational search. The finite words can be enumerated, their entries can be enclosed by rational intervals, and their errors can be certified with slack. The search uses those facts to find an approximation; density ensures that a sufficient one will eventually be found. It supplies no practical running-time guarantee.

A.8 A complete record-and-field assembly

The pulse theorem needs a full register and a positive holding operator on it. We now give the record-and-field extension used for the native two-flux construction. The retained source is supplied on $14 + 2N$ eight-state cells with a positive interior Hamiltonian $H_{\mathrm{old}}(N, m)$. Here $N \geq 0$ fixes the size of its two reference banks, and $m \in \mathbb{Z}$ is a fixed source-flux parameter. Its material construction is outside this extension. The task here is to specify every added space and energy term, then check that the whole space has the form required by the pulse theorem.

We work in the dimensionless energy units of the following cell clock. The energy scale and $\hbar$ must be used consistently when applying Chapter 18.

One complete cell pair

Let $\mathscr{H} = \mathbb{C}^8$, with the S and F already specified in this appendix. Define

$$Q = iSF, \qquad P = \frac{I - Q}{2}, \qquad \bar{P} = I - P.$$

Because $SF = -FS$ and $S^2 = F^2 = I$, the matrix Q is a Hermitian involution and $P, \bar{P}$ are complementary orthogonal projections. They each have rank four. An explicit orthonormal basis for the range of $\bar{P}$ is given by the columns

$$B_j = \frac{e_{2j} - i\sigma_{2j}e_{2j+1}}{\sqrt{2}}, \qquad j = 0, 1, 2, 3.$$

Direct multiplication gives $QB = B$, $B^\dagger B = I_4$ and $BB^\dagger = \bar{P}$. The columns of FB form an orthonormal basis for the range of P, since $QF = -FQ$.

The eight-level clock is the positive matrix

$$C = T\,\mathrm{diag}(0, 1, \dots, 7)T^\dagger, \qquad T_{jk} = \frac{e^{-i\pi jk/4}}{\sqrt{8}}. \tag{A.8}$$

The finite geometric sum shows that the columns of T are orthonormal. Thus $0 \leq C \leq 7I$. Average its four conjugates to obtain

$$\bar{C} = \frac{C + SCS + FCF + QCQ}{4} \geq 0.$$

On the complete pair space $\mathscr{P} = \mathscr{H} \otimes \mathscr{H}$, introduce the isometry

$$J = \bar{P} \otimes B + P \otimes FB : \mathscr{H} \otimes \mathbb{C}^4 \longrightarrow \mathscr{P}.$$

Orthogonality of P and $\bar{P}$ gives

$$J^\dagger J = I_{32}, \qquad JJ^\dagger = \bar{P} \otimes \bar{P} + P \otimes P.$$

It puts the two cells in matching occupation sectors, while retaining all four reference coordinates in either sector. Define the full pair holding by

$$H_{\text{pair}} = J(C \otimes I_4)J^\dagger + (\bar{P}C\bar{P}) \otimes P + (PCP) \otimes \bar{P} + I_8 \otimes \bar{C} + 7I_{64}. \tag{A.9}$$

Every summand is positive. For example, $v^\dagger J(C \otimes I_4)J^\dagger v \geq 0$ by positivity of $C \otimes I_4$, and PCP is positive by the same argument. The two middle terms keep the clock on the unmatched occupation sectors. Equation (A.9) is therefore an operator on all 64 pair coordinates, with its seven-unit scalar baseline included.

For n pairs, write

$$\mathscr{B}_n = \mathscr{P}^{\otimes n}, \qquad H_n = \sum_{r=1}^{n} (H_{\text{pair}})_r.$$

The subscript r places the pair operator in slot r and identities in every other slot. The space has dimension $64^n = 8^{2n}$, and $H_n \geq 0$. For $n = 0$, the space is one-dimensional and the sum is zero. Each pair retains its complete clock and reference contribution.

Three fresh pairs and their connecting edge

The added record has three original cells and three compensating reference cells. Its full space is $\mathscr{R} = \mathscr{B}_3$, of dimension 8^6, and its internal holding is H_3. The source-minus-reference occupation is

$$Q_{\text{fresh}} = \sum_{r=1}^{3} (P \otimes I - I \otimes P)_r.$$

In the occupation basis of each cell, its eigenvalue is $\sum_r (u_r - v_r)$, where $u_r, v_r \in \{0, 1\}$. The four-dimensional coordinate inside each occupation sector is retained. Thus the fresh charge takes the integer values from -3 to 3 on the complete space, including sectors outside a neutral preparation.

The selected edge energy is

$$c(j) = 4\left[j \operatorname{arsinh}(j/2) - \sqrt{j^2 + 4} + 2\right], \qquad j \in \mathbb{Z}. \tag{A.10}$$

The coefficient four is part of this specified apparatus. To see positivity, put $t = \operatorname{arsinh}(j/2)$. The bracket becomes $2(t \sinh t - \cosh t + 1)$. This is even, vanishes at zero and has derivative $2t \cosh t \geq 0$ for $t \geq 0$. Hence $c(j) \geq 0$.

The connecting-edge operator E_{fresh} is diagonal in the occupation basis, with entry $c(\sum_r (u_r - v_r))$ on that coordinate. Equivalently, it is $c(Q_{\text{fresh}})$ by the finite spectral calculus. It is positive on the entire fresh record. The new edge contributes zero on the neutral preparation, but its operator remains in the full holding.

Fix also an exterior flux $\beta \in \mathbb{Z}$. With all operators in physical cell coordinates, the placed record holding is

$$H_{\text{placed}} = H_{\text{old}}(N, m) \otimes I_{\mathscr{R}} + I_{\text{old}} \otimes H_3 + c(\beta)I + I_{\text{old}} \otimes E_{\text{fresh}}. \tag{A.11}$$

The retained interior source holding excludes the exterior edge counted by $c(\beta)I$ here. This expression counts that edge once, adds the fresh connecting edge once, and preserves every old and fresh coordinate. Each term is positive. The old-source positivity is the supplied input; the added terms have just been constructed and proved positive.

Two finite field banks

Choose nonnegative integers a, b. The two banks have $2a$ and $2b$ complete pairs:

$$\mathscr{F}_{a,b} = \mathscr{B}_{2a} \otimes \mathscr{B}_{2b}, \qquad H_{\text{field}} = H_{2a} \otimes I + I \otimes H_{2b}.$$

Their full dimension is 8^{4a+4b}, and their holding is positive. A useful code in a bank of n pairs has a chain label $k \in \{0, \dots, n\}$ and two lists of n four-valued coordinates. The first k source cells are occupied and the others unoccupied; each reference cell has matching occupation. The two lists choose the coordinates inside the source and reference occupation sectors. Distinct code labels give orthogonal vectors, so this is an isometric encoding of dimension $(n+1)4^n4^n$ into the full 64^n-dimensional bank.

For the two banks, their chain labels k, l describe the integer pair $(k-a, l-b)$. These pairs cover the box $[-a, a] \times [-b, b]$. If W is the resulting field-code isometry, then

$$WW^\dagger + (I - WW^\dagger) = I.$$

The second projection keeps the unused coordinates visible. The holding operator remains H_{field} on the whole space; no invariance of the selected code under that holding is assumed.

These field labels do not themselves make the old-source parameter m or the exterior parameter β vary with the encoded state. They remain fixed in (A.11). A source coupling that reads those labels as variable physical flux would be an additional operator correspondence. It is not needed for the full-register pulse theorem proved here.

The whole register and the coordinate bijection

The complete carrier and holding are

$$\mathscr{K} = (\mathscr{H}^{\otimes(14+2N)} \otimes \mathscr{B}_3) \otimes \mathscr{F}_{a,b}, \tag{A.12}$$

$$H_{\text{reg}} = H_{\text{placed}} \otimes I_{\text{field}} + I_{\text{placed}} \otimes H_{\text{field}}. \tag{A.13}$$

Both terms are positive, hence $H_{\text{reg}} \geq 0$. This conclusion concerns the full holding, including the scalar edge energy and every unmatched or unused coordinate.

To identify its cell count, take a tuple of

$$n = 20 + 2N + 4a + 4b$$

labels from $\{0, \dots, 7\}$. Split it into successive blocks of lengths $14 + 2N$, 6, $2a$, $2a$, $2b$, $2b$. The first is the old source. Group the six fresh labels into three source–reference pairs. Pair the two $2a$-blocks coordinate by coordinate to form the first field bank, and do the same for the two $2b$-blocks. Reading the source and reference entries of each pair and concatenating the blocks reverses this map. This gives the required basis bijection with n eight-state cells. It proves the tensor-power form directly, rather than inferring it from finite dimension alone.

The permutation matrix of this bijection transports the input layout, holding, evolution and complete reader together. Conjugation preserves products, adjoints, exponentials and operator norms, so it preserves the pulse error bound. This is a change of mathematical coordinates. It does not supply a free physical permutation actuator. A separate unitary choice of occupation coordinates can likewise be applied to the full operators without compressing their space.

For a requested instrument, choose the register sizes large enough for the fixed layout of Chapter 18. Since $n \geq 20$, the requirement of at least two cells is already met. The positive-pulse theorem now applies to this specified H_{reg}, conditional on the retained positive source holding, preparation, complete readout, selectable controls and external switching. Shorter pulses still require the larger amplitudes in (18.14). The construction supplies the complete finite extension and its error accounting under precisely those interfaces.

Appendix B

Deriving the conserved native count

The recorder bound uses the sum of the projections P_c across the source and reference cells. This appendix derives its conservation from the two native conserved quantities, clock energy and occupation. The calculation is finite. It gives an expression for P_c using the two one-cell charges, identity, linear combinations and commutators. Those operations transport to sums of charges over arbitrarily many cells.

B.1 Separate the spectral gaps of the clock

Conjugate the one-cell operators by the Fourier matrix W of Chapter 19. Write

$$D = W^* K W = \operatorname{diag}(0, 1, \dots, 7), \qquad T = W^*(iSF)W.$$

Since $N = (I - iSF)/2$, we also have $T = I - 2W^*NW$. Thus D and T are available from the two charges and identity. The matrix T is Hermitian.

Let E_{ij} denote a matrix unit, with indices $0, \dots, 7$. For any matrix X,

$$[D, X]_{ij} = (i - j)X_{ij}.$$

The possible integer gaps are $-7, -6, \dots, 7$. For one of these gaps d, define the polynomial

$$p_d(t) = \prod_{\substack{-7 \le k \le 7 \\ k \ne d}} \frac{t - k}{d - k}.$$

Every denominator is nonzero. At an allowed integer gap, p_d is 1 for gap d and 0 for all the others. Therefore

$$\big(p_d(\operatorname{ad}_D)X\big)_{ij} = \begin{cases} X_{ij}, & i - j = d, \\ 0, & i - j \ne d, \end{cases} \qquad \operatorname{ad}_D(X) = [D, X]. \tag{B.1}$$

The left side is a finite linear combination of iterated commutators. This formula extracts a specified spectral gap without assuming that its matrix entries are independently controllable.

Put $A_d = p_d(\operatorname{ad}_D)T$. Because T is Hermitian, $A_{-d} = A_d^*$. Both sides are obtained by the same gap-filter construction; taking an adjoint introduces no extra generator.

B.2 The entries needed for the certificate

The Fourier entries can be calculated directly:

$$T_{ij} = \frac{1}{8} \sum_{k=0}^{7} \overline{\omega^{ki}}\, i s_k\, \omega^{f(k)j}. \tag{B.2}$$

Here s_k is the kth diagonal entry of S, and f interchanges 0 with 1, 2 with 3, 4 with 5, and 6 with 7. The powers of ω are

$$1,\ \frac{1-i}{\sqrt{2}},\ -i,\ -\frac{1+i}{\sqrt{2}},\ -1,\ \frac{-1+i}{\sqrt{2}},\ i,\ \frac{1+i}{\sqrt{2}}.$$

Only gaps 7, 5 and 3 are needed. Substituting these eight powers in (B.2) gives

$$\begin{aligned}
A_7 &= a_7 E_{70},\\
A_5 &= a_{50}E_{50} + a_{61}E_{61} + a_{72}E_{72},\\
A_3 &= a_{30}E_{30} + a_{30}E_{41} + a_{52}E_{52} + a_{63}E_{63} + a_{74}E_{74},
\end{aligned}$$

where

$$\begin{aligned}
a_7 &= \frac{-1+i-i\sqrt{2}}{4}, & a_{50} &= \frac{1+i+i\sqrt{2}}{4},\\
a_{61} &= \frac{-1+\sqrt{2}+i}{4}, & a_{72} &= \frac{1-\sqrt{2}-i}{4},\\
a_{30} &= \frac{-1+i+i\sqrt{2}}{4}, & a_{52} &= \frac{1-\sqrt{2}+i}{4},\\
a_{63} &= \frac{-1+\sqrt{2}-i}{4}, & a_{74} &= \frac{1-i-i\sqrt{2}}{4}.
\end{aligned}$$

All remaining entries in these three gap matrices vanish by (B.1).

The numbers needed below are their squared magnitudes. Set

$$\alpha = \frac{2+\sqrt{2}}{8}, \qquad \beta = \frac{2-\sqrt{2}}{8}, \qquad c_+ = 8+4\sqrt{2}, \quad c_- = 8-4\sqrt{2}.$$

The displayed coefficients give

$$\begin{aligned}
|a_7|^2 = |a_{61}|^2 = |a_{72}|^2 &= \beta,\\
|a_{50}|^2 = |a_{30}|^2 = |a_{74}|^2 &= \alpha,\\
c_+\beta = 1, \qquad c_-\alpha &= 1.
\end{aligned}$$

For example, $|a_{50}|^2 = (1+(1+\sqrt{2})^2)/16 = (2+\sqrt{2})/8$. These exact radical identities fix all coefficients in the count expression.

B.3 A finite expression for the odd-mode projection

First isolate the two end levels:

$$D_{70} = c_+[A_7, A_7^*] = E_{77} - E_{00}.$$

For a diagonal matrix D', the coefficient of E_{ij} in $[D', X]$ is multiplied by $D'_{ii} - D'_{jj}$. Hence

$$B_5 = [D_{70}, A_5] = a_{50}E_{50} + a_{72}E_{72}, \qquad B_3 = [D_{70}, A_3] = a_{30}E_{30} + a_{74}E_{74}.$$

The interior entries have disappeared. Their adjoints are likewise finite expressions: $B_5^* = [A_5^*, D_{70}]$ and $B_3^* = [A_3^*, D_{70}]$.

Introduce four diagonal matrices obtained by further commutators:

$$\begin{aligned} Q_{\mathrm{all}} &= [A_5, A_5^*], \\ Q_5 &= [B_5, B_5^*], \\ T_5 &= [[Q_5, B_5], B_5^*], \\ Q_3 &= [B_3, B_3^*]. \end{aligned}$$

The rule $E_{ij}E_{kl} = \delta_{jk}E_{il}$ makes their calculation short. The nonzero entries of A_5, B_5 and B_3 have different source and target indices, so cross terms vanish. We obtain

$$Q_{\mathrm{all}} = \alpha(E_{55} - E_{00}) + \beta(E_{66} - E_{11}) + \beta(E_{77} - E_{22}), \tag{B.3}$$

$$Q_5 = \alpha(E_{55} - E_{00}) + \beta(E_{77} - E_{22}), \tag{B.4}$$

$$T_5 = 2\alpha^2(E_{55} - E_{00}) + 2\beta^2(E_{77} - E_{22}), \tag{B.5}$$

$$Q_3 = \alpha(E_{33} - E_{00} + E_{77} - E_{44}). \tag{B.6}$$

For (B.5), the two entries of $[Q_5, B_5]$ acquire factors 2α and 2β. Commuting with B_5^* gives the stated squared coefficients.

Proposition B.1 (The count identity)**.** *The odd-mode projection is the following finite expression:*

$$\begin{aligned} P_{\mathrm{odd}} = \frac{1}{2}\big(I - D_{70} - c_+ Q_{\mathrm{all}} + (24 + 4\sqrt{2})Q_5 \\ - 16T_5 + c_- Q_3\big), \end{aligned} \tag{B.7}$$

where $P_{\mathrm{odd}} = \mathrm{diag}(0, 1, 0, 1, 0, 1, 0, 1)$.

Proof. All matrices on the right are diagonal. Set $d = 24 + 4\sqrt{2}$ and write $s = \sqrt{2}$. In addition to $c_+\beta = c_-\alpha = 1$, direct substitution using $s^2 = 2$ gives

$$(d - c_+)\alpha - 32\alpha^2 = 1, \qquad (d - c_+)\beta - 32\beta^2 = 1.$$

The diagonal entries inside the parentheses in (B.7), in index order, are therefore

$$\begin{gathered} 2 - (d - c_+)\alpha + 32\alpha^2 - c_-\alpha = 0, \\ 1 + c_+\beta = 2, \\ 1 - (d - c_+)\beta + 32\beta^2 = 0, \\ 1 + c_-\alpha = 2, \\ 1 - c_-\alpha = 0, \\ 1 + (d - c_+)\alpha - 32\alpha^2 = 2, \\ 1 - c_+\beta = 0, \\ (d - c_+)\beta - 32\beta^2 + c_-\alpha = 2. \end{gathered}$$

Thus the diagonal inside the parentheses is $(0, 2, 0, 2, 0, 2, 0, 2)$. Division by 2 proves the formula. □

Finally, the jth Fourier column is an eigenvector of the four-step shift with eigenvalue $\omega^{4j} = (-1)^j$. Consequently

$$W^* P_c W = P_{\mathrm{odd}}.$$

Conjugating (B.7) by W gives the required expression for P_c in I, K, N. Conjugation preserves linear combinations and commutators. The gap filters and all intermediate matrices above are explicit finite expressions in those operations.

B.4 Transport to a conserving recorder

For m cells, possibly accompanied by a neutral factor, write $\mathscr{L}_m(T) = \sum_{j=1}^{m} T^{(j)}$. This map preserves addition and scalar multiplication. Expanding the commutator of two such sums,

$$[\mathscr{L}_m(T), \mathscr{L}_m(T')] = \sum_{j,k} [T^{(j)}, T'^{(k)}] = \sum_{j} [T, T']^{(j)} = \mathscr{L}_m([T, T']).$$

Terms on different slots vanish. Also $\mathscr{L}_m(I) = mI$; this scalar multiple of identity commutes with every interaction.

If an operator U commutes with two matrices, it commutes with their products, sums, scalar multiples and commutator. Start with the two conserved collective charges. Apply these facts successively to the finite expression just proved. The result is

$$[U, \mathscr{L}_m(H_0)] = [U, \mathscr{L}_m(N)] = 0 \quad \Longrightarrow \quad [U, \mathscr{L}_m(P_c)] = 0,$$

using the nonzero factor in $H_0 = \varepsilon_0 K$. Taking $m = r + 2$ and grouping the first two slots as the source gives

$$\mathscr{L}_m(P_c) = A \otimes I + I \otimes R,$$

the count used in the recorder theorem. No assumption about the state of the r recorder cells occurs in this transport argument.

Appendix C

A toolkit for reading the proofs

A long proof becomes easier to follow when its small moves are familiar. This appendix explains the moves used throughout the book and points to places where they do actual work. It can be read before the main text or consulted when a particular step becomes difficult.

The notation guide in Appendix N gives shorter reminders. Here the aim is to explain how to use the notation while following an argument.

C.1 Read a theorem as a task

A theorem separates the data supplied from the conclusion to be obtained. Start by identifying both. In Theorem 2.3, the supplied data are a carrier, a start and a step. The conclusion asks for a map with two equations, and says that only one such map exists. There are therefore two tasks: construct the map and rule out a different one.

The construction comes first. Its recursive equations tell us what value to give the start and how to continue after a step. For uniqueness, the proof introduces an arbitrary competing map. It uses only the two equations required of that competitor, then proves agreement at every finite record. The competitor's arbitrariness is what lets the conclusion cover all permitted maps.

When the next theorem adds injectivity, do not carry that condition backward into the earlier proof. The unique reading exists even for a target that merges records. The conditions in Definition 2.4 enter the later proof that the reading is bijective. Separating the tasks prevents a uniqueness theorem from acquiring a stronger conclusion than it proves.

An efficient way to read a displayed calculation is to mark each equality by its source: a definition, the current hypothesis or an earlier result. If the source is unclear, inspect that one step before continuing. Long strings of equalities are usually several short substitutions in sequence.

C.2 Induction follows a finite construction

In Chapter 1, an orbit expression is built by the start constructor or by applying the step constructor to an earlier expression. A proof by structural induction follows these two cases. The induction hypothesis is the assertion already available for the earlier expression. The step case must turn that assertion into the assertion for the new one.

Consider the second round trip in Theorem 1.4:

$$e(r(a)) = a.$$

At the start, the defining equations of e and r give the result. In the step case, suppose the

displayed identity holds for a. Then

$$e(r(S(a))) = e(r(a) + 1) = S(e(r(a))) = S(a).$$

The first two equalities unfold definitions. The last uses the induction hypothesis inside S. That is the whole step. It does not assume the round-trip identity for the expression currently being proved.

The object of induction changes across the book. An induction on an orbit expression follows its start and step. An induction on a formula follows its logical constructors. An induction on a derivation follows its last rule and the derivations of its premises. These proofs have a common shape, but their cases come from different definitions.

Some induction hypotheses must quantify over an extra parameter. In the injectivity proof of Chapter 2, the statement for a says that *for every* c, equality of the two readings implies $a = c$. This lets the step proof use the hypothesis at the predecessor d of a newly examined expression $c = S(d)$. A hypothesis fixed at one earlier choice of c would not supply that step.

Recursion constructs an object by the same pattern. Induction proves a property of all objects so constructed. The distinction becomes especially important in Chapter 9, where the available construction rules are themselves being compared inside a specified language.

C.3 Maps, round trips and quotients

A map specifies one output for each input, so a relation with exactly one output for each input is a map; this reading is the principle of unique choice, and the paragraph before Definition 12.21 notes where it matters. A map is *injective* when equal outputs imply equal inputs, and *surjective* when every member of its stated target is an output. A bijection has both properties. The target matters: being onto the range of a map is different from being onto a larger ambient carrier.

The two round trips of Theorem 1.4 do different jobs. Reading and then expanding recovers the original tally. Expanding and then reading recovers the original number. Together they establish a reversible change of representation. Chapter 8 repeats this argument for lists of one mark and then uses both directions to transport quantified formulas. With only the first direction, as Theorem 8.8 shows, purely existential statements go up and purely universal statements come down, and Proposition 8.9 shows that no other quantifier prefix transfers.

A commuting diagram records an equality of routes. In Figure 2.1, the upper and right arrows mean "step, then translate." The left and lower arrows mean "translate, then step." The diagram commutes because both routes have the value required by (2.1). The drawing summarizes an equation; it does not prove the equation by itself.

A quotient has a different purpose. It deliberately identifies objects related by a specified equivalence relation. A representative is one object used to describe a class. In Chapter 4, a signed difference has representatives (a, b), and balance is the relation

$$(a, b) \sim (c, d) \quad \Longleftrightarrow \quad a + d = c + b.$$

An operation on representatives becomes an operation on classes only after we show that replacing the representatives by equivalent ones gives an equivalent output. This is the

well-definedness argument. Without it, the proposed answer could depend on a choice that the quotient has discarded.

For a reader r, the kernel relation identifies exactly those inputs with the same reading. Theorem 8.13 sends the class of x to $r(x)$. The definition of the kernel proves both that this is well-defined and that it is injective. Its target is the range, so an element of that target already comes with a preimage. This is why the theorem gives a bijection to the range without claiming that the reader reaches every value in a larger target space.

C.4 Quantifiers say what information must be supplied

The assertion $\forall x\, P(x)$ asks for the property at an arbitrary input. The assertion $\exists x\, P(x)$ is established constructively by giving an input together with its property. A negation $\neg P$ means that P would lead to an impossible case. These forms provide different information to a later proof.

For example, a proof of $\neg\neg\exists n\, P(n)$ rules out the denial of all witnesses. It does not, by its form alone, display a witness. Chapter 6 states the additional Markov principle used to make that passage for decidable predicates. On the continuum this passage is exactly the step from "not zero" to a sign (Theorem 12.11). The pairwise decisions and the global witness are separate inputs to the reasoning.

Quantifier order is just as important. The finite-prefix result of Chapter 10 gives a program for each supplied finite table. The program may depend on that table and its budget. A uniform name asks for one program that works at every precision. Moving the existence of the program ahead of the precision request changes what must be constructed. Theorem 11.11 proves that this change has real content in the specified classical comparison.

Freshness conditions enforce arbitrariness inside the proof language. When a universal variable is introduced, the old hypotheses are lifted past it. They cannot silently fix its value. When an existential witness is used, the final conclusion must not depend on which fresh witness was chosen. The lifting marks in Appendix D are the bookkeeping that enforces these conditions.

C.5 Equivalences and countermodels answer different questions

To prove $A \iff B$, prove both directions. In the catalogue results, one direction uses a logical principle to obtain a classification. The reverse direction turns a question about that principle into a particular congruence. Applying the proposed classification to that congruence supplies the desired answer. This reverse construction is what makes the logical price exact.

Merely finding an EM-labelled proof does not establish that its conclusion requires excluded middle. Chapter 6 gives two proofs of the same small disjunction with different ledgers. A ledger describes the route actually taken. A necessity result must exclude a cheaper route or recover the claimed resource from the conclusion.

A countermodel excludes a proposed rule by satisfying the retained rules while failing the

proposed conclusion. The two-chain model of Chapter 9 supports indexed recursion on both chains, but the designated start reaches only the first. The proof then exhibits an expressible family that distinguishes this failure.

Two checks are indispensable. The interpretation must satisfy every rule of the weaker language, including conversion and substitution. And the failed statement must really be expressible in that language. An informal property outside the language cannot serve as its separating judgment. Section 9.8 supplies the soundness argument that makes the concrete models usable for this purpose.

The same two checks govern the models that separate logical principles. In Sections 7.10 and 7.12 a formula takes its value among the open sets of a space, or in a chain, rather than among true and false. Lemma 7.21 is the soundness check: every derivable sentence takes the top value. The principles and the versions of the classification are sentences of the system, which is the expressibility check. A principle whose value lies below the top is then not derivable, and two principles with different values in one model are not equivalent.

C.6 Reading the finite matrices

Chapters 18 and 19 use finite complex matrices. A column vector lists the coordinates of a state vector. A matrix lists the coefficients of a linear map: each output coordinate is obtained by multiplying a row by the input column and adding the products. The order of a matrix product matters because the right-hand map acts first.

The adjoint, written A^* or $A^\dagger$, is the conjugate transpose. Both symbols mean the same operation here. A Hermitian matrix equals its adjoint. An orthogonal projection satisfies $P^* = P$ and $P^2 = P$; applying it twice has the same effect as applying it once. A unitary matrix satisfies $U^*U = UU^* = I$, so its adjoint reverses its action.

An isometry V may be rectangular. It satisfies $V^*V = I$ on its input space. Its columns have unit norm and are mutually orthogonal. The matrix VV^* acts on the larger output space and projects onto the embedded input. This is the distinction used in the dilation proof of Theorem 18.3: the complement $I - VV^*$ is a necessary part of the full operation.

Block notation groups coordinates without removing them. In the dilation, the two block rows specify outputs in the input-sized space and the larger space. To check the square of that block matrix, multiply block rows by block columns in order. The off-diagonal blocks vanish because the complement projection kills the image of V. The diagonal blocks become identities. The proof in the chapter displays all four blocks.

A state matrix ρ is positive with trace one. Positivity says that $x^*\rho x \geq 0$ for every column x; the trace is the sum of the diagonal entries. In a finite instrument, the output is divided into blocks indexed by the retained mark. The trace of a block is that mark's probability. The block itself also contains the returned quantum state. Keeping only its trace would discard part of the operation being compared.

The norm tells us which size of error is controlled. For an operator, its norm bounds its action on unit vectors. For a Hermitian state difference, the trace norm is the sum of the absolute eigenvalues. Chapter 18 uses the full trace norm, with no factor of one half. Chapter 19

instead bounds the absolute probability error of one sharp event, uniformly over all unit source vectors. The hypotheses and constants should be read with those different comparisons in mind.

C.7 Eigenvalues, positivity and evolution

An eigenvector of a matrix is a nonzero vector whose direction is unchanged by the matrix; the eigenvalue is its scalar multiplier. The finite spectral theorem says that a Hermitian matrix has an orthonormal basis of eigenvectors and real eigenvalues. In that basis, checking positivity means checking that the diagonal eigenvalues are nonnegative. Changing back to the original coordinates keeps the same operator.

This is the theorem used when Proposition 18.2 takes the square root of a positive Choi matrix: take the nonnegative square root of each eigenvalue and change coordinates back. The proof then reshapes its columns into branch matrices. The spectral theorem establishes the existence of this factorization. It does not by itself give the effective naming procedure established later by rational search.

The same method explains the exponential of a Hermitian energy operator. In an eigenbasis, evolution multiplies each coordinate by a complex phase determined by that coordinate's energy and the elapsed time. Each phase has absolute value one, so the evolution preserves lengths. A skew-Hermitian generator is the corresponding object with the factor of i already incorporated; its real-time exponential is unitary.

Products of evolutions require care. Two energy operators need not have the same eigenvectors, and their order can matter. This is why the pulse proof does not split the background holding energy from the control by pretending they commute. It bounds the difference of the full exponentials in (18.15). The scalar baseline can be separated because an identity operator commutes with every matrix. Appendix A then explains how products and commutators make further matrix directions available in the closure of finite operation sequences. A limiting existence proof and a practical bound on the required sequence length remain different questions.

C.8 Keeping both systems in the calculation

A tensor product keeps the coordinates of two systems together. A product vector $x \otimes p$ describes the particular separated preparation used in Chapter 19. An operator $A \otimes I$ acts on the first factor, and $I \otimes R$ acts on the second. The total count is their sum. Grouping several cells into the recorder factor does not require those cells to be mutually uncorrelated.

This distinction is visible in the variance calculation. The proof uses the product between the unknown source and the whole fixed recorder. It does not split the recorder into independent cell states. The projection-sum estimate therefore remains valid when its cells and neutral memory have internal correlations.

A retained reference plays another role. It is an additional system whose correlations with the input must survive the comparison of instruments. The construction in Chapter 18 leaves that reference untouched while comparing the complete output on the joint state. The error

bound is independent of the finite reference dimension. This is stronger information than a comparison of mark probabilities alone.

Whenever a tensor product appears, name the factors before manipulating the formula. Then identify which factors each operator acts on. That small step explains the commutation of operators on different slots, the role of the neutral pointer and the exact place where an initial product preparation is used.

Appendix D

The rules at a glance

This appendix collects the rules of Chapters 5 and 6 in one place. It is a reference for the specified arithmetic language. The typed language of Chapter 9 has its own formation, conversion and elimination rules; its three orbit constructions are recalled at the end.

D.1 Reading the notation

Terms are variables, 0, successors, sums and products. Formulas are equalities, $\bot$, conjunctions, disjunctions, implications and quantified formulas. Write $\neg\varphi$ for $\varphi \to \bot$. A context Γ is a finite list of hypotheses. In a displayed rule, the judgments above the line are premises and the judgment below is the conclusion. A judgment displayed without premises is an available leaf.

The expression $\varphi(t)$ means capture-avoiding substitution at variable position zero. The lift $\varphi\uparrow$ moves the free variables past a new position; $\Gamma\uparrow$ lifts every formula of the context. These operations are defined in Definition 5.2. In ordinary named-variable notation, they enforce the familiar requirement that the newly bound variable is fresh for the old hypotheses.

D.2 The arithmetic base

Hypothesis and equality

$$\frac{\varphi \in \Gamma}{\Gamma \vdash \varphi}, \qquad \Gamma \vdash t = t, \qquad \frac{\Gamma \vdash t = s \qquad \Gamma \vdash \varphi(t)}{\Gamma \vdash \varphi(s)}.$$

Start, step and operations

$$\Gamma \vdash \neg(S(t) = 0), \qquad \frac{\Gamma \vdash S(t) = S(u)}{\Gamma \vdash t = u}.$$

$$\Gamma \vdash t + 0 = t, \qquad \Gamma \vdash t + S(u) = S(t + u),$$
$$\Gamma \vdash t \cdot 0 = 0, \qquad \Gamma \vdash t \cdot S(u) = t \cdot u + t.$$

$$\frac{\Gamma \vdash \varphi(0) \qquad \Gamma \vdash \forall x\big(\varphi(x) \to \varphi(S(x))\big)}{\Gamma \vdash \forall x\, \varphi(x)}.$$

The induction variable in the last display is fresh for Γ. Parameters other than that variable may remain free. The formula φ may contain quantifiers; that fact affects its ledger entry.

D.3 The logical rules

Implication and falsehood

$$\frac{\Gamma, \varphi \vdash \psi}{\Gamma \vdash \varphi \to \psi}, \qquad \frac{\Gamma \vdash \varphi \to \psi \qquad \Gamma \vdash \varphi}{\Gamma \vdash \psi}, \qquad \frac{\Gamma \vdash \bot}{\Gamma \vdash \chi}.$$

Conjunction

$$\frac{\Gamma \vdash \varphi \qquad \Gamma \vdash \psi}{\Gamma \vdash \varphi \wedge \psi}, \qquad \frac{\Gamma \vdash \varphi \wedge \psi}{\Gamma \vdash \varphi}, \qquad \frac{\Gamma \vdash \varphi \wedge \psi}{\Gamma \vdash \psi}.$$

Disjunction

$$\frac{\Gamma \vdash \varphi}{\Gamma \vdash \varphi \vee \psi}, \qquad \frac{\Gamma \vdash \psi}{\Gamma \vdash \varphi \vee \psi},$$

$$\frac{\Gamma \vdash \varphi \vee \psi \qquad \Gamma, \varphi \vdash \chi \qquad \Gamma, \psi \vdash \chi}{\Gamma \vdash \chi}.$$

Quantifiers

$$\frac{\Gamma\uparrow \vdash \varphi}{\Gamma \vdash \forall \varphi}, \qquad \frac{\Gamma \vdash \forall \varphi}{\Gamma \vdash \varphi(t)}, \qquad \frac{\Gamma \vdash \varphi(t)}{\Gamma \vdash \exists \varphi},$$

$$\frac{\Gamma \vdash \exists \varphi \qquad \Gamma\uparrow, \varphi \vdash \psi\uparrow}{\Gamma \vdash \psi}.$$

The final conclusion of existential elimination is lifted in the second premise. It therefore cannot depend on the fresh witness position.

D.4 Additional schemas and their records

The three optional schemas are

$$\begin{aligned}
&\text{EM:} && \Gamma \vdash \varphi \vee \neg\varphi,\\
&\text{LPO:} && \Gamma \vdash \big[\forall x(\varphi(x) \vee \neg\varphi(x))\big]\\
&&& \qquad \to \big[(\exists x\, \varphi(x)) \vee (\forall x \neg\varphi(x))\big],\\
&\text{MP:} && \Gamma \vdash \neg\neg\exists x\, \varphi(x) \to \exists x\, \varphi(x).
\end{aligned}$$

The MP schema is restricted to quantifier-free φ. Its interpretation uses the decidability established in Lemma 6.2; it is not an unrestricted double-negation elimination rule. So

restricted, and with induction on every formula, it is derivable from the base rules: a quantifier-free formula is eventually constant in its searched variable (Lemma 6.8), and the existential is a finite search (Theorem 6.9). The LPO schema applies to every formula, and with induction on every formula it proves every instance of the EM schema (Theorem 6.10). At that level the three schemas therefore mark two strengths: MP with the base rules, and LPO with EM (Theorem 6.11). Without induction, or with induction on quantifier-free formulas only, they mark four (Propositions 6.13 and 6.14).

For a derivation, the ledger $(e, \ell, m; i)$ records, in order, occurrence of EM, LPO, MP and induction on a formula containing a quantifier. Combine premises by inclusive-or in each coordinate, then add the contribution of the current rule. Thus the ledger records occurrence, not multiplicity. An empty ledger has four false coordinates. A posit-free derivation has its first three coordinates false and may still have the fourth coordinate true.

These schemas are formulas of the arithmetic language. Principles about arbitrary propositions and predicates in the surrounding mathematics are stated separately in Definition 6.1. The soundness argument explains how the latter validate the former. A reader should not replace one level by the other merely because both use the same abbreviation. The two levels also differ in strength. In the metatheory the three principles keep their separate strengths; as schemas of this language, with induction on every formula, MP is derivable and LPO is equivalent to EM. Interpreting any derivation needs at most the metatheoretic LPO, applied to the predicates that formulas define, and interpreting all derivations with an EM entry, or all with an LPO entry, needs exactly that (Corollary 6.15).

Peano arithmetic, as presented in Chapter 8, uses the same formulas. It states successor injectivity as the axiom $S(t) = S(u) \to t = u$, makes excluded middle an ordinary rule and keeps no ledger. By Theorem 8.11 it proves exactly what these rules prove with EM allowed and LPO and MP excluded, from every finite context. Deleting excluded middle from it gives Heyting arithmetic, which proves exactly what the posit-free derivations prove (Corollary 8.12).

D.5 The three orbit constructions

Chapter 9 specifies a typed language with orbit type O, an empty type, dependent functions and identity types. An iterator has a fixed target type B, a starting value $b : B$ and an update $g : B \to B$:

$$I(B, b, g, 0) \equiv b, \qquad I(B, b, g, S(x)) \equiv g(I(B, b, g, x)).$$

An indexed recursor still has fixed target B, but its update receives the preceding orbit point as well as the preceding value:

$$R(B, b, g, 0) \equiv b, \qquad R(B, b, g, S(x)) \equiv g(x, R(B, b, g, x)).$$

Here $g : \Pi x : O(B \to B)$. A dependent eliminator has a family $P(x)$, a start $b : P(0)$ and a step $g : \Pi x : O(P(x) \to P(S(x)))$:

$$E(P, b, g, 0) \equiv b, \qquad E(P, b, g, S(x)) \equiv g(x, E(P, b, g, x)).$$

Its result at x has type $P(x)$.

The symbol $\equiv$ here denotes the conversion relation of that language. It includes the specified computation equations and their closure under constructors and capture-avoiding substitution. The language does not silently add equality reflection, function extensionality or a uniqueness rule for recursive definitions.

The optional discriminator has computation equations

$$D(0) \equiv \mathrm{Id}_O(0,0), \qquad D(S(x)) \equiv \mathbf{0}.$$

It is part of the language used for the relevant separation result. Full formation and identity-elimination rules remain in Chapter 9. These displays are a reminder of their inputs and computation equations, not permission to ignore the typing conditions in that chapter.

Appendix E

The prices of the three rules: supporting proofs

This appendix supplies the routine verifications behind four proofs of Chapter 6: the derivation of every restricted Markov instance (Theorem 6.9), the realizability argument (Theorem 6.11), and the two models with two stages (Propositions 6.13 and 6.14). The central steps are proved in the chapter; here we check the cases.

E.1 Arithmetic inside the rules

The derivations in this section are from no hypotheses, use no EM, LPO or MP rule, and leave their variables free; a derivation of an implication serves as a derived rule. Equality is symmetric and transitive, and is respected by S, $+$ and $\cdot$, by one use of equality substitution each together with reflexivity, as in the proof of Proposition 5.6. We use the abbreviations $u \le w$, $u < w$ and $\leftrightarrow$ of the proof of Theorem 6.9. The equivalence $\leftrightarrow$ is reflexive, symmetric and transitive, and is respected by $\wedge$, $\vee$ and $\to$; these are derivations by the propositional rules alone.

Lemma E.1 (Arithmetic facts)**.** *The following have derivations.*

1. *The laws* $0 + x = x$, $S(x) + y = S(x + y)$, $x + y = y + x$, $(x + y) + z = x + (y + z)$, $0 \cdot x = 0$, $S(x) \cdot y = x \cdot y + y$, $x \cdot y = y \cdot x$, $x \cdot (y + z) = x \cdot y + x \cdot z$, $(x + y) \cdot z = x \cdot z + y \cdot z$, $(x \cdot y) \cdot z = x \cdot (y \cdot z)$, $S(0) \cdot x = x$, *and cancellation* $a + c = b + c \to a = b$. *Each uses induction on a quantifier-free formula only.*
2. *For every quantifier-free* ψ, $\psi \vee \neg\psi$.
3. *Every number is* 0 *or a successor:* $x = 0 \vee \exists k\,(x = S(k))$.
4. *The order facts* $\neg(y < 0)$; $a + c = b \to (a < b \vee a = b)$; $y < S(n) \to (y < n \vee y = n)$; $c \le c + u$; $y \le b \to y \le a + b$; $0 \le u$; *and* $y \le a \to S(a) \le X \to y < X$.
5. *Comparison:* $x < y \vee y \le x$.
6. *Uniqueness of remainders:* $q \cdot d + r = p \cdot d + s \to r < d \to s < d \to r = s$.
7. *Cancellation of a nonzero factor:* $A \cdot S(m) = B \cdot S(m) \to A = B$.

Items 2, 3, 5, 6 and 7 use induction on formulas with quantifiers, and item 4 uses item 3.

Proof. Item 1. Follow the proofs of Lemma 3.2, Theorem 3.3, Proposition 3.4, Lemma 3.6, Proposition 3.7, Theorem 3.8 and Proposition 3.9, as Corollary 5.9 does for commutativity. Each induction there is on an equation, or for cancellation on the implication $a + c = b + c \to a = b$ in c, whose step uses injectivity; the other variables are parameters. The right distributive law follows from the left one and commutativity, and $S(0) \cdot x = 0 \cdot x + x = x$.

Item 2. Equations are decided by (6.9), which is derived in the proof of Theorem 6.10 by an induction on the formula $\forall y(x = y \vee \neg(x = y))$. The other cases of that proof, for $\bot$, $\wedge$, $\vee$ and $\to$, use no additional rule.

Item 3. Induct on x with the formula itself. At 0 take the left side; at $S(x)$ take the right side with witness x.

Item 4. From $y + S(j) = 0$ the recursive equation gives $S(y + j) = 0$, against separation. For the second fact split c by item 3: if $c = 0$ then $a = a + 0 = b$; if $c = S(k)$ then $a + S(k) = b$ is $a < b$. For the third, $y + S(j) = S(n)$ gives $S(y + j) = S(n)$, injectivity gives $y + j = n$, and the second fact applies. The fourth has witness u; for the fifth, $y + j = b$ gives $y + (a + j) = a + b$ by the laws of item 1; the sixth has witness u by $0 + u = u$. For the last, $y + j = a$ and $S(a) + j' = X$ give $y + S(j + j') = S(a + j') = S(a) + j' = X$.

Item 5. Induct on x, with y a parameter, on the formula $x < y \vee y \leq x$. At 0 split y by item 3: $y = 0$ gives $y \leq 0$ with witness 0, and $y = S(k)$ gives $0 + S(k) = y$. For the step, if $x + S(k) = y$ then $S(x) + k = y$, and the second order fact gives $S(x) < y$ or $S(x) = y$, the latter giving $y \leq S(x)$ with witness 0; if $y + k = x$ then $y + S(k) = S(x)$.

Item 6. Induct on q with the formula $\forall p\,(q \cdot d + r = p \cdot d + s \to r < d \to s < d \to r = s)$, keeping d, r, s as parameters, and split p by item 3. If $q = p = 0$ the equation is $r = s$. If $q = 0$ and $p = S(p')$, then $r = (p' \cdot d + s) + d$, and $r + S(k) = d$ gives $S((p' \cdot d + s) + k) + d = 0 + d$, so cancellation yields a successor equal to 0, which is impossible; the case $q = S(q')$, $p = 0$ is symmetric, using $s < d$. If $q = S(q')$ and $p = S(p')$, the equation reads $(q' \cdot d + r) + d = (p' \cdot d + s) + d$; cancel d and apply the induction hypothesis at p'.

Item 7. Induct on A with the formula $\forall B(A \cdot S(m) = B \cdot S(m) \to A = B)$, and split B by item 3. If $A = B = 0$ there is nothing to prove. If exactly one of them is 0, the other side is $k \cdot S(m) + S(m) = S(k \cdot S(m) + m)$, a successor equal to 0, which is impossible. If $A = S(a)$ and $B = S(k)$, the equation is $a \cdot S(m) + S(m) = k \cdot S(m) + S(m)$; cancellation gives $a \cdot S(m) = k \cdot S(m)$, the induction hypothesis at k gives $a = k$, and so $S(a) = S(k)$. □

Lemma E.2 (Polynomial forms)**.** *For every term s and every term X, there is a derivation of $s(X) = h_X(\vec{c})$, where $\vec{c}$ is the coefficient list of s defined in the proof of Theorem 6.9. It uses only the laws of Lemma E.1(1).*

Proof. Recursion on s in the metatheory. For x, $(0 \cdot X + S(0)) \cdot X + 0$ equals X because $0 \cdot X + S(0) = S(0)$ and $S(0) \cdot X = X$. A parameter p equals $0 \cdot X + p$, and 0 is $h_X()$. For $S(s)$, the form of s is 0 or $h \cdot X + c$, and $S(0) = 0 \cdot X + S(0)$ and $S(h \cdot X + c) = h \cdot X + S(c)$. For sums, recursion on the two lists uses $(a \cdot X + c) + (b \cdot X + d) = (a + b) \cdot X + (c + d)$ and $0 + h = h = h + 0$. For products, a separate recursion on the list $\vec{d}$ gives

$$c \cdot h_X(\vec{d}) = h_X(c \cdot \vec{d}),$$

from $c \cdot (h \cdot X + d) = (c \cdot h) \cdot X + c \cdot d$. Then recursion on the first list uses $0 \cdot h = 0$ and

$$(h \cdot X + c) \cdot g = (h \cdot g) \cdot X + c \cdot g = h_X(0, \vec{e}) + h_X(c \cdot \vec{d}),$$

where $g = h_X(\vec{d})$, $h \cdot g = h_X(\vec{e})$ by the recursion, and $h_X(0, \vec{e}) = h_X(\vec{e}) \cdot X + 0$; the sum case then combines the two forms. Each displayed identity follows from the laws of Lemma E.1(1), and the derivations are combined by the congruence of equality. □

E.2 Structures with two stages

Two-stage structures, the passage h, the environments $h\rho$ and the forcing relation $\rho \Vdash \varphi$ are defined in the proof of Proposition 6.13. Throughout this section the metatheory is classical, and satisfaction at the later stage, $M_1, \sigma \vDash \varphi$, is that of Definition 5.7. A context is forced at ρ when each of its formulas is.

Lemma E.3 (Persistence and binding)**.** *Let (M_0, M_1, h) be a two-stage structure, ρ an environment in M_0, t a term, φ a formula and a an element of M_0.*

1. *The value of t in M_1 under $h\rho$ is h of its value in M_0 under ρ, and $h[a, \rho] = [h(a), h\rho]$.*
2. *If $\rho \Vdash \varphi$, then $M_1, h\rho \vDash \varphi$.*
3. *$[a, \rho] \Vdash \varphi\uparrow$ if and only if $\rho \Vdash \varphi$; and $\rho \Vdash \varphi(t)$ if and only if $[E_\rho(t), \rho] \Vdash \varphi$, where $E_\rho(t)$ is the value of t in M_0. Replacing the variable x_0 of φ by $S(x_0)$ replaces its assigned element a by $S(a)$: $[a, \rho] \Vdash \varphi^S$ if and only if $[S(a), \rho] \Vdash \varphi$.*

Proof. For the first assertion induct on t. A variable takes the value $h(\rho(k))$ on both sides by the definition of $h\rho$; zero goes to zero; and the successor, sum and product cases are the three equations that h preserves. The identity of environments holds position by position.

For persistence induct on φ, with ρ arbitrary. For an equation apply h to both values and use the first assertion. Falsehood is never forced. Conjunction and disjunction follow from the induction hypotheses for their components. For an implication or a universal formula the later clause of the forcing definition is exactly the required statement (for $\forall\varphi$, the clause at every b is satisfaction of $\forall\varphi$ in M_1 under $h\rho$). For $\exists\varphi$, a witness a with $[a, \rho] \Vdash \varphi$ gives $M_1, h[a, \rho] \vDash \varphi$ by the induction hypothesis, that is $M_1, [h(a), h\rho] \vDash \varphi$, so $h(a)$ is a witness in M_1.

For the third assertion, Lemma 5.4 holds in every structure, with the same proof (as noted in the proof of Theorem 5.8), and it holds for lifting and substitution at every cutoff and position, since its proof inducts with those parameters arbitrary. Repeat that proof for forcing. Equations use the term identities of that lemma in M_0. The connectives other than implication follow from the induction hypotheses. In the clauses for implication and the universal quantifier, the later conditions are statements of satisfaction in M_1 under $h\rho$ or $[b, h\rho]$; by the first assertion the modified environments correspond under h, because $h[a, \rho] = [h(a), h\rho]$ and h carries the value of a substituted term in M_0 to its value in M_1; so the lemma in M_1 transforms them as required. The statement about φ^S is the substitution identity at the term $S(x_0)$, whose value at $[a, \rho]$ is $S(a)$, as in the final assertion of Lemma 5.4. □

The later stage is an ordinary structure read classically. Its soundness needs no new idea.

Lemma E.4 (Soundness at the later stage)**.** *Let M be a structure satisfying the six arithmetic rules, and read satisfaction in M classically. Every derivation with no induction rule is sound in M, whatever EM, LPO and MP rules it contains: if σ satisfies its context, σ satisfies its conclusion. If, moreover, M satisfies every instance*

$$\big(\varphi(0) \wedge \forall x\,(\varphi(x) \to \varphi(S(x)))\big) \to \forall x\,\varphi(x)$$

with φ quantifier-free, under every environment, then the same holds for every derivation whose induction formulas are all quantifier-free.

Proof. The base rules are covered by the first case of Theorem 5.8, and the induction rule on a quantifier-free formula by the assumed instances. The three additional rules are true in M because the metatheory is classical. An EM instance $\varphi \vee \neg\varphi$ holds since $\sigma \vDash \varphi$ either holds or fails. For an LPO instance, either some b has $[b, \sigma] \vDash \varphi$, which gives $\exists x\,\varphi$, or none has, which gives $\forall x\,\neg\varphi$. For an MP instance, if $\exists x\,\varphi$ were false then $\neg\exists x\,\varphi$ would hold and contradict $\neg\neg\exists x\,\varphi$; so $\exists x\,\varphi$ holds. □

Theorem E.5 (Soundness at the earlier stage)**.** *Let (M_0, M_1, h) be a two-stage structure, and let d be a derivation of $\Gamma \vdash \varphi$ whose EM and MP entries are false, so that its only additional rules are LPO rules. Assume one of the following:*

(a) d contains no induction rule; or

(b) every induction formula of d is quantifier-free, M_1 satisfies the quantifier-free induction instances of Lemma E.4, and the earlier stage forces quantifier-free induction*: for every quantifier-free ψ and every environment ρ in M_0, if $\rho \Vdash \psi(0)$ and $\rho \Vdash \forall x(\psi(x) \to \psi(S(x)))$, then $\rho \Vdash \forall x\,\psi(x)$.*

Then every environment ρ in M_0 that forces Γ forces φ.

Proof. Induct on d, keeping the context, the conclusion and ρ arbitrary. Lemma E.3 is used throughout; its third assertion is called the binding lemma below. The subderivations of d inherit the hypotheses (a) or (b), so Lemma E.4 applies to each of them in M_1.

Hypotheses, reflexivity and equality substitution. A hypothesis is forced because the context is. Reflexivity compares a value with itself. For substitution, the premises give equal values $E_\rho(t) = E_\rho(s)$ in M_0 and $\rho \Vdash \varphi(t)$, that is $[E_\rho(t), \rho] \Vdash \varphi$ by the binding lemma; replacing the value by the equal one and applying the binding lemma again gives $\rho \Vdash \varphi(s)$.

The arithmetic rules. The rule $\neg(S(t) = 0)$ is an implication. Its earlier clause holds because no successor is zero in M_0, and its later clause because no successor is zero in M_1. Injectivity and the four recursive equations are statements about values in M_0, where they hold.

Implication. For introduction, let d' derive $\Gamma, \varphi \vdash \psi$. If $\rho \Vdash \varphi$, then ρ forces the context Γ, φ, and the induction hypothesis gives $\rho \Vdash \psi$. For the later clause, persistence gives $M_1, h\rho \vDash \Gamma$; if also $M_1, h\rho \vDash \varphi$, then Lemma E.4 applied to d' gives $M_1, h\rho \vDash \psi$. For elimination, apply the earlier clause of the forced implication to the forced antecedent.

Conjunction, disjunction and falsehood. Introductions and the eliminations of conjunction are immediate. For disjunction elimination, $\rho \Vdash \varphi \vee \psi$ means that one side is forced; add it to the forced context and apply the induction hypothesis for that branch. Falsehood is never forced, so the rule for an impossible case is vacuous.

Universal quantifier. For introduction, let d' derive $\Gamma\uparrow \vdash \varphi$. For an element a of M_0, the binding lemma shows that $[a, \rho]$ forces $\Gamma\uparrow$, and the induction hypothesis gives $[a, \rho] \Vdash \varphi$. For an element b of M_1, persistence gives $M_1, h\rho \vDash \Gamma$, hence $M_1, [b, h\rho] \vDash \Gamma\uparrow$ by (5.3) in M_1, and Lemma E.4 applied to d' gives $M_1, [b, h\rho] \vDash \varphi$. For elimination at a term t, use the earlier clause at $a = E_\rho(t)$ and the binding lemma.

Existential quantifier. For introduction at t, the element $E_\rho(t)$ is a witness by the binding lemma. For elimination, the first premise gives an element a with $[a,\rho] \Vdash \varphi$. The environment $[a,\rho]$ forces $\Gamma\uparrow$ by the binding lemma, so it forces the context $\Gamma\uparrow, \varphi$ of the second premise, whose induction hypothesis gives $[a,\rho] \Vdash \psi\uparrow$. The binding lemma turns this into $\rho \Vdash \psi$.

Induction. Under (a) there is no such rule. Under (b) the induction formula ψ is quantifier-free, the induction hypotheses give $\rho \Vdash \psi(0)$ and $\rho \Vdash \forall x(\psi(x) \to \psi(S(x)))$, and the assumption on the earlier stage gives $\rho \Vdash \forall x \psi$.

The LPO rule. Its conclusion is the implication $\forall x(\varphi \vee \neg\varphi) \to (\exists x \varphi \vee \forall x \neg\varphi)$. Its later clause holds by Lemma E.4. For the earlier clause, assume $\rho \Vdash \forall x(\varphi \vee \neg\varphi)$; we use only its earlier part, that $[a,\rho] \Vdash \varphi$ or $[a,\rho] \Vdash \neg\varphi$ for every element a of M_0. Either some a has $[a,\rho] \Vdash \varphi$, and then $\rho \Vdash \exists x \varphi$, the left alternative. Or none has; then every a has $[a,\rho] \Vdash \neg\varphi$, whose later clause says $M_1, h[a,\rho] \nVdash \varphi$, that is $M_1, [h(a), h\rho] \vDash \neg\varphi$. The earlier part of $\rho \Vdash \forall x \neg\varphi$ is the statement that every a forces $\neg\varphi$. For the later part let b be an element of M_1. Since h is onto, $b = h(a)$ for some a, and then $M_1, [b, h\rho] \vDash \neg\varphi$. So $\rho \Vdash \forall x \neg\varphi$, the right alternative.

There are no EM or MP rules. Every rule has been covered. □

A derivation from no hypotheses is therefore forced at every environment, because the empty context is forced. Contrapositively, a formula that is not forced at some environment has no derivation from no hypotheses that meets the conditions of the theorem.

E.3 Realizers

Programs, the notation $\{r\}(a)\downarrow v$, realizability, the environments ρ_l and the list codes $\ulcorner l \urcorner$ are those of the proof of Theorem 6.11. The metatheory is classical. We say that a program *computes* a function when it returns the function's value on every input; the functions computed in this section are assembled from the constructors of Definition 10.5, the universal program and the fixing of part of an input, as described in that proof.

Lemma E.6 (Realizability respects binding)**.** *For every formula φ, term t, environment ρ, and numbers r and n: r realizes $\varphi\uparrow$ at $[n,\rho]$ exactly when it realizes φ at ρ; and r realizes $\varphi(t)$ at ρ exactly when it realizes φ at $[E_\rho(t),\rho]$. Replacing the induction variable by its successor replaces its value n by $n+1$. The realizers of a formula at ρ depend only on the values ρ gives to the free variables of the formula.*

Proof. The clauses of realizability use the environment only through the values of terms and the extension $[n,\rho]$, exactly as the clauses of satisfaction do. The proof of Lemma 5.4 therefore applies word for word, with "r realizes" in place of "satisfies", the induction keeping r arbitrary. The last assertion is proved by the same induction. □

Lemma E.7 (Quantifier-free formulas)**.** *Let φ be quantifier-free. If some number realizes φ at ρ, then $\rho \vDash \varphi$. There is a program q_φ that returns a value on every input and, for every list l with $\rho_l \vDash \varphi$, returns on $\ulcorner l \urcorner$ a number that realizes φ at ρ_l. Whether $\rho_l \vDash \varphi$ is computed from $\ulcorner l \urcorner$.*

Proof. Truth is computed by evaluating the terms of φ under ρ_l and following Lemma 6.2. The other two claims are proved together by induction on φ. For an equation, realizability is truth

and q_φ returns 0. Nothing realizes $\bot$, which is false, and $q_\bot$ returns 0. For $\varphi \wedge \psi$, a realizer is a pair of realizers, so both components are true, and q runs q_φ and q_ψ on $\ulcorner l \urcorner$ and pairs their outputs. For $\varphi \vee \psi$, a realizer realizes the side its tag names, which is therefore true; q decides φ at ρ_l and returns $\langle 0, v\rangle$ if it holds, with v the output of q_φ on $\ulcorner l \urcorner$, and $\langle 1, w\rangle$ otherwise, with w the output of q_ψ there. For $\varphi \to \psi$, let r realize the implication at ρ and suppose $\rho \vDash \varphi$. Let l list $\rho(0), \dots, \rho(m-1)$, where m exceeds the index of every variable of $\varphi \to \psi$. Then ρ_l agrees with ρ on the variables of φ and ψ, so q_φ supplies a realizer of φ at ρ_l, which realizes φ at ρ (Lemma E.6); $\{r\}$ turns it into a realizer of ψ, so ψ is true. For the program, $q_{\varphi\to\psi}$ returns the code of the constant program whose value is the output of q_ψ on $\ulcorner l \urcorner$. If $\rho_l \vDash \varphi \to \psi$ and a realizes φ, then φ is true, hence ψ is, and the constant value realizes ψ. □

Lemma E.8 (Formulas without implication)**.** *Let ψ be built from equations and $\bot$ by $\wedge$, $\vee$, $\forall$ and $\exists$. If some number realizes ψ at ρ, then $\rho \vDash \psi$. If $\rho \nvDash \psi$, every number realizes $\neg\psi$ at ρ.*

Proof. Induct on ψ with ρ arbitrary. A realized equation is true, and $\bot$ is never realized. The components of a realized conjunction, the named side of a realized disjunction, the witness of a realized existential statement and every instance of a realized universal statement are realized, hence true by the induction hypothesis, and so the whole formula is true. If ψ is false, nothing realizes it, and every number realizes $\psi \to \bot$ vacuously. □

Theorem E.9 (Derivations from MP rules are realized)**.** *For every derivation d of $\gamma_1, \dots, \gamma_k \vdash \varphi$ whose additional rules are all MP rules, with any induction rules, there is a program c_d such that for every list l and all numbers $a_1, \dots, a_k$ with a_i realizing γ_i at ρ_l, c_d returns on $\langle \ulcorner l \urcorner, \ulcorner (a_1, \dots, a_k) \urcorner\rangle$ a number that realizes φ at ρ_l.*

Proof. Induct on d. Write $\vec{a}$ for $(a_1, \dots, a_k)$ and m for the input $\langle \ulcorner l \urcorner, \ulcorner \vec{a} \urcorner\rangle$, and assume throughout that each a_i realizes γ_i at ρ_l. When a premise has a larger context, its program receives the extended list of realizers.

Hypothesis γ_i: return a_i. *Reflexivity, the four recursive equations and $\neg(S(t) = 0)$:* return 0. The equations are true, and $S(t) = 0$ has no realizer, so every number realizes its negation. *Injectivity:* the premise $S(t) = S(u)$ is realized, hence true, so $t = u$ is true and 0 realizes it. *Equality substitution:* the first premise is realized, so t and s have equal values E; a realizer of $\varphi(t)$ realizes φ at $[E, \rho_l]$, hence $\varphi(s)$ (Lemma E.6); return the output of the second premise's program.

Implication. For introduction from $\varphi, \gamma_1, \dots, \gamma_k \vdash \psi$ with program c', return the code of the program that, on b, runs c' on $\langle \ulcorner l \urcorner, \ulcorner (b, \vec{a}) \urcorner\rangle$; it is obtained from m by fixing part of an input. On every b realizing φ it returns a realizer of ψ. For elimination, run the two premise programs on m, obtaining r and a, and return the value of U on $\langle r, a\rangle$, which realizes the conclusion because r realizes the implication and a its antecedent.

Conjunction and disjunction. Pair the outputs of the two premises, or take the first or second component. For the introductions of a disjunction return $\langle 0, a\rangle$ or $\langle 1, a\rangle$. For disjunction elimination, run the program of the disjunction to obtain $\langle i, a\rangle$; if $i = 0$ run the program of the left branch on $\langle \ulcorner l \urcorner, \ulcorner (a, \vec{a}) \urcorner\rangle$, and otherwise the program of the right branch on the same input.

The rule for an impossible case. Return the output of the premise's program. That output would realize $\bot$, which is impossible, so no list l and realizers $\vec{a}$ meet the assumption and there is nothing to check.

Universal quantifier. Introduction is treated in the proof of Theorem 6.11. For elimination at a term t, run the premise's program to obtain r, compute the value n of t under ρ_l, and return the value of U on $\langle r, n\rangle$. It realizes the body at $[n, \rho_l]$, which is $\varphi(t)$ at ρ_l.

Existential quantifier. For introduction at t, return the pair of the value of t and the premise's output. For elimination, the first premise's program returns $\langle n, b\rangle$ with b realizing the body at $[n, \rho_l] = \rho_{(n,l)}$. The a_i realize $\gamma_i{\uparrow}$ at $\rho_{(n,l)}$. Run the second premise's program on $\langle \ulcorner (n, l)\urcorner, \ulcorner (b, \vec{a})\urcorner\rangle$; its output realizes $\psi{\uparrow}$ at $[n, \rho_l]$, hence ψ at ρ_l.

Induction and the MP rule are treated in the proof of Theorem 6.11. There are no EM or LPO rules.

In each case the program is assembled from the programs of the premises by the constructors of Definition 10.5, the universal program and the fixing of part of an input, so it is a program. □

E.4 The halting matrix

We read programs within an allowance, as the rows of Table 20.1 do. Say that program c returns v on input n *within allowance* K, written $c(n){\downarrow_K}v$, according to the following recursion on K and, for a fixed K, on the code c. Nothing is returned within allowance 0. With allowance $k+1$ nothing is returned on an input $n > k$; for $n \le k$:

- the zero, successor, left and right programs return 0, $n+1$ and the two components of n;
- pair(f, g) returns $\langle y, z\rangle$ when $f(n){\downarrow_{k+1}}y$ and $g(n){\downarrow_{k+1}}z$;
- $f \circ g$ returns v when $g(n){\downarrow_{k+1}}y$ and $f(y){\downarrow_{k+1}}v$;
- for $n = \langle a, w\rangle$, rec(f, g) returns v when $w = 0$ and $f(a){\downarrow_{k+1}}v$, or when $w = w' + 1$, rec$(f, g)(\langle a, w'\rangle){\downarrow_k}i$ and $g(\langle a, \langle w', i\rangle\rangle){\downarrow_{k+1}}v$;
- for $n = \langle a, w\rangle$, search(f) returns v when $f(n){\downarrow_{k+1}}x$ and either $x = 0$ and $v = w$, or $x > 0$ and search$(f)(\langle a, w+1\rangle){\downarrow_k}v$.

The parts f, g of a program have smaller codes than the program, by (10.4), and the repeated calls of rec and search have the smaller allowance k; so the recursion is well founded. It computes, from K, c and n, whether anything is returned and what: every call is to a smaller allowance or a smaller code, and the only search is the one built into search(f), here cut off by the allowance.

Lemma E.10 (Allowances)**.** *Program c returns v on input n exactly when $c(n){\downarrow_K}v$ for some allowance K; and if $c(n){\downarrow_K}v$, then $c(n){\downarrow_{K'}}v$ for every $K' \ge K$.*

Proof. For the second assertion induct on K, then on c: each clause at K is a clause at $K+1$, with the premises at allowance K or $K-1$ raised by the induction hypothesis. If $c(n){\downarrow_K}v$, an induction on K and c shows that c returns v on n: each clause is the matching evaluation clause

of Definition 10.5. Conversely, induct on the finite evaluation of c on n. Each evaluation clause has finitely many sub-evaluations, which return within allowances given by the induction hypothesis. Take K larger than all of them, larger than one plus the allowance of the repeated call of a recursion or search, and larger than n; by the second assertion every sub-evaluation returns within the required allowance K or $K-1$, and the clause gives $c(n)\downarrow_K v$. □

A table is read through Gödel's remainder function β of Section 20.3.3: the *cell* (k,c,n) of the table named by A,B is the number w with $\beta(A,B,\langle k,\langle c,n\rangle\rangle,w)$, which exists and is unique by Lemma K.1. A cell holding 0 makes no claim; a cell holding $v+1$ claims $c(n)\downarrow_k v$. The cell (K,c,n), holding $v+1$, is *justified* when $K=k+1$, $n\le k$, and the claim follows from one clause of the recursion above whose premises are read from cells of the same table, with the inputs of those cells bounded explicitly:

- c is 0, 1, 2 or 3 and v is the value that clause prescribes;
- $c=\mathrm{pair}(f,g)$, the cells (K,f,n) and (K,g,n) hold $y+1$ and $z+1$, and $v=\langle y,z\rangle$;
- $c=f\circ g$, the cell (K,g,n) holds $y+1$ with $y<K$, and the cell (K,f,y) holds $v+1$;
- $c=\mathrm{rec}(f,g)$ and $n=\langle a,w\rangle$; either $w=0$, $a<K$ and the cell (K,f,a) holds $v+1$, or $w=w'+1$, $\langle a,w'\rangle<k$, the cell $(k,c,\langle a,w'\rangle)$ holds $i+1$, $\langle a,\langle w',i\rangle\rangle<K$ and the cell $(K,g,\langle a,\langle w',i\rangle\rangle)$ holds $v+1$;
- $c=\mathrm{search}(f)$, $n=\langle a,w\rangle$, the cell (K,f,n) holds $x+1$, and either $x=0$ and $v=w$, or $x>0$, $\langle a,w+1\rangle<k$ and the cell $(k,c,\langle a,w+1\rangle)$ holds $v+1$.

Let $\theta(e,x)$ say: there are A,B such that every cell (k,c,n) with $k\le x$, $c\le e$ and $n\le x$ holds 0 or is justified, and the cell $(x,e,0)$ holds $v+1$ for some v. Written in the arithmetic language, $u\le w$ is $\exists j(u+j=w)$ and $u<w$ is written $S(u)\le w$, which is equivalent to the form used in Section E.1; pairs, including the code of a compound program, are read through the pairing graph G; the cell with index i is the w with $\exists q\,(A=q\cdot m+w\wedge w<m)$ for $m=B\cdot S(i)+S(0)$, which is $\beta(A,B,i,w)$ in another notation; and each bounded universal statement "for all $k\le x$" is $\forall k\,(S(x)\le k\vee\cdots)$. The alternatives above are joined by $\vee$, and the remaining letters are existentially quantified.

Lemma E.11 (The halting matrix)**.** *The formula $\theta(e,x)$ has the properties (i)–(iii) stated in the proof of Theorem 6.11.*

Proof. Property (i) holds by construction: the formula uses equations, $\wedge$, $\vee$, $\exists$ and $\forall$, and no implication.

For (ii), suppose first that A,B witness $\theta(e,x)$. We show that every claim of a cell (k,c,n) in the rectangle $k\le x$, $c\le e$, $n\le x$ is correct, by induction on k and then on c. The cells a justification reads lie in the rectangle: their allowances are K or k, their codes are c or the smaller codes of its parts, and their inputs are at most $n\le k$ or bounded explicitly by K or k. Each is read at a smaller allowance, or at the same allowance and a smaller code. By the induction hypothesis their claims are correct, and the clause then gives the claim of (k,c,n). Applied to the cell $(x,e,0)$, this gives $e(0)\downarrow_x v$. Conversely, suppose $e(0)\downarrow_x v$. Fill each cell of the rectangle with

$u+1$ if $c(n)\downarrow_k u$ and with 0 otherwise. Finitely many indices are involved, and a finite list of numbers is named by some A, B through β: by Lemma K.3, read in $\mathbb{N}$ by Theorem 5.5, one entry can be appended at a time. Each nonzero cell is justified by the clause that produced its value; the explicit bounds hold because a call within allowance K requires its input to be below K. The cell $(x, e, 0)$ holds $v+1$. So $\theta(e, x)$ is true exactly when program e returns a value on input 0 within allowance x, and the rest of (ii) is Lemma E.10.

For (iii), whether $e(0)\downarrow_x v$ for some v is computed by the recursion above, so by (ii) truth of $\theta(e, x)$ is decided. When it is true, search the pairs $\langle A, B\rangle = 0, 1, 2, \ldots$ for the first one whose table is justified on the rectangle and claims a value at $(x, e, 0)$. That check is a finite computation, since every cell is a remainder and every quantifier in it is bounded, and by (ii) the search stops. From A, B, e and x a realizer of $\theta(e, x)$ is then assembled clause by clause. Each existential quantifier in θ below A, B has a witness computed from the values at hand: a quotient and a remainder in β, a difference in $\leq$ or $<$, a component of a pair in G, the predecessor k of K, the code of a part, or the content of a cell. An equation is realized by 0, a conjunction by the pair of realizers of its parts, and a disjunction by the tag of a true alternative, found by checking the alternatives in turn, with its realizer. A bounded universal statement $\forall k\,(S(x) \leq k \vee \chi)$ is realized by the program that, on k, returns $\langle 0, \langle k - x - 1, 0\rangle\rangle$ when $S(x) \leq k$ and otherwise $\langle 1, \cdot\rangle$ with the realizer of χ at k, which is true there. Each of these steps is computed from the values of the free variables, so the whole realizer is. $\square$

Appendix F

Proofs for the continuum chapter

This appendix carries the routine verifications behind Theorems 12.22, 12.38 and 12.63. Notation is that of the chapter and of the proofs that refer here.

F.1 Realizers for the rules

We complete the proof that every theorem of the theory of Theorem 12.22 has a modified realizer, and every theorem of that theory with $\mathrm{MP}_{\mathrm{bin}}$ added a Kleene realizer. For a derivation of A from hypotheses $B_1, \dots, B_m$ we give one program c. Its input lists the values of the free number variables, the total programs assigned to the free sequence variables, and numbers $s_1, \dots, s_m$, one for each hypothesis. For the modified reading we prove two properties: if $s_j \in \mathrm{HRO}_{\tau(B_j)}$ for every j, then c halts with a value in $\mathrm{HRO}_{\tau(A)}$ (the *typing property*); if moreover $s_j \Vdash_{\mathrm{m}} B_j$ for every j, the value realizes A (the *realizing property*). For Kleene's reading we prove only that c halts with a realizer of A when every s_j realizes B_j. The program is built by induction on the derivation; in each case below c_1, c_2, c_3 are the programs of the premises, and "run c_1" means run it on the same input. A premise may have free variables that do not occur in the conclusion, as in implication elimination; its program is run with those number variables assigned 0 and those sequence variables assigned the program 0, which is total. Any assignment would do, because the premise is derived for every valuation. Two facts are used throughout. First, the realizers of a formula depend only on the values that the valuation gives to its free variables, so substituting a term for a variable amounts to assigning the term's value. Second, $\tau(A)$ does not change under substitution or renaming of variables.

Hypothesis B_j. Return s_j. Both properties are immediate.

An axiom. Each choice schema is realized, under every valuation, by the fixed program E of the proof of Theorem 12.22, which lies in the type of the schema; return E. In Kleene's reading the same holds for the program M realizing $\mathrm{MP}_{\mathrm{bin}}$.

From $\bot$ infer A. Return 0, which lies in $\mathrm{HRO}_{\tau(A)}$. If every s_j realized B_j, then c_1 would return a realizer of $\bot$, and there is none; so the realizing property holds vacuously. In Kleene's reading the same argument applies.

Conjunction. For $A \wedge B$ return $\pi(v_1, v_2)$, with v_1, v_2 the values of c_1, c_2; to eliminate, return $(v)_0$ or $(v)_1$. Both properties follow from the clauses for $\times$ and $\wedge$.

Disjunction. To introduce $A \vee B$ from A return $\pi(0, v)$, and from B return $\pi(1, v)$. To infer C from $A \vee B$, from C under the extra hypothesis A and from C under the extra hypothesis B: run c_1 to obtain r; if $(r)_0 = 0$, run c_2 with $(r)_1$ added as the realizer of the extra hypothesis, and otherwise run c_3 in the same way. By the typing property of c_1, the number r lies in $\mathrm{HRO}_{\tau(A)+\tau(B)}$, so $(r)_1$ lies in the type of the branch taken, and that branch halts in $\mathrm{HRO}_{\tau(C)}$. If the hypotheses are realized, r realizes $A \vee B$, so $(r)_1$ realizes the side named by the tag, and the branch returns a realizer of C.

Implication. Introduction is treated in the proof of the theorem. For elimination, run c_1 to obtain r and c_2 to obtain s, and return $\{r\}(s)$. By the typing property, $r \in \mathrm{HRO}_{\tau(A)\to\tau(B)}$ and $s \in \mathrm{HRO}_{\tau(A)}$, so $\{r\}(s)$ halts in $\mathrm{HRO}_{\tau(B)}$; this is where the typing property is used to show that a run halts. If the hypotheses are realized, s realizes A and r realizes $A \to B$, so $\{r\}(s)$ realizes B. In Kleene's reading the last sentence is the whole argument.

Number quantifiers. To introduce $\forall x\, A(x)$, where x is not free in any hypothesis, return a program computing $n \mapsto c_1(n, \ldots)$, the program of the premise with x given the value n. For every n it halts in $\mathrm{HRO}_{\tau(A)}$, since the types of the hypotheses do not depend on x; and if the hypotheses are realized, they remain realized when x is given the value n, so the value realizes $A(n)$. To instantiate at a term t, compute the value v of t, which needs finitely many runs of the total programs assigned to the sequence variables of t, run c_1 to obtain r, and return $\{r\}(v)$. To introduce $\exists x\, A(x)$ from $A(t)$, return $\pi(v, w)$ with v the value of t and w the value of c_1. To infer C from $\exists x\, A(x)$ and from C under the extra hypothesis $A(x)$, where x is not free in C or in the other hypotheses, run c_1 to obtain r and run c_2 with x given the value $(r)_0$ and with $(r)_1$ as the realizer of $A(x)$.

Sequence quantifiers. To introduce $\forall \alpha\, A(\alpha)$, where α is not free in any hypothesis, return a program computing $i \mapsto c_1(\ldots, i, \ldots)$, the program of the premise with α assigned i. On every total program i it halts, with a value of the right type and, if the hypotheses are realized, realizing $A(i)$. To instantiate at a sequence variable β, apply the value of c_1 to the program assigned to β. To introduce $\exists \alpha\, A(\alpha)$ from $A(\beta)$, return $\pi(i_\beta, w)$, where i_β is the program assigned to β, total by the definition of a valuation. To infer C from $\exists \alpha\, A(\alpha)$ and from C under the extra hypothesis $A(\alpha)$, with α not free in C or in the other hypotheses, run c_1 to obtain r; its component $(r)_0$ is total, by the typing property or by the realizing clause, and c_2 is run with α assigned $(r)_0$ and with $(r)_1$ as the realizer of $A(\alpha)$.

Equality. Reflexivity is realized by 0, a realizer of a true equation. To infer $A(s)$ from $t = s$ and $A(t)$, return the value of the program for $A(t)$. Its type is $\tau(A(s)) = \tau(A(t))$. If the hypotheses are realized, $t = s$ is realized and therefore true, the two terms have the same value, and a realizer of $A(t)$ realizes $A(s)$.

Arithmetic axioms. Each is realized by 0. The equations for $+$ and $\cdot$ are true. For $\neg(St = 0)$, the number 0 lies in $\mathrm{HRO}_{\mathbb{N}\to\mathbb{N}}$ and the false equation $St = 0$ has no realizer. For $St = Ss \to t = s$, the program 0 returns 0 on every input, and when its input realizes the equation $St = Ss$, that equation is true, so $t = s$ is true and realized by 0.

Induction. This case is treated in the proof of the theorem: with the values r_0 and r_1 of the two premise programs, the program returns a program for the primitive recursion $R(0) = r_0$, $R(n+1) = \{\{r_1\}(n)\}(R(n))$.

In every case the program is computed from the programs of the premises by an explicit procedure, so it exists by the standard facts recalled in the proof of the theorem.

F.2 Located cuts and Archimedean ordered fields

Throughout, $C = (\mathscr{L}_C, \mathscr{U}_C)$ and D, E are located cuts, and ratios are compared, added and multiplied as in Chapter 4; every comparison of two ratios is decided by an integer computation.

Lemma F.1 (Crossing)**.** *Every lower member of a located cut lies below every upper member. If no lower member of C is an upper member of D and no lower member of D is an upper member of C, then $C = D$. In particular a located cut is determined by its lower set, and also by its upper set.*

Proof. The first statement is Lemma 12.28(1). For the second statement let $q \in \mathscr{L}_C$, and take $q' > q$ in $\mathscr{L}_C$. Locatedness of D at $q < q'$ gives $q \in \mathscr{L}_D$ or $q' \in \mathscr{U}_D$, and the second is excluded because q' is a lower member of C. So $\mathscr{L}_C \subseteq \mathscr{L}_D$, and symmetrically $\mathscr{L}_D \subseteq \mathscr{L}_C$. The same argument with upper sets, using a smaller upper member and locatedness at the pair it forms, gives $\mathscr{U}_C = \mathscr{U}_D$. If C and D have the same lower set, a lower member of either is a lower member of the other, hence not an upper member of it, and the hypothesis holds; likewise for upper sets. □

Lemma F.2 (Approximation between given members)**.** *Let C be a located cut, $a_0 \in \mathscr{L}_C$, $a_1 \in \mathscr{U}_C$ and n a natural number. There are $q \in \mathscr{L}_C$ and $r \in \mathscr{U}_C$ with $a_0 \le q, r \le a_1$ and $r - q < 1/(n+1)$. No choice principle is used.*

Proof. Lemma 12.32 gives $q \in \mathscr{L}_C$ and $r \in \mathscr{U}_C$ with $r - q < 1/(n+1)$. Replace q by a_0 if $q < a_0$ and r by a_1 if $a_1 < r$; both comparisons are decided, membership is kept, and the gap only shrinks. □

Lemma F.3 (The ratios in an Archimedean ordered field)**.** *Let F be an Archimedean ordered field and $u \mapsto u_F$ the map from $\mathbb{Z}_\delta$ preserving 1, sums and products. Then:*

(a) if $0 < a + b$, then $0 < a$ or $0 < b$;

(b) $u_F < v_F$ exactly when $u < v$;

(c) multiplying by a positive element preserves $<$, the inverse of a positive element is positive, and multiplying by a positive element reflects $<$;

(d) for a ratio $q = \langle u; d\rangle$ the element $q_F = u_F d_F^{-1}$ depends only on q; $q \mapsto q_F$ preserves sums and products; and $q < r$ exactly when $q_F < r_F$.

Proof. (a) Cotransitivity at a applied to $0 < a + b$ gives $0 < a$ or $a < a + b$, and adding $-a$ to the second gives $0 < b$.

(b) By induction, $0 < n_F$ for every natural number $n \ge 1$: $0 < 1$, and adding n_F to $0 < 1$ gives $n_F < n_F + 1_F = (n+1)_F$. If $u < v$, then $0 < (v - u)_F$, and adding u_F gives $u_F < v_F$. Conversely, suppose $u_F < v_F$. The integers are compared by decision. If $v = u$, the order would not be irreflexive; if $v < u$, then $v_F < u_F$ and transitivity gives $u_F < u_F$. Hence $u < v$.

(c) If $x < y$ and $0 < c$, then $0 < y - x$, so $0 < (y - x)c$, and adding xc gives $xc < yc$. Let c be positive with inverse e. Take a natural number K with $c < K_F$; then $K + 1 \ge 1$, and $(K+1)_F$ is positive, so it has an inverse w. Since $(K+1)_F w = 1$ is positive, a summand of the sum of $K + 1$ copies of w is positive by (a), so $0 < w$. Cotransitivity applied to $0 < w$ gives $0 < e$ or $e < w$. In the second case, multiplying by c gives $1 < wc$, and multiplying $c < (K+1)_F$ by w gives $wc < 1$; so $1 < 1$, which is impossible. Hence $0 < e$. If $xc < yc$ with c positive, multiplying by the positive inverse of c gives $x < y$.

(d) For $d \geq 1$, d_F is positive by (b), so it has an inverse, unique because inverses in a commutative ring are. If $ue = vd$, then $u_F e_F = v_F d_F$, and multiplying by $d_F^{-1} e_F^{-1}$ gives $u_F d_F^{-1} = v_F e_F^{-1}$. Sums and products are preserved because $(de)_F^{-1} = d_F^{-1} e_F^{-1}$: $(ue + vd)_F (de)_F^{-1} = u_F d_F^{-1} + v_F e_F^{-1}$ and $(uv)_F (de)_F^{-1} = u_F d_F^{-1}\, v_F e_F^{-1}$. Finally $\langle u; d\rangle < \langle v; e\rangle$ means $ue < vd$, which by (b) means $(ue)_F < (vd)_F$; multiplying by the positive element $d_F^{-1} e_F^{-1}$, which (c) allows in both directions, this is $q_F < r_F$. □

For x in F, the cut $\kappa_F(x)$ has lower set $\{q : q_F < x\}$ and upper set $\{r : x < r_F\}$. The ratios form an Archimedean ordered field, with their order decided; their cut map sends q to the cut of the ratio q, $\kappa(q) = (\{p : p < q\}, \{p : q < p\})$. The sum, negation, product and order of located cuts are defined in the proof of Theorem 12.38.

Lemma F.4 (The box law)**.** *Let F be an Archimedean ordered field. If $A < x < A'$, $B < y < B'$, and the four corners AB, AB', $A'B$, $A'B'$ lie below Q, then $Q < xy$ is impossible; if the four corners lie above Q, then $xy < Q$ is impossible. For ratios with $a < a'$ and $b < b'$: if $a \leq x \leq a'$, $b \leq y \leq b'$ and q lies below the four corners, then $q < xy$; if r lies above them, then $xy < r$.*

Proof. In every commutative ring,

$$(A'-x)\big[(B'-y)(Q-AB)+(y-B)(Q-AB')\big]+(x-A)\big[(B'-y)(Q-A'B)+(y-B)(Q-A'B')\big] + \big((x-A)+(A'-x)\big)\big((y-B)+(B'-y)\big)(xy-Q) = 0.$$

If the corners lie below Q and $Q < xy$, every product on the left is a product of positive elements, so the left side is positive, and $0 < 0$. The second statement uses the same identity with every bracket negated. For ratios, the identity

$$(a'-a)(b'-b)(xy-q) = (a'-x)(b'-y)(ab-q) + (a'-x)(y-b)(ab'-q) + (x-a)(b'-y)(a'b-q) + (x-a)(y-b)(a'b'-q)$$

expresses $xy - q$, after the positive factor $(a'-a)(b'-b)$, as a sum of positive multiples of the corner differences with nonnegative weights whose sum is $(a'-a)(b'-b) > 0$; so it is positive. The upper statement is the same with $r - xy$. □

Lemma F.5 (The cut of an element)**.** *Let F be an Archimedean ordered field. For every x in F, $\kappa_F(x)$ is a located cut. For every ratio q, $\kappa_F(q_F) = \kappa(q)$. Moreover $x < y$ exactly when $\kappa_F(x) < \kappa_F(y)$, and $\kappa_F(x) = \kappa_F(y)$ implies $x = y$.*

Proof. By the Archimedean condition $-x < N_F$ and $x < M_F$ for natural numbers N, M, so $-N$ is a lower and M an upper member. If $q' < q$ and $q_F < x$, then $q'_F < q_F < x$; the upper set is closed upward in the same way. The lower set has no greatest element, as shown in the proof of Theorem 12.38, using Lemma F.3(c) to multiply by the positive element $x - q_F$; the upper set has no least element by the same argument applied to $-x$. A ratio in both sets would give $q_F < x < q_F$. Locatedness is cotransitivity, as shown in the proof of the theorem. For a ratio q, the lower set of $\kappa_F(q_F)$ is $\{p : p_F < q_F\} = \{p : p < q\}$ by Lemma F.3(d), and so $\kappa_F(q_F) = \kappa(q)$ by Lemma F.1.

Let $x < y$. The positive element $y - x$ has an inverse e, and some natural number N has $e < N_F$; then $N \geq 1$ and $1 < N_F(y - x)$, so $\langle 1; N\rangle_F < y - x$. Lemma 12.32 gives q in the lower and r in

the upper set of $\kappa_F(x)$ with $r - q < \langle 1; N\rangle$. Then $r_F < q_F + \langle 1; N\rangle_F < x + (y - x) = y$, so r lies in the upper set of $\kappa_F(x)$ and in the lower set of $\kappa_F(y)$: $\kappa_F(x) < \kappa_F(y)$. Conversely, a ratio r in both sets gives $x < r_F < y$. Finally, if $\kappa_F(x) = \kappa_F(y)$, then $x < y$ would give $\kappa_F(x) < \kappa_F(x)$, that is a ratio in both the lower and the upper set of one located cut; so $\neg(x < y)$, likewise $\neg(y < x)$, and the field axiom on such pairs gives $x = y$. □

Lemma F.6 (The field of located cuts)**.** *With the sum, negation, product and order defined in the proof of Theorem 12.38, and with zero and one the cuts of the ratios* 0 *and* 1*:*

(a) $C + D$, $-C$ and CD are located cuts;

(b) for every Archimedean ordered field F, $\kappa_F(x+y) = \kappa_F(x) + \kappa_F(y)$ and $\kappa_F(xy) = \kappa_F(x)\,\kappa_F(y)$; in particular cuts of ratios add and multiply as the ratios do;

(c) the located cuts form a commutative ring;

(d) they form an Archimedean ordered field.

Proof. (a) *Sum.* For $a \in \mathscr{L}_C$, $b \in \mathscr{L}_D$, $a' \in \mathscr{U}_C$ and $b' \in \mathscr{U}_D$, the ratio $a + b - 1$ is a lower and $a' + b' + 1$ an upper member. The lower set is closed downward by its definition, and if $q < a + b$ then $(q + a + b)/2$ is a larger member; the upper set is treated in the same way. A common member q would satisfy $a' + b' < q < a + b$ for lower members a, b and upper members a', b', while $a < a'$ and $b < b'$. For locatedness let $q < r$ and $\varepsilon = r - q$. By Lemma 12.32 choose $a \in \mathscr{L}_C$, $a' \in \mathscr{U}_C$ with $a' - a < \varepsilon/2$, and $b \in \mathscr{L}_D$, $b' \in \mathscr{U}_D$ likewise. Compare q with $a + b$. If $q < a + b$, then q is a lower member. Otherwise $a + b \le q$, and $a' + b' < a + b + \varepsilon \le r$, so r is an upper member.

Negation. Negation of ratios reverses their order, so every law of $-C$ is a law of C read in reverse; locatedness at $q < r$ is locatedness of C at $-r < -q$, with the two cases exchanged.

Product. Choose $a \in \mathscr{L}_C$, $a' \in \mathscr{U}_C$, $b \in \mathscr{L}_D$, $b' \in \mathscr{U}_D$. A ratio below the smallest of the four corners is a lower member, and a ratio above the largest an upper member. The lower set is closed downward by definition; if q lies below the four corners of some brackets, the mean of q and the smallest corner is a larger lower member. The upper set is treated in the same way. Suppose q is a lower member through brackets (a, a', b, b') and an upper member through brackets (c, c', d, d'). Let x be the larger of a and c, and y the larger of b and d; then x is a lower member of C, so $a \le x < a'$ and $c \le x < c'$, and likewise for y. The box law (Lemma F.4) for ratios gives $q < xy$ from the first brackets and $xy < q$ from the second, a contradiction.

For locatedness let $q < r$ and $\varepsilon = r - q$. Fix $a_0 \in \mathscr{L}_C$, $a_1 \in \mathscr{U}_C$, $b_0 \in \mathscr{L}_D$, $b_1 \in \mathscr{U}_D$, and a natural number $B \ge 1$ with $|a_0|, |a_1|, |b_0|, |b_1| \le B$. By Lemma F.2 choose $a \in \mathscr{L}_C$ and $a' \in \mathscr{U}_C$ with $a_0 \le a < a' \le a_1$ and $a' - a < \varepsilon/(8B)$, and b, b' for D likewise. All four ratios have absolute value at most B, so each corner differs from ab by at most $B\varepsilon/(8B) + B\varepsilon/(8B) = \varepsilon/4$; for instance $|a'b' - ab| \le |a'|\,|b' - b| + |b|\,|a' - a|$. Compare $ab - q$ with $\varepsilon/2$. If $ab - q > \varepsilon/2$, every corner exceeds $q + \varepsilon/4$, so q is a lower member. Otherwise $ab \le q + \varepsilon/2$, every corner is at most $q + 3\varepsilon/4 < r$, and r is an upper member.

(b) For the sum, suppose q is a lower member of $\kappa_F(x+y)$ and an upper member of $\kappa_F(x)+\kappa_F(y)$, through $x < a'_F$, $y < b'_F$ and $a' + b' < q$. Then $q_F < x + y < a'_F + b'_F < q_F$, which is impossible.

If q is a lower member of the sum through $q < a + b$ with $a_F < x$ and $b_F < y$, and an upper member of $\kappa_F(x + y)$, then $q_F < a_F + b_F < x + y < q_F$. By Lemma F.1 the two cuts are equal. For the product, suppose $q_F < xy$ and q lies above the four corners of ratios with $a_F < x < a'_F$ and $b_F < y < b'_F$. Since $q \mapsto q_F$ preserves products and order, the box law in F excludes $q_F < xy$. The other crossing is excluded in the same way, and Lemma F.1 gives equality. For the field of ratios, (b) and Lemma F.5 give $\kappa(q) + \kappa(r) = \kappa(q + r)$ and $\kappa(q)\kappa(r) = \kappa(qr)$.

(c) Every law is proved by Lemma F.1, or by comparing lower sets. Finitely many brackets $[a_i, a'_i]$ of one cut, with lower ends in its lower set and upper ends in its upper set, have a common ratio: the largest a_i, a lower member, which lies below every a'_j. Call it a *common point* of the brackets.

Addition. The lower set of $(C + D) + E$ is the set of q with $q < a + b + e$ for lower members a, b, e of C, D, E: if $q < s + e$ with $s < a + b$ this holds, and if $q < a + b + e$ then $s = a + b - (a + b + e - q)/2$ is a lower member of $C + D$ with $q < s + e$. The same description holds for $C + (D + E)$. Commutativity is visible in the definition. The lower set of $C + 0$ is $\mathcal{L}_C$: if $q < a + z$ with $z < 0$, then $q < a$; if $q < a$ with $a \in \mathcal{L}_C$, then $z = (q - a)/2$ is negative and $q < a + z$. The lower set of $C + (-C)$ is the set of negative ratios: if $q < a + b$ with $a \in \mathcal{L}_C$ and $-b \in \mathcal{U}_C$, then $a < -b$ and $q < 0$; conversely, if $q < 0$, Lemma 12.32 gives $a \in \mathcal{L}_C$, $a' \in \mathcal{U}_C$ with $a' - a < -q$, and $b = -a'$ satisfies $q < a + b$.

Multiplication. Commutativity is visible in the definition. For $C \cdot 1 = C$: if q is a lower member of $C \cdot 1$ through brackets (a, a', b, b'), with $b < 1 < b'$, the box law at the point $(a, 1)$ gives $q < a$, so q is a lower member of C and not an upper member. If q is an upper member of $C \cdot 1$, the box law at $(a', 1)$ gives $a' < q$, so q is an upper member of C and not a lower member. Lemma F.1 gives $C \cdot 1 = C$.

For associativity, suppose q is a lower member of $(CD)E$ and an upper member of $C(DE)$. The first means that q lies below the four corners of brackets $p \in \mathcal{L}_{CD}$, $p' \in \mathcal{U}_{CD}$, $e \in \mathcal{L}_E$, $e' \in \mathcal{U}_E$, where p and p' come with brackets of C and D; the second means that q lies above the four corners of brackets of C and of DE, which come with brackets of D and E. Let x, y, z be common points of all the brackets of C, of D and of E that occur. By the box law, $p < xy < p'$; by the box law again, $q < (xy)z$. In the same way $x(yz) < q$. Since $(xy)z = x(yz)$, this is impossible. The other crossing is excluded in the same way, and Lemma F.1 gives $(CD)E = C(DE)$.

For distributivity, suppose q is a lower member of $C(D + E)$ and an upper member of $CD + CE$. The first means that q lies below the four corners of brackets a, a' of C and s, s' of $D + E$, with $s < b_1 + e_1$ and $b'_1 + e'_1 < s'$ for lower members b_1, e_1 and upper members b'_1, e'_1 of D and E. The second means $t + w < q$ with t an upper member of CD and w an upper member of CE, each above the corners of its brackets. Let x, y, z be common points of the brackets of C, D and E that occur. Then $s < b_1 + e_1 \le y + z < b'_1 + e'_1 < s'$, so the box law gives $q < x(y + z)$; and it gives $xy < t$ and $xz < w$, so $xy + xz < q$. Since $x(y + z) = xy + xz$, this is impossible. The other crossing is the same with lower and upper exchanged.

These are the laws of a commutative ring.

(d) *Order.* No ratio lies in both sets of one cut, so $<$ is irreflexive. If $q \in \mathcal{U}_C \cap \mathcal{L}_D$ and $p \in \mathcal{U}_D \cap \mathcal{L}_E$, then $q < p$, so $p \in \mathcal{U}_C$ and $C < E$. For cotransitivity let $q \in \mathcal{U}_C \cap \mathcal{L}_D$, take a smaller $q' \in \mathcal{U}_C$, and apply the locatedness of E at $q' < q$: either $q' \in \mathcal{L}_E$ and $C < E$, or $q \in \mathcal{U}_E$ and $E < D$. If $\neg(C < D)$, every $q \in \mathcal{L}_D$ lies in $\mathcal{L}_C$: take a larger $q' \in \mathcal{L}_D$, and

locatedness of C at $q < q'$ gives $q \in \mathscr{L}_C$ or $q' \in \mathscr{U}_C$, the latter meaning $C < D$. So if neither $C < D$ nor $D < C$, the lower sets agree and $C = D$.

If $C < D$ through $q \in \mathscr{U}_C \cap \mathscr{L}_D$, take $p < q$ in $\mathscr{U}_C$ and $p' > q$ in $\mathscr{L}_D$, put $\delta = p' - p$, and choose $e \in \mathscr{L}_E$, $e' \in \mathscr{U}_E$ with $e' - e < \delta$. The ratio $p + e'$ lies above a sum of upper members of C and E, since C has an upper member below p; and $p + e' < p' + e$, a sum of lower members of D and E. So $p + e'$ lies in the upper set of $C + E$ and in the lower set of $D + E$, and $C + E < D + E$.

If $0 < C$ and $0 < D$, there are positive $a \in \mathscr{L}_C$ and $b \in \mathscr{L}_D$. With any upper members $a' > a$ and $b' > b$, the four corners are at least $ab > 0$, so 0 and then a positive ratio are lower members of CD, and $0 < CD$. The ratio $1/2$ shows $0 < 1$.

Inverses. Let $0 < C$, so that C has a positive lower member. Let C' have the lower and upper sets

$$\{q : \ qa' < 1 \text{ for some } a' \in \mathscr{U}_C\}, \qquad \{r : \ 1 < ra \text{ for some positive } a \in \mathscr{L}_C\}.$$

Every upper member of C is positive, so 0 is a lower member of C', and $2/a$ is an upper member for a positive lower member a. If $qa' < 1$ and $p < q$, then $pa' < 1$; and $q + (1 - qa')/(2a')$ is a larger lower member. If $1 < ra$, every $r'' > r$ has $1 < r''a$, and $r - (ra - 1)/(2a)$ is a smaller upper member. A common member q would satisfy $qa' < 1 < qa$ with $q > 0$ and $a < a'$, which is impossible. For locatedness let $q < r$. If $q \le 0$, then q is a lower member. Otherwise $0 < 1/r < 1/q$, and the locatedness of C gives $1/r \in \mathscr{L}_C$ or $1/q \in \mathscr{U}_C$. In the first case a larger lower member $a > 1/r$ is positive with $1 < ra$; in the second a smaller upper member $a' < 1/q$ has $qa' < 1$.

Now $CC' = 1$. If q is a lower member of CC', through brackets (a, a', b, b') with b a lower member of C' through $bc' < 1$, let x be a common point of the brackets of C that occur, together with a positive lower member of C; then $x > 0$, $x < c'$, and $xb < 1$ whether b is positive or not, so the box law gives $q < xb < 1$. If q is an upper member of CC', through brackets (a, a', b, b') with b' an upper member of C' through $1 < b'c$ for a positive $c \in \mathscr{L}_C$, let x be a common point of the brackets of C that occur, together with c; then $x \ge c$ and $1 < b'c \le b'x < q$. So no lower member of CC' is above 1, and no upper member is below 1, and Lemma F.1, with the cut of the ratio 1, gives $CC' = 1$.

Archimedean bound. For an upper member r of C take a natural number $n > r$. By (b) the sum of n copies of the cut of 1 is the cut of the ratio n, which has r as a lower member; so $C < n$. □

F.3 Limits in the recursive model

Lemma F.7 (Regular sequences read classically)**.** *Reasoning classically, every regular sequence s has a limit $\lim s$, a real number with $|s_n - \lim s| \le 1/(n+1)$ for every n. Two regular sequences name the same point exactly when their limits agree. A point x is positive exactly when $\lim x > 0$; hence $x < y$ exactly when $\lim x < \lim y$, and $x \le y$ exactly when $\lim x \le \lim y$. Two points are within $1/(k+1)$ exactly when their limits differ by at most $1/(k+1)$, and a ratio q lies in the lower set of the cut of x exactly when $q < \lim x$.*

Proof. Regularity makes (s_n) a Cauchy sequence of rational numbers, and letting m grow in $|s_n - s_m| \le 1/(n+1) + 1/(m+1)$ gives the bound. If $s \approx t$, the differences $s_n - t_n$ eventually

stay within every $1/(k+1)$, so the limits agree; conversely, equal limits give $|s_n - t_n| \le 1/(n+1)+1/(n+1)$, which is eventually within every tolerance. If $s_N > 2/(N+1)$, Lemma 12.16 gives $s_m > 1/(2N+2)$ from $m = 2N+1$ on, so $\lim s \ge 1/(2N+2) > 0$. If $\lim s = \delta > 0$, then $s_N \ge \delta - 1/(N+1) > 2/(N+1)$ once $N+1 > 3/\delta$. The stages of $y - x$ are $y_{2n+1} - x_{2n+1}$, whose limit is $\lim y - \lim x$; this gives the statement on $<$, and $\le$ is its negation. Being within $1/(k+1)$ is a pair of order statements, and the lower set of the cut of x consists of the ratios q with $\eta(q) < x$, which by the statement on $<$ holds exactly when $q = \lim \eta(q) < \lim x$. □

F.4 Stage estimates on the line

These lemmas complete the proof of Proposition 12.19. Throughout, s, t, u are regular sequences of ratios and $K_s = \lfloor |s_0| \rfloor + 3$, so that $|s_n| \le K_s$ for every n.

Lemma F.8 (Naming the same point)**.** *Let s and t be regular sequences.*

(a) If $|s_n - t_n| \le C/(n+1)$ for every n, for a fixed C, then $s \approx t$.

(b) $s \approx t$ exactly when $|s_n - t_n| \le 2/(n+1)$ for every n.

(c) A point is $\eta(0)$ exactly when it is neither positive nor negative.

Proof. (a) For the tolerance $1/(k+1)$, every $n \ge C(k+1)$ has $C/(n+1) < 1/(k+1)$. (b) One direction is (a). Conversely let $s \approx t$ and fix n. For any k take a stage $p \ge k$ beyond the one from which s and t agree within $1/(k+1)$. Then $|s_n - t_n| \le |s_n - s_p| + |s_p - t_p| + |t_p - t_n| \le 2/(n+1) + 2/(p+1) + 1/(k+1) \le 2/(n+1) + 3/(k+1)$, and the Archimedean step leaves $2/(n+1)$, as in the proof of Theorem 12.17. (c) The constant sequence 0 has no stage above $2/(n+1)$ or below $-2/(n+1)$, and positivity and negativity belong to the point. Conversely, if s names a point that is neither positive nor negative, no stage of s lies above $2/(n+1)$ or below $-2/(n+1)$; each of these comparisons is decided, so $|s_n| \le 2/(n+1)$ at every stage, and Lemma 12.15 gives $s \approx \eta(0)$. □

Lemma F.9 (Following ratios)**.** *Say that s follows ratios $f(M)$ with constant C when $|s_n - f(M)| \le C\big(1/(n+1) + 1/(M+1)\big)$ for all n and M.*

(a) Every s follows its own stages with constant 1, and the constant sequence of q follows the constant ratios q with constant 0.

(b) If s follows f with constant C and t follows g with constant D, then $s + t$ follows $f + g$ with constant $C + D$, $-s$ follows $-f$ with constant C, and, when $|f(M)| \le B$ for every M, st follows fg with constant $K_t C + BD$.

(c) If s follows f with constant C, t follows g with constant D, and $|f(M) - g(M)| \le F/(M+1)$ for every M, then $|s_n - t_n| \le (C+D)/(n+1)$ for every n, so $s \approx t$.

Proof. (a) is regularity. (b) The stage n of $s + t$ reads both sequences at $2n+1 \ge n$, and $1/(2n+2) \le 1/(n+1)$; negation changes no distance. The stage n of st is $s_j t_j$

with $j \geq n$, and $|s_j t_j - f(M)g(M)| \leq |t_j|\,|s_j - f(M)| + |f(M)|\,|t_j - g(M)|$, which is at most $(K_t C + BD)\big(1/(j+1) + 1/(M+1)\big)$. (c) For every M,

$$|s_n - t_n| \leq |s_n - f(M)| + |f(M) - g(M)| + |g(M) - t_n| \leq \frac{C+D}{n+1} + \frac{C+D+F}{M+1},$$

and the Archimedean step removes the last term. Then (a) of Lemma F.8 applies. □

Lemma F.10 (Positive points). *If $a + b > 0$, then $a > 0$ or $b > 0$. If $a > 0$ and $b > 0$, then $a + b > 0$ and $ab > 0$.*

Proof. Let s name a and t name b. Positivity belongs to the point, so the sum sequence has a positive stage N: $s_{2N+1} + t_{2N+1} > 2/(N+1)$. One of the two ratios, by a decided comparison, exceeds $1/(N+1) = 2/((2N+1)+1)$, a positive stage of a or of b. Now let $s_N > 2/(N+1)$ and $t_M > 2/(M+1)$, and let L be the larger of N and M. By Lemma 12.16, every $m \geq 2L+1$ has $s_m > 1/(2L+2)$ and $t_m > 1/(2L+2)$. The sum at stage $n = 2L+2$ reads stage $2n+1 \geq 2L+1$, so it exceeds $1/(L+1) > 2/(2L+3) = 2/(n+1)$. The product at stage $n = 2(2L+2)^2$ reads a stage $j \geq n \geq 2L+1$, so it exceeds $1/(2L+2)^2 > 2/(n+1)$. □

Lemma F.11 (The inverse of a point apart from zero). *Let s name x and suppose $|s_N| > 2/(N+1)$. Then every $m \geq 2N+1$ has $|s_m| > 1/(2N+2)$, the ratios $r_n = 1/s_{k(n)}$ with $k(n) = 4(N+1)^2(n+1) - 1$ form a regular sequence, and its point y has $xy = \eta(1)$.*

Proof. The first statement is Lemma 12.16 applied to s or to $-s$, according to the decided sign of s_N. Since $4(N+1)^2 \geq 2N+2$, every $k(n)$ is at least $2N+1$. For stages a, b of modulus above $1/(2N+2)$, $|1/a - 1/b| = |a-b|/(|a|\,|b|) \leq 4(N+1)^2|a-b|$, so

$$|r_m - r_n| \leq 4(N+1)^2\Big(\frac{1}{k(m)+1} + \frac{1}{k(n)+1}\Big) = \frac{1}{m+1} + \frac{1}{n+1}.$$

For the product, s follows the ratios $s_{k(M)}$ with constant 1, since $k(M) \geq M$, and the sequence r follows its own stages $1/s_{k(M)}$ with constant 1. The products of these ratios are all 1, and $|s_{k(M)}| \leq K_s$, so by Lemma F.9 the product sequence follows the constant ratios 1, as does $\eta(1)$; hence $xy = \eta(1)$. □

Lemma F.12 (Square roots by trisection). *Every point $x \geq 0$ has a square root $y \geq 0$, computed from any one regular sequence naming x, with no choice.*

Proof. We use four facts. (i) For every stage m of a sequence s naming x, $x \leq \eta(s_m + 1/(m+1))$ and $\eta(s_m - 1/(m+1)) \leq x$: the stages of $x - \eta(s_m + 1/(m+1))$ are $s_{2n+1} - s_m - 1/(m+1) \leq 1/(2n+2)$, never above $2/(n+1)$, and similarly for the other side. (ii) If $u \leq v$, then $u + w \leq v + w$, by item 1 of the proposition. (iii) If $u \geq 0$ and $v \geq 0$, then $u + v \geq 0$ and $uv \geq 0$. For the sum, $u + v < 0$ would make $-u$ or $-v$ positive by Lemma F.10. For the product, if $uv < 0$, then uv is invertible by item 3, so u and v are invertible, hence apart from 0, hence positive since they are not negative; then $uv > 0$, which contradicts $uv < 0$. In particular $0 \leq a \leq y$ gives $y\,y - a\,a = (y-a)(y+a) \geq 0$. (iv) Two points in an interval $[\eta(a), \eta(b)]$ are within $b - a$ of each other, by (ii).

Let s name x, take n_0 with $x < \eta(n_0)$ from item 4, and put $K = n_0 + 1$, so that $K \geq 1$ and $x \leq \eta(K^2)$. Define ratios $a_n \leq b_n$ by $a_0 = 0$, $b_0 = K$, and the following step. Let $w = b_n - a_n$, $c_1 = a_n + w/3$, $c_2 = a_n + 2w/3$, and $m = 6 \cdot 9^n$. Since $a_n \geq 0$,

$$c_2^2 - c_1^2 = \frac{w}{3}(c_1 + c_2) \geq \frac{w^2}{3},$$

and we will have $w = K(2/3)^n$, so the gap is at least $1/(3 \cdot 9^n)$, more than $2/(m+1)$. If $s_m > c_1^2 + 1/(m+1)$, put $a_{n+1} = c_1$ and $b_{n+1} = b_n$; then $\eta(c_1^2) < \eta(s_m - 1/(m+1)) \leq x$ by (i). Otherwise put $a_{n+1} = a_n$ and $b_{n+1} = c_2$; then $x \leq \eta(s_m + 1/(m+1)) \leq \eta(c_1^2 + 2/(m+1)) < \eta(c_2^2)$. Each step is a comparison of two ratios. By induction, $0 \leq a_n < b_n \leq K$, $b_n - a_n = K(2/3)^n$, (a_n) does not decrease, (b_n) does not increase, and $\eta(a_n^2) \leq x \leq \eta(b_n^2)$.

Put $\varphi(k) = 2K(k+1)$. Since $(3/2)^n \geq 1 + n/2$, $K(2/3)^{\varphi(k)} \leq K/(1 + K(k+1)) < 1/(k+1)$. The ratios $r_k = a_{\varphi(k)}$ satisfy $a_{\varphi(k)} \leq r_l < b_{\varphi(k)}$ for $l \geq k$, so $|r_k - r_l| < 1/(k+1)$, and r is regular; let y be its point. No stage of r is negative, so $y \geq 0$. Every stage r_l lies below $b_{\varphi(k)}$, and $a_{\varphi(k)} - r_l$ is at most 0 when $l \geq k$ and less than $1/(l+1)$ when $l < k$. So neither $y - \eta(b_{\varphi(k)})$ nor $\eta(a_{\varphi(k)}) - y$ has a stage above $2/(n+1)$, and $\eta(a_{\varphi(k)}) \leq y \leq \eta(b_{\varphi(k)})$. By (iii), $\eta(a_{\varphi(k)}^2) \leq y\,y \leq \eta(b_{\varphi(k)}^2)$, and x lies in the same interval, whose width is $(b-a)(b+a) \leq 2K(b-a) < 2K/(k+1)$ at $\varphi(k)$. By (iv), $y\,y$ and x are within every $1/(k+1)$ of each other, hence equal. $\square$

Appendix G

Proofs for the linear-algebra chapter

This appendix proves the rows of Table 14.1 on matrices, unique roots and monotone maps, and the results on unique choice used in Section 14.9. Notation and conventions, including the meaning of *no choice*, are those of Chapter 14.

G.1 Matrices

Proposition G.1 (Counting independent vectors)**.** *Independent vectors and injective matrices are counted with no principle.*

1. *If $v_0, \dots, v_{k-1}$ is an independent family of vectors of $\mathbb{R}^n_\delta$, then $k \le n$.*
2. *If an $n \times m$ matrix A has zero kernel, that is $Ax = 0$ gives $x = 0$, then $m \le n$.*

No omniscience principle and no choice is used.

Proof. For the first statement, $k \le n$ is a decided comparison of natural numbers, so it suffices to refute $n < k$. We show by induction on n that no family of more than n vectors of $\mathbb{R}^n_\delta$ is independent. For $n = 0$ every vector is the empty tuple, and the combination with every coefficient 1 vanishes, so independence of a nonempty family would give $1 = 0$.

Let $v_0, \dots, v_{k-1}$ be an independent family of vectors of $\mathbb{R}^{n+1}_\delta$ with $k \ge n + 2$; we derive a contradiction. Write a_i for the first coordinate of v_i and $\bar{v}_i$ for the others. Two cases each lead to a contradiction.

Every a_i is 0. A vanishing combination of the $\bar{v}_i$ is then a vanishing combination of the v_i, so the $\bar{v}_i$ are $k > n$ independent vectors of $\mathbb{R}^n_\delta$, against the induction hypothesis.

Some a_{i_0} is apart from 0. Let α be its inverse, and put $w_r = \bar{v}_r - a_r \alpha \bar{v}_{i_0}$ for $r \neq i_0$. These are $k - 1 > n$ vectors of $\mathbb{R}^n_\delta$, and they are independent. Indeed, let $\sum_{r \neq i_0} c_r w_r = 0$, put $S = \sum_{r \neq i_0} c_r a_r$, and give v_{i_0} the coefficient $c_{i_0} = -\alpha S$. The first coordinate of $\sum_i c_i v_i$ is $S - \alpha S a_{i_0} = 0$, and the others are

$$\sum_{r \neq i_0} c_r \big(w_r + a_r \alpha \bar{v}_{i_0} \big) - \alpha S \bar{v}_{i_0} = \sum_{r \neq i_0} c_r w_r = 0.$$

Independence of the v_i gives $c_r = 0$ for every r. This again contradicts the induction hypothesis.

Since the goal is a contradiction, neither case has to be decided. The second case shows that no a_i is apart from 0, so every a_i is 0 by Lemma F.8(c), and the first case applies.

For the second statement, $\sum_j c_j \operatorname{col}_j = Ac$, so a matrix with zero kernel has m independent columns in $\mathbb{R}^n_\delta$, and the first statement gives $m \le n$. □

Definition G.2 (Determinants, minors and rank)**.** The determinant of an $n \times n$ matrix M is defined by expansion along the first column: the 0×0 matrix has determinant 1, and for $n \geq 1$

$$\det M = \sum_{i<n} (-1)^i M_{i0} \det M^{(i,0)},$$

where $M^{(i,j)}$ is M with row i and column j deleted. For an $m \times n$ matrix A, an $r \times r$ *minor* is given by injective maps ρ from $\{0, \dots, r-1\}$ to $\{0, \dots, m-1\}$ and σ from $\{0, \dots, r-1\}$ to $\{0, \dots, n-1\}$; its entries are $A_{\rho(a)\sigma(b)}$. The matrix A has *rank* r when some $r \times r$ minor has a determinant $\neq 0$ and every $(r+1) \times (r+1)$ minor has determinant 0.

Proposition G.3 (Two identities of determinants)**.** *For every $(n+1) \times (n+1)$ matrix M over $\mathbb{R}_\delta$,*

$$\det M = \sum_{j \leq n} (-1)^j M_{0j} \det M^{(0,j)} \qquad \textit{and} \qquad \det M^{\mathsf{T}} = \det M.$$

No omniscience principle and no choice is used.

Proof. Both are identities of the ring operations, whose laws hold with no principle by Proposition 12.19. For the first, argue by induction on n. For $n = 0$ both sides are M_{00}. Let $n \geq 1$, and write $M^{\{0,i\},\{0,j\}}$ for M with rows $0, i$ and columns $0, j$ deleted. In the definition of $\det M$, the term $i = 0$ is $M_{00} \det M^{(0,0)}$. For $i \geq 1$, the first row of $M^{(i,0)}$ consists of the entries M_{0j} with $j \geq 1$, at position $j - 1$, and the induction hypothesis expands $\det M^{(i,0)}$ along that row. So

$$\det M = M_{00} \det M^{(0,0)} + \sum_{i \geq 1} \sum_{j \geq 1} (-1)^{i+j-1} M_{i0} M_{0j} \det M^{\{0,i\},\{0,j\}}.$$

In the right side of the claim, the term $j = 0$ is again $M_{00} \det M^{(0,0)}$. For $j \geq 1$, the first column of $M^{(0,j)}$ consists of the entries M_{i0} with $i \geq 1$, at position $i - 1$, and the definition expands $\det M^{(0,j)}$ along it. This gives the same double sum.

For the second identity, again by induction on n, the case $n = 0$ being clear: the definition, the induction hypothesis for the minors, and the first identity give

$$\det M^{\mathsf{T}} = \sum_i (-1)^i M_{0i} \det\big(M^{(0,i)}\big)^{\mathsf{T}} = \sum_i (-1)^i M_{0i} \det M^{(0,i)} = \det M. \qquad \square$$

Theorem G.4 (The rank costs WLPO)**.** *The assertion that every matrix over $\mathbb{R}_\delta$ has a rank which is also the rank of its transpose is equivalent to WLPO. Neither direction uses a choice principle.*

Proof. Assume WLPO, and let A be an $m \times n$ matrix. For each minor, WLPO decides whether its determinant is 0 or $\neq 0$. The minors of a given size are finitely many, since maps between finite sets can be listed and their injectivity decided; so "some $r \times r$ minor has a determinant $\neq 0$" is decided for each r. It holds for $r = 0$, since the empty minor has determinant 1. It fails for $r = m + 1$, since no map from $\{0, \dots, m\}$ into $\{0, \dots, m-1\}$ is injective. Let $r \leq m$ be the largest number for which it holds, found by a bounded search. Every $(r+1) \times (r+1)$ minor then has $\neg(\det \neq 0)$, hence determinant 0, since $x = 0$ says that x is neither positive nor negative and is therefore stable under double negation (Lemma F.8(c)). So A has rank r.

The minors of A^{T} are the transposes of those of A, obtained by exchanging ρ and σ, and by Proposition G.3 they have the same determinants; so r is also the rank of A^{T}.

Conversely, let x be a point, and let r be a rank of the 1×1 matrix (x). No map from $\{0,1\}$ into $\{0\}$ is injective, so $r \leq 1$. If $r = 1$, the only 1×1 minor has determinant $x \neq 0$; if $r = 0$, every 1×1 minor has determinant 0, so $x = 0$. Hence $x = 0 \vee x \neq 0$ for every point, which is WLPO by Corollary 12.18. □

For 2×2 matrices the definition gives $\det A = A_{00}A_{11} - A_{10}A_{01}$. Write $\operatorname{adj} A$ for the matrix with rows $(A_{11}, -A_{01})$ and $(-A_{10}, A_{00})$; then $A \operatorname{adj} A = \operatorname{adj} A \, A = (\det A)\, I$, and $\det(AB) = \det A \det B$, by computation in the ring. Call A *injective* when $Av = 0$ gives $v = 0$, *surjective* when every w is Av for some v, and *invertible* when $AB = BA = I$ for some B.

Theorem G.5 (Inverses of 2×2 matrices)**.** *For 2×2 matrices over $\mathbb{R}_\delta$:*

1. *every matrix with $\det A \neq 0$ is invertible if and only if $\mathrm{MP}_{\mathrm{bin}}$ holds;*
2. *every injective matrix is surjective if and only if $\mathrm{MP}_{\mathrm{bin}}$ holds;*
3. *every surjective matrix is injective.*

No choice is used.

Proof. The first statement. Under $\mathrm{MP}_{\mathrm{bin}}$ a determinant $\neq 0$ is apart from 0 (Corollary 12.18), with an inverse e, and $e \operatorname{adj} A$ inverts A. Conversely, let $x \neq 0$. The diagonal matrix D with entries x and 1 has determinant x; an inverse B gives $xB_{00} = 1$ from the entry $(0,0)$ of $DB = I$. So every $x \neq 0$ is invertible, which is $\mathrm{MP}_{\mathrm{bin}}$ by the eighth row of Table 12.2.

The second. Let A be injective. Then $\det A \neq 0$: if $\det A = 0$, the vectors $(A_{01}, -A_{00})$ and $(A_{11}, -A_{10})$ lie in the kernel, since

$$A\begin{pmatrix} A_{01} \\ -A_{00} \end{pmatrix} = \begin{pmatrix} 0 \\ -\det A \end{pmatrix}, \qquad A\begin{pmatrix} A_{11} \\ -A_{10} \end{pmatrix} = \begin{pmatrix} \det A \\ 0 \end{pmatrix},$$

so all four entries vanish, $A = 0$, and injectivity applied to $Ae_0 = 0$ would give $1 = 0$. Under $\mathrm{MP}_{\mathrm{bin}}$ the first statement makes A invertible, with inverse B, and $w = A(Bw)$. Conversely, let $x \neq 0$. The matrix D above is injective: $(xv_0, v_1) = 0$ gives $v_1 = 0$ and, by Lemma 14.4, $v_0 = 0$. A vector v with $Dv = e_0$ has $xv_0 = 1$, so x is invertible, and the eighth row of Table 12.2 gives $\mathrm{MP}_{\mathrm{bin}}$.

The third. Let A be surjective, and take u, w with $Au = e_0$ and $Aw = e_1$. The matrix B with columns u and w has $AB = I$, so $\det A \det B = 1$ and $\det A$ is invertible. If $Av = 0$, then $(\det A)\, v = \operatorname{adj} A\,(Av) = 0$, and multiplying by the inverse of $\det A$ gives $v = 0$. □

G.2 Unique roots and monotone maps

Lemma G.6 (Quotients exist up to double negation)**.** *Let a and b be points with $b \neq 0$.*

1. *It is not the case that no c has $bc = a$.*

2. *If* $0 \le a \le b$, *then some* c *has* $bc = a$ *exactly when exactly one point* c *of* $[0,1]$ *has* $bc = a$.

No omniscience principle and no choice is used.

Proof. If no c had $bc = a$, then b would have no inverse, since an inverse u would give $b(ua) = a$. So b would be neither positive nor negative, and $b = 0$ by Lemma F.8(c), contrary to $b \neq 0$. The second statement is Lemma 14.10. □

So for $0 \le a \le b$ with $b \neq 0$ the quotient is unique and cannot fail to exist. A stronger, quantitative uniqueness has a price. Say that a function f has a *quantitatively unique root* on $[0,1]$ when for every k there is a j such that any two points x, y of $[0,1]$ with $f(x)$ and $f(y)$ within $1/(j+1)$ of 0 are within $1/(k+1)$ of each other.

Theorem G.7 (Quantitative uniqueness costs $\mathrm{MP}_{\mathrm{bin}}$)**.** *The assertion that for all points* $0 \le a \le b$ *with* $b \neq 0$ *the function* $c \mapsto bc - a$ *has a quantitatively unique root on* $[0,1]$ *is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$. *Together with WLPO it gives LPO. No choice is used.*

Proof. Assume $\mathrm{MP}_{\mathrm{bin}}$, and let $0 \le a \le b$ with $b \neq 0$. Then b is apart from 0 and not negative, so $b > 0$, and its inverse d is positive, as in the proof of Lemma 14.5. Take a natural number $K \ge 1$ with $d \le K$. Given k, put $j + 1 = 2K(k+1)$. If $bx - a$ and $by - a$ are within $1/(j+1)$ of 0, then $|bx - by| \le 2/(j+1)$, and $|x - y| = d\,|bx - by| \le 2K/(j+1) = 1/(k+1)$.

Conversely, let $x \neq 0$, and apply the assertion to $a = 0$ and $b = |x|$, which satisfy $0 \le 0 \le |x|$ and $|x| \neq 0$. Take j for $k = 1$. The points 0 and 1 of $[0,1]$ are not within $1/2$ of each other. Cotransitivity of $1/(2j+2) < 1/(j+1)$ at $|x|$ gives $|x| > 1/(2j+2)$ or $|x| < 1/(j+1)$. In the second case $|x| \cdot 1$ and $|x| \cdot 0$ are both within $1/(j+1)$ of 0, so 1 and 0 would be within $1/2$; this is impossible. So $|x| > 0$, and x is apart from 0. Every nonzero point is therefore apart from 0, which is $\mathrm{MP}_{\mathrm{bin}}$ by Corollary 12.18. With WLPO, Proposition 12.9 gives LPO. □

The last row priced $\mathrm{MP}_{\mathrm{bin}}$ concerns maps of the whole line. A map f of $\mathbb{R}_\delta$ to itself is *continuous* when it is continuous at every point: for every x and k some j has $f(y)$ within $1/(k+1)$ of $f(x)$ whenever y is within $1/(j+1)$ of x. It is *injective* when $f(x) = f(y)$ gives $x = y$, and *strictly increasing*, respectively *strictly decreasing*, when $x < y$ gives $f(x) < f(y)$, respectively $f(y) < f(x)$.

Lemma G.8 (A barrier for nowhere-zero functions)**.** *Assume* $\mathrm{MP}_{\mathrm{bin}}$. *No function* g *continuous at every point of* $[0,1]$ *has* $g(0) \le 0 \le g(1)$ *and* $g(t) \neq 0$ *for every* t *in* $[0,1]$. *No choice is used.*

Proof. Suppose g is such a function. For each pair (n, j) with $j \le 2^n$ the point $y = g(j/2^n)$ is not zero, so $\mathrm{MP}_{\mathrm{bin}}$ makes it apart from 0 (Corollary 12.18). Exactly one of $y > 0$ and $y < 0$ then holds, and which one is computed from the point itself, as in the proof of Theorem 14.30: search any regular sequence naming y for its first stage above $2/(N+1)$ or below $-2/(N+1)$. The search is proved to terminate, because y is apart from 0, and two sequences naming y give the same answer, since a point is not both positive and negative. Put $B(n,j) = 1$ when $y < 0$ and $B(n,j) = 0$ when $y > 0$, and $B(n,j) = 0$ for the pairs with $j > 2^n$. This table is computed from g with no selection: $B(n,j) = 1$ gives $g(j/2^n) \le 0$, and $B(n,j) = 0$ gives $g(j/2^n) \ge 0$. The second part of the proof of Theorem 12.54, which uses continuity only at the limit point it constructs, turns this table into a root t of g in $[0,1]$, contrary to $g(t) \neq 0$. □

Theorem G.9 (Continuous injective maps are monotone at the price $\mathrm{MP}_{\mathrm{bin}}$)**.** *Consider the assertion that every continuous injective map of $\mathbb{R}_\delta$ to itself is strictly increasing or strictly decreasing.*

1. *The assertion implies $\mathrm{MP}_{\mathrm{bin}}$. No choice is used.*
2. *$\mathrm{MP}_{\mathrm{bin}}$ implies the assertion. No choice is used.*

Proof. For the first statement, let $a \neq 0$. The map $x \mapsto ax$ is continuous, since $|ax - ay| \leq K|x - y|$ for a natural number K with $|a| \leq K$, and it is injective by Lemma 14.4. If it is strictly increasing, then $a \cdot 0 < a \cdot 1$ and $a > 0$; if strictly decreasing, $a < 0$. So every nonzero point is apart from 0, which is $\mathrm{MP}_{\mathrm{bin}}$ by Corollary 12.18.

For the second, assume $\mathrm{MP}_{\mathrm{bin}}$, and let f be continuous and injective. Then $f(0) \neq f(1)$, and the seventh row of Table 12.2 gives $f(0) < f(1)$ or $f(1) < f(0)$. In the second case $-f$ is continuous and injective with $-f(0) < -f(1)$, and f is strictly decreasing if $-f$ is strictly increasing. So we may assume $f(0) < f(1)$ and show that f is strictly increasing.

Let $x < y$. Then $f(x) \neq f(y)$, so $f(x) < f(y)$ or $f(y) < f(x)$; we refute the second. Suppose $f(y) < f(x)$, and put

$$g(t) = f(xt) - f\big(1 + (y-1)t\big).$$

Then $g(0) = f(0) - f(1) \leq 0$ and $g(1) = f(x) - f(y) \geq 0$. The two arguments of f stay apart on $[0,1]$. By Lemma 12.52, item 1, there is a ratio ε with $0 < \varepsilon \leq 1$ and $\varepsilon < y - x$. For t in $[0,1]$,

$$1 + (y-1)t - xt = (1-t) + t(y-x) \geq (1-t)\varepsilon + t\varepsilon = \varepsilon > 0,$$

since $1 - t \geq 0$ and $t \geq 0$. So $f(xt) \neq f(1 + (y-1)t)$ by injectivity, that is $g(t) \neq 0$. The function g is continuous at every point of $[0,1]$: the maps $t \mapsto xt$ and $t \mapsto 1 + (y-1)t$ multiply distances by at most a natural number K bounding $|x|$ and $|y-1|$, so continuity of f at xt and at $1 + (y-1)t$, each for the tolerance $1/(2k+2)$, and the triangle inequality give a modulus for g at t. Lemma G.8 now gives a contradiction. Hence $f(x) < f(y)$. □

G.3 Without unique choice

Theorem G.10 ($\mathrm{MP}^\vee_{\mathrm{seq}}$ is $\mathrm{MP}^\vee$ with unique choice for Π^0_1 relations)**.** *The sequence form of $\mathrm{MP}^\vee$ is $\mathrm{MP}^\vee$ together with a choice principle.*

1. *$\mathrm{MP}^\vee_{\mathrm{seq}}$ is equivalent to $\mathrm{MP}^\vee$ together with unique choice of bits for Π^0_1 relations.*
2. *$\mathrm{MP}_{\mathrm{bin}}$ implies $\mathrm{MP}^\vee_{\mathrm{seq}}$, and hence unique choice of bits for Π^0_1 relations.*

No choice is used.

Proof. From $\mathrm{MP}^\vee_{\mathrm{seq}}$ to $\mathrm{MP}^\vee$. Apply $\mathrm{MP}^\vee_{\mathrm{seq}}$ to the matrix all of whose rows are the given sequence.

From $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ *to unique choice.* Let $r(i,b,n)$ be such that exactly one bit passes each row, in the sense of Definition 14.20. Call n a *failure* of row i when $r(i,0,n) = 0$ or $r(i,1,n) = 0$. Build a first-failure row F_i: $F_i(2n) = 1$ when n is the least failure of row i and $r(i,0,n) = 0$, and $F_i(2n+1) = 1$ when n is the least failure, $r(i,0,n) = 1$ and $r(i,1,n) = 0$; all other entries are 0, and each is a bounded search. A row has at most one least failure, so F_i has at most one entry 1. It is not all zero: otherwise, by induction on n, no n would be a failure, both bits would pass row i, and uniqueness would fail. So $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ gives a binary sequence f.

Suppose $f(i) = 1$, so the even entries of F_i vanish. We show that the bit 0 passes row i. Fix n; the value $r(i,0,n)$ is decided, so suppose it is 0. Then n is a failure, and a bounded search finds the least failure $j \le n$. Since $F_i(2j) = 0$, $r(i,0,j) = 1$, and so $r(i,1,j) = 0$: the bit 1 does not pass. The bit that passes is therefore 0, and $r(i,0,n) = 1$, which is a contradiction. So $r(i,0,n) = 1$ for every n. If $f(i) = 0$, the odd entries of F_i vanish, and in the same way the least failure j below any n with $r(i,1,n) = 0$ has $r(i,0,j) = 0$, so the bit 1 passes row i. The sequence $1 - f$ chooses the passing bit of every row. *The converse* is Lemma 14.21.

From $\mathrm{MP}_{\mathrm{bin}}$. Let $(\alpha_i(n))$ be a matrix as in Definition 14.18. Each row is not all zero, so $\mathrm{MP}_{\mathrm{bin}}$ gives an index with $\alpha_i(n) = 1$, and the least such index n_i is found by a search that is proved to terminate. It is the only entry 1 of the row. Put $f(i) = 1$ when n_i is odd and $f(i) = 0$ when it is even; then the entries of the other parity vanish. Unique choice of bits for Π^0_1 relations follows from the first statement. □

A failure index would name the surviving bit directly. Searching for one costs exactly $\mathrm{MP}_{\mathrm{bin}}$, Markov's principle for binary sequences.

Theorem G.11 (Searching for a failed test costs $\mathrm{MP}_{\mathrm{bin}}$)**.** *Let $r(i,b,n)$ be such that exactly one bit passes each row. Call n a failure of row i when $r(i,0,n) = 0$ or $r(i,1,n) = 0$.*

1. *For every i it is not the case that row i has no failure.*
2. *The assertion that, for every such r, every row has a failure is equivalent to* $\mathrm{MP}_{\mathrm{bin}}$.
3. *That assertion implies unique choice of bits for Π^0_1 relations.*
4. *WLPO implies that assertion if and only if WLPO implies* $\mathrm{MP}_{\mathrm{bin}}$.

No choice is used.

Proof. If row i had no failure, both bits would pass it, and uniqueness would fail. This is the first statement.

For the second, assume $\mathrm{MP}_{\mathrm{bin}}$. For row i let $e(n) = 1$ when n is a failure. By the first statement e is not all zero, and $\mathrm{MP}_{\mathrm{bin}}$ gives a failure. Conversely, assume the assertion, and let α be a binary sequence that is not all zero. Put $r(i,0,n) = 1$ and $r(i,1,n) = 1 - \alpha(n)$ for all i and n. The bit 0 passes every row, and the bit 1 passes a row only if α is all zero, which is excluded; so exactly one bit passes each row. The assertion gives a failure n of row 0, which cannot be one of the bit 0; so $r(0,1,n) = 0$, that is $\alpha(n) = 1$.

For the third, let every row have a failure. The least failure n_i of row i is found by a search that is proved to terminate. Put $f(i) = 1$ when $r(i,0,n_i) = 0$, and $f(i) = 0$ otherwise, in which

case $r(i, 1, n_i) = 0$. In either case the bit $1 - f(i)$ fails row i at n_i, so the passing bit is $f(i)$. The fourth statement follows from the second. □

WLPO together with $\mathrm{MP}_{\mathrm{bin}}$ is LPO (Proposition 12.9), which intuitionistic second-order arithmetic does not derive from WLPO (Theorem 7.38); so a search for failed tests is not a route from WLPO to unique choice.

Theorem G.12 (What remains without unique choice)**.** *The following hold with no choice.*

1. *Scalar pair division is equivalent to WLPO together with affine trisection control. The same holds for basis selection for every finite family, and for rank–nullity, in place of scalar pair division.*
2. *WLPO implies scalar pair division if and only if WLPO implies affine trisection control.*
3. *Scalar pair division implies unique choice of bits for Π^0_1 relations if and only if it implies absolute-quotient collection for every sequence of nonzero points given by regular sequences. These implications hold exactly when scalar pair division, basis selection for every finite family and rank–nullity are each equivalent to WLPO together with unique choice of bits for Π^0_1 relations, with no choice in either direction.*
4. *WLPO implies unique choice of bits for Π^0_1 relations if and only if both the implication of the second statement and those of the third hold. In that case scalar pair division, basis selection for every finite family and rank–nullity are each equivalent to WLPO, with no choice in either direction.*

Proof. The first statement. Theorem 14.15 makes scalar pair division WLPO together with dominated division by nonzero points, and Theorem 14.27 makes the latter affine trisection control. Theorems 14.13 and 14.14 give the other two assertions.

The second. Under WLPO, the first statement makes scalar pair division equivalent to affine trisection control.

The third. Under scalar pair division WLPO holds, so LLPO and $\mathrm{MP}^{\vee}$ hold (Theorem 14.19). Given $\mathrm{MP}^{\vee}$, unique choice of bits for Π^0_1 relations is equivalent to $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ (Lemma 14.21 and Theorem G.10), and $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ is equivalent to absolute-quotient collection (Theorem 14.30). This gives the first sentence. For the second, Corollary 14.29 proves each of the three assertions from WLPO and that principle, and each assertion gives scalar pair division (Theorems 14.13 and 14.14), hence WLPO. So each assertion is equivalent to WLPO with that principle exactly when it implies the principle, and by the same two theorems this is the case for one of them exactly when it is for scalar pair division.

The fourth. If WLPO implies unique choice of bits for Π^0_1 relations, then WLPO implies scalar pair division by Corollary 14.29, and scalar pair division implies that choice, since it gives WLPO. Conversely, assume the implication of the second statement and those of the third, and assume WLPO. Then scalar pair division holds, and so does unique choice of bits for Π^0_1 relations. In that case WLPO implies each of the three assertions, and each of them implies WLPO by Theorem 14.16, with no choice in either direction. □

Appendix H

Proofs for certified computation

This appendix proves Proposition 15.26, Theorem 15.29 and Corollary 15.30. Notation is that of Chapter 15. Section H.1 is a bookkeeping of integers. Sections H.2 and H.3 are classical real analysis: they use the real numbers, their completeness and right derivatives, as the statements they prove do.

H.1 The size of every operand

A ratio is stored as a pair (u, e) of an integer and a positive integer, without reduction. Say that it has *width* b if $|u| \le 2^b$ and $e \le 2^b$. The ratio then has at most $2b + 3$ binary digits in all, counting a sign: $\mathrm{bl}(|u|) \le b + 1$ and $\mathrm{bl}(e) \le b + 1$. Every stored ratio $q = (u, e)$ has the width $\mathrm{cap}(q) = \mathrm{bl}(|u|) + \mathrm{bl}(e)$.

Lemma H.1 (Width rules)**.** *Let q and r have widths a and b.*

(a) A width b is also a width b' for every $b' \ge b$.

(b) The product qr has width $a + b$, and the sum $q + r$, with numerator $u_q e_r + u_r e_q$ over $e_q e_r$, has width $a + b + 1$.

(c) For a natural number $k \ge 1$, q/k has width $a + \mathrm{bl}(k)$, and 2^{-e} has width e.

(d) If $|q| \le V \le 2^h$ and the denominator of q is at most 2^w, then q has width $h + w$.

(e) A sum of L ratios of width b, formed term by term from 0, has width $(b + 1)L$, and so has each of its partial sums.

Proof. (a) is immediate. (b) $|u_q u_r| \le 2^{a+b}$ and $e_q e_r \le 2^{a+b}$; and $|u_q e_r + u_r e_q| \le 2 \cdot 2^{a+b}$. (c) The numerator is unchanged and the denominator is multiplied by $k < 2^{\mathrm{bl}(k)}$; and 2^{-e} is $(1, 2^e)$. (d) $|u| = |q|\, e \le 2^h 2^w$. (e) Induction on L with (b): the sum of a ratio of width b and a partial sum of width $(b + 1)(L - 1)$ has width $(b + 1)L$; the empty sum 0 has width 0. □

Let the problem have a coefficient field. Put

$$s = \max_i \Big(\mathrm{cap}(c_i) + \sum_{(a,j)} \mathrm{cap}(a) + \sum_{(b,j,k)} \mathrm{cap}(b) \Big), \qquad L = \max_i \big(\#A\text{-terms} + \#B\text{-terms} \big),$$

the sums and counts running over the terms of coordinate i, and $s_0 = \max_i \mathrm{cap}(y_{0,i})$. Then every c_i and every coefficient of the field has width s, every coordinate has at most L terms of each kind, and every $y_{0,i}$ has width s_0. Let $r = \mathrm{bl}(M) + \mathrm{bl}(R) + 1$.

Lemma H.2 (Stored coefficients)**.** *Let $\|z\| \le M$, and let every coordinate of z have denominator exactly 2^w. In the table at z with rounding $[\cdot]_w$, every coefficient a_k has denominator 2^w and width $\mathrm{bl}(M) + \mathrm{bl}(R)\,k + w$. For $w = N$ and $k \le N$ this is at most $\rho(N) = r(N+1)$. If the region certificate holds at level n_0 and $n \ge n_0$, every row stored during the S steps at level n has width $\rho(N(n))$.*

Proof. The rounding $[\cdot]_w$ produces the denominator 2^w, and $a_0 = z$ has it by hypothesis. By Lemma 15.14, $\|a_k\| \le MR^k \le 2^{\mathrm{bl}(M)}2^{\mathrm{bl}(R)k}$, and Lemma H.1(d) gives the width. Expanding $r(N+1)$ shows that it is at least $\mathrm{bl}(M) + \mathrm{bl}(R)k + N$ when $k \le N$. At level n, each step starts from $y_k^{(n)}$, which has denominator $2^{N(n)}$ and, by Theorem 15.20, norm at most M. □

Lemma H.3 (New coefficients before rounding)**.** *If $f_0, \dots, f_k$ have coordinates of width b, then* $\mathrm{next}(f, k)$*, for the coefficient field, has coordinates of width*

$$v(b,k) = s + (s+b+1)L + 1 + (k+1)\big((s+2b+1)L+1\big) + 1 + \mathrm{bl}(k+1),$$

and so do all partial sums formed while computing it.

Proof. By Lemma H.1: c_i has width s; each term $a\,u_j$ of $(Af_k)_i$ has width $s+b$, and the at most L terms sum to width $(s+b+1)L$; adding c_i gives $s + (s+b+1)L + 1$. Each term $b\,u_j v_k$ of a coordinate of $B(f_i, f_{k-i})$ has width $s+2b$, so the coordinate has width $(s+2b+1)L$; the Cauchy sum of $k+1$ such vectors has width $(k+1)\big((s+2b+1)L+1\big)$. One more addition and the division by $k+1$ give $v(b,k)$. □

Lemma H.4 (Taylor sums before rounding)**.** *If $f_0, \dots, f_N$ have coordinates of width b, then $S_N(f)$ and all its partial sums have coordinates of width $b + (\sigma N + b + 1)N$.*

Proof. Let $\theta(0) = b$ and $\theta(j+1) = \theta(j) + \sigma(j+1) + b + 1$: the term $2^{-\sigma(j+1)} f_{j+1}$ has width $\sigma(j+1) + b$, and adding it costs one more. So $S_j(f)$ has width $\theta(j)$, and induction on $j \le N$ gives $\theta(j) \le b + (\sigma N + b + 1)j$. □

With $b = \rho(N)$ and $k \le N$, $\mathrm{bl}(k+1) \le N+1$, so $v(\rho(N), k) \le v^*(N)$, where $v^*(N)$ is $v(\rho(N), N)$ with its last summand replaced by $N+1$. Define the *capacity*

$$\mathscr{B}(N) = s_0 + s + \rho(N) + v^*(N) + \big(\rho(N) + (\sigma N + \rho(N) + 1)N\big) + N + 3. \tag{H.1}$$

Expanding, $\mathscr{B}(N) = q_P N^2 + l_P N + c_P$ with

$$q_P = 2rL + \sigma + r, \qquad l_P = 3r + (s + 5r + 1)L + 4, \qquad c_P = s_0 + 2s + 2r + (2s + 3r + 2)L + 7.$$

Proof of Proposition 15.26. The computation of a_m at level $n = \max(m, n_0)$, with $N = N(n)$, consists of the following operations, and in each case the operands and results have width at most one of the summands of (H.1), hence at most $\mathscr{B}(N)$ by Lemma H.1(a).

(i) The rounding of y_0: operands of width s_0, results of width $\rho(N)$ by Lemma H.2.

(ii) In each step, the products, sums and divisions that form next of the stored rows: field coefficients of width s, stored rows of width $\rho(N)$ (Lemma H.2, which is where the region certificate is used), and every intermediate value of width at most $v^*(N)$ by Lemma H.3.

(iii) The rounding of each new row: operand of width $v^*(N)$, result of width $\rho(N)$.

(iv) The scalings and additions of the Taylor sum: width at most $\rho(N) + (\sigma N + \rho(N) + 1)N$ by Lemma H.4; its rounding gives the next stored vector, of width $\rho(N)$.

(v) The final rounding to the integer a_m, from a stored value of width $\rho(N)$.

A rounding $[q]_w$ of $q = (u, e)$ of width b is the floor division of $2u2^w + e$ by $2e$, whose integers have absolute value at most 2^{b+w+2} and 2^{b+1}; here $w \le N$, and the last summand $N + 3$ of (H.1) covers them. Divisions are by $k + 1 \le N + 1$. The expansion of $\mathscr{B}$ follows from $\rho(N) = rN + r$ by collecting powers of N. Finally N^2, N and 1 are at most $(N + 1)^2$, and $N + 1 = \max(m, n_0) + \kappa + 1 \le m + n_0 + \kappa + 1$, so $\mathscr{B}(N) \le (q_P + l_P + c_P)(m + n_0 + \kappa + 1)^2$. The count of digits is the remark at the start of this section. $\square$

The quadratic growth comes from the sums formed without reduction: the Cauchy sums of next, which contribute $2rL$ to q_P, and the Taylor sum, which contributes $\sigma + r$. A sum formed without reduction multiplies the denominators of its terms. For the Taylor sum of stored rows these are $2^{\sigma j + N}$, $j \le N$, and their product is a power of two with exponent $(N + 1)(\sigma N/2 + N)$. So this bookkeeping gives a capacity quadratic, not linear, in N.

The answer itself needs far fewer digits than the capacity allows. The width $W_m = 4\mathscr{B}(N) + 4$ of the answer word in Definition 15.32 is therefore always enough.

Lemma H.5 (The answer fits its width)**.** *Let a problem have a coefficient field and satisfy the region certificate at level n_0. Then the answer a_m of Theorem 15.22 satisfies $|a_m| < 2^{W_m + 1}$.*

Proof. Let $z = y_S^{(\max(m, n_0))}$. By Theorem 15.20, $|z_i| \le M$, and $M \le 2^{\mathrm{bl}(M)} - 1$. So

$$|a_m| \le 2^m |z_i| + \tfrac{1}{2} \le 2^{m + \mathrm{bl}(M)} - 2^m + \tfrac{1}{2} < 2^{m + \mathrm{bl}(M)}.$$

Since $N = \max(m, n_0) + \kappa \ge m$, $m + \mathrm{bl}(M) \le \mathrm{bl}(M) + N + 1 \le \rho(N) \le \mathscr{B}(N) \le W_m + 1$. $\square$

H.2 The classical solution value

Throughout this section $\mathbb{R}^d$ carries the sup norm, A and B are the real linear and bilinear maps of Theorem 15.29, and $f(x) = c + Ax + B(x, x)$.

Lemma H.6 (The field on the doubled ball)**.** *On the ball of radius $2M$, f is Lipschitz with constant $L = \alpha + 4\beta M$.*

Proof. By linearity and bilinearity, $f(x) - f(x') = A(x - x') + B(x - x', x) + B(x', x - x')$, so $\|f(x) - f(x')\| \le \big(\alpha + \beta\|x\| + \beta\|x'\|\big)\|x - x'\| \le (\alpha + 4\beta M)\|x - x'\|$. $\square$

Lemma H.7 (The Taylor polynomial nearly solves the equation). *Let z be a rational vector with $\|z\| \le M$, let a_j be the exact coefficients at z, let $N \ge 1$, and put $\Pi(\tau) = \sum_{j=0}^{N} \tau^j a_j$. Then*

$$\Pi'(\tau) - f(\Pi(\tau)) = -\tau^N A a_N - \sum_{\substack{i,l \le N \\ i+l \ge N}} \tau^{i+l} B(a_i, a_l).$$

If $0 \le \tau$ and $R\tau \le 1/8$, then $\|\Pi'(\tau) - f(\Pi(\tau))\| \le \big(\alpha M + \beta M^2 (N+1)^2\big) 8^{-N}$ and $\|\Pi(\tau)\| \le 2M$.

Proof. The real maps agree with A and B on rational vectors, so the exact coefficients satisfy $(j+1)a_{j+1} = c\,[j=0] + A a_j + \sum_{i \le j} B(a_i, a_{j-i})$ in $\mathbb{R}^d$. Hence

$$\Pi'(\tau) = \sum_{j<N} (j+1)\tau^j a_{j+1} = c + \sum_{j<N} \tau^j A a_j + \sum_{i+l<N} \tau^{i+l} B(a_i, a_l),$$

the last sum collecting the Cauchy sums by antidiagonals, while $f(\Pi(\tau)) = c + \sum_{j \le N} \tau^j A a_j + \sum_{i,l \le N} \tau^{i+l} B(a_i, a_l)$ by linearity and bilinearity. Subtracting gives the identity. By Lemma 15.14, $\|a_j\| \le M R^j$. So $\|\tau^N A a_N\| \le \alpha M (R\tau)^N \le \alpha M 8^{-N}$, and each of the at most $(N+1)^2$ terms of the double sum is at most $\beta M^2 (R\tau)^{i+l} \le \beta M^2\, 8^{-N}$, because $i + l \ge N$ and $R\tau \le 1/8$. Finally $\|\Pi(\tau)\| \le M \sum_j (R\tau)^j \le M \sum_j 8^{-j} \le 2M$. □

The next two lemmas are the classical Gronwall inequality, first for a single function with a one-sided growth bound, then for two approximate solutions with right derivatives in a region where the field is Lipschitz.

Lemma H.8 (A one-sided comparison). *Let $\delta : [a, a+h] \to \mathbb{R}$ be continuous, with $h > 0$, and let $L, \varepsilon \ge 0$. Suppose that for every $t \in [a, a+h)$ and every $\lambda > L\delta(t) + \varepsilon$ there is $\zeta > 0$ with $\delta(s) - \delta(t) \le \lambda (s - t)$ for all $s \in [t, t+\zeta)$. Then $\delta(t) \le e^{L(t-a)}\big(\delta(a) + \varepsilon(t-a)\big)$ for every $t \in [a, a+h]$.*

Proof. Fix $\eta > 0$ and put

$$\psi(t) = e^{L(t-a)}\big(\delta(a) + \eta + (\varepsilon + \eta)(t-a)\big).$$

Then

$$\psi'(t) = L\psi(t) + e^{L(t-a)}(\varepsilon + \eta) \ge L\psi(t) + \varepsilon + \eta.$$

We show $\delta \le \psi$ on $[a, a+h]$. Otherwise the set U of points where $\delta > \psi$ is nonempty and open in $[a, a+h]$; let t^* be its infimum. The point a is not in U, since $\delta(a) < \psi(a)$; as U is open, $t^* \notin U$, so $\delta(t^*) \le \psi(t^*)$. Points of U approach t^*, necessarily from the right, so $\delta(t^*) \ge \psi(t^*)$ by continuity. Hence $\delta(t^*) = \psi(t^*)$ and $t^* < a + h$. Take $\lambda = L\delta(t^*) + \varepsilon + \eta/2$, which is at most $\psi'(t^*) - \eta/2$. By hypothesis $\delta(s) - \delta(t^*) \le \lambda (s - t^*)$ for s slightly larger than t^*, while $\psi(s) - \psi(t^*) > \lambda (s - t^*)$ for such s, since $\psi'(t^*) > \lambda$. So $\delta(s) < \psi(s)$ on an interval $(t^*, t^* + \zeta')$, which contains points of U: a contradiction. So $\delta \le \psi$ for every $\eta > 0$, and letting η tend to 0 gives the claim. □

The infimum of a set of real numbers and the passage to the limit are where the completeness of the classical real numbers enters.

Lemma H.9 (Gronwall for approximate solutions)**.** *Let f be Lipschitz with constant $L \geq 0$ on a set $\Omega \subseteq \mathbb{R}^d$, and let $h > 0$. Let $u, v : [a, a+h] \to \mathbb{R}^d$ be continuous, with $u(t), v(t) \in \Omega$ and right derivatives $u'(t)$, $v'(t)$ at every $t \in [a, a+h)$ satisfying $\|u'(t) - f(u(t))\| \leq \varepsilon_u$ and $\|v'(t) - f(v(t))\| \leq \varepsilon_v$. Then, with $\varepsilon = \varepsilon_u + \varepsilon_v$,*

$$\|u(a+h) - v(a+h)\| \leq e^{Lh}\big(\|u(a) - v(a)\| + \varepsilon h\big).$$

Proof. Let $\delta(t) = \|u(t) - v(t)\|$, a continuous function. At $t \in [a, a+h)$ the right derivatives give $\delta(s) - \delta(t) \leq \|(u(s) - v(s)) - (u(t) - v(t))\| = (s-t)\big(\|u'(t) - v'(t)\| + o(1)\big)$ as $s \downarrow t$, and $\|u'(t) - v'(t)\| \leq \|f(u(t)) - f(v(t))\| + \varepsilon \leq L\delta(t) + \varepsilon$. So the hypothesis of Lemma H.8 holds, and its conclusion at $t = a + h$ is the claim. □

Lemma H.10 (One step against the true solution)**.** *Under the hypotheses of Theorem 15.29, let $n \geq n_0$, $h = 2^{-\sigma}$, $k < S$ and $e_k = \|y(kh) - y_k^{(n)}\|$. Then*

$$e_{k+1} \leq e^{Lh}\big(e_k + (\alpha M + \beta M^2)2^{-n}h\big) + (M+2)2^{-n}.$$

Proof. Let $z = y_k^{(n)}$ and $N = N(n)$. By Theorem 15.20, $\|z\| \leq M$. Since $8R \leq 2^{\sigma}$, $Rh \leq 1/8$. On $[kh, (k+1)h]$ compare $u = y$, which solves the equation exactly and stays in the ball of radius M, with $v(t) = \Pi(t - kh)$, which by Lemma H.7 misses the equation by at most $\varepsilon_N = (\alpha M + \beta M^2(N+1)^2)8^{-N}$ and stays in the ball of radius $2M$. Lemmas H.6 and H.9 give $\|y((k+1)h) - \Pi(h)\| \leq e^{Lh}(e_k + \varepsilon_N h)$, because $\Pi(0) = z$. Since $(N+1)^2 \leq 4^N$ and $N \geq n$, $\varepsilon_N \leq (\alpha M + \beta M^2)2^{-N} \leq (\alpha M + \beta M^2)2^{-n}$. Next, $\Pi(h) = S_N(a(z)) = \Phi_N(z)$, and by Lemma 15.17(b) with $N_0 = N$ and the estimate in the proof of Lemma 15.19, $\|\Phi_N(z) - y_{k+1}^{(n)}\| \leq (M+2)2^{-N} \leq (M+2)2^{-n}$. Add the two bounds. □

Proof of Theorem 15.29. Put $\delta' = (\alpha M + \beta M^2)2^{-n}h + (M+2)2^{-n}$. We show $e_k \leq e^{Lkh}(2^{-n} + k\delta')$ for $k \leq S$. At $k = 0$, $e_0 = \|y_0 - [y_0]_{N(n)}\| \leq 2^{-(N(n)+1)} \leq 2^{-n}$. If the bound holds at k, Lemma H.10 and $1 \leq e^{Lh}$ give $e_{k+1} \leq e^{Lh}(e_k + \delta') \leq e^{L(k+1)h}(2^{-n} + (k+1)\delta')$. At $k = S$ we have $Sh = T$, so

$$e_S \leq e^{LT}\Big(1 + S\big((\alpha M + \beta M^2)2^{-\sigma} + M + 2\big)\Big)2^{-n} = C_P\, 2^{-n}.$$

For the answers, fix m and i. For every $M' \geq m$, Theorem 15.22 and the bound just proved, at the level $\max(M', n_0) \geq n_0$, give

$$\big|a_m/2^m - y_i(T)\big| \leq 2^{-m} + C_P\, 2^{-M'}.$$

Letting M' grow gives $|a_m/2^m - y_i(T)| \leq 2^{-m}$. □

For the oscillator, the realization is $A(x_0, x_1) = (x_1, -x_0)$, with $\|Ax\| \leq \|x\|$, and $B = 0$; the solution $(\sin t, \cos t)$ has the derivative $(\cos t, -\sin t) = Ay(t)$ and norm at most $1 \leq M = 2$. With $\alpha = 1$, $\beta = 0$, $S = 32$ and $\sigma = 5$ the constant is $C_P = e\big(1 + 32(2 \cdot 2^{-5} + 4)\big) = 131e$, so the trajectory at level n ends within $131e \cdot 2^{-n} < 2^{9-n}$ of $(\sin 1, \cos 1)$. The constant does not enter the answers: the last step of the proof removes it, because the levels agree among themselves to within $2^{-(m+2)}$ by Theorem 15.21.

H.3 Polynomial fields

Proof of Corollary 15.30. The quadratized field is a coefficient field, and its sums define a real linear map (here 0) and a real bilinear map B on $\mathbb{R}^{d_Q}$ that agree with the rational maps on rational vectors; the triangle inequality over the terms, as in the proof of Proposition 15.25, gives $\|B(w,w')\| \le \beta\|w\|\,\|w'\|$. For $x \in \mathbb{R}^d$ let $W(x) = (x^\alpha)_{|\alpha|\le D}$. Collecting the terms of the variable w_α,

$$B\big(W(x),W(x)\big)_\alpha = \sum_{i\colon \alpha_i>0} \sum_{(q,\xi)\in p_i} \alpha_i q\, x^{\alpha-e_i}x^{\xi} = \sum_i \alpha_i x^{\alpha-e_i}p_i(x),$$

because $\alpha - e_i$ and ξ have degree at most D and so are among the variables (Theorem 15.28(a)). By the product rule for right derivatives, $t \mapsto x(t)^\alpha$ has the right derivative $\sum_i \alpha_i x(t)^{\alpha-e_i}x_i'(t) = \sum_i \alpha_i x(t)^{\alpha-e_i}p_i(x(t))$. Hence $w(t) = W(x(t))$ is continuous on $[0,T]$, starts at the monomials of x_0, has the right derivative $B(w(t),w(t))$ on $[0,T)$, and stays in the ball of radius M by hypothesis. Theorem 15.29 for the quadratized problem gives $|a_m/2^m - w_{e_i}(T)| \le 2^{-m}$, and $w_{e_i}(T) = x_i(T)$. For the last assertion, if $\|x(t)\| \le r$ with $r \ge 1$, then $|x(t)^\alpha| \le r^{|\alpha|} \le r^D \le M$ for $|\alpha| \le D$. □

The quadratized system has no other solutions with these initial values. The proof is again classical; it uses that a continuous function on a closed interval is bounded.

Proposition H.11 (Quadratized solutions are monomial vectors)**.** *Let $w : [0,T] \to \mathbb{R}^{d_Q}$ be continuous, with $w(0) = W(x_0)$ and right derivative $B(w(t),w(t))$ at every $t \in [0,T)$, for the quadratized field of p. Let $x(t) = (w_{e_i}(t))_{i<d}$. Then $w(t) = W(x(t))$ for every $t \in [0,T]$, and x is continuous, $x(0) = x_0$, and x has the right derivative $p(x(t))$ at every $t \in [0,T)$.*

Proof. Let $\pi(t) = W(x(t))$ and $E = w - \pi$. Both w and π are continuous on $[0,T]$, so they are bounded there, say $\|w\| \le C_1$ and $\|\pi\| \le C_2$. Write $f(w) = B(w,w)$. By the product rule, π_α has the right derivative $\sum_i \alpha_i x^{\alpha-e_i} f(w)_{e_i}$. At a monomial vector the identity in the proof of Corollary 15.30 reads $f(\pi)_\alpha = \sum_i \alpha_i x^{\alpha-e_i}p_i(x) = \sum_i \alpha_i x^{\alpha-e_i} f(\pi)_{e_i}$, because $f(\pi)_{e_i} = p_i(x)$. So E has the right derivative

$$E'_\alpha = \big(f(w) - f(\pi)\big)_\alpha - \sum_i \alpha_i x^{\alpha-e_i}\big(f(w) - f(\pi)\big)_{e_i}.$$

Each $x^{\alpha-e_i}$ is a coordinate of π, so $|x^{\alpha-e_i}| \le C_2$, and $\sum_i \alpha_i \le D$. Bilinearity gives $f(w) - f(\pi) = B(w-\pi,w) + B(\pi,w-\pi)$, so $\|f(w) - f(\pi)\| \le \beta(C_1+C_2)\|E\|$. Hence $\|E'\| \le K\|E\|$ with $K = (1 + DC_2)\beta(C_1+C_2)$. Since $E(0) = W(x_0) - W(x_0) = 0$, Lemma H.8 (for $T > 0$; for $T = 0$ there is nothing to prove) with $\delta = \|E\|$, $L = K$ and $\varepsilon = 0$ gives $E = 0$ on $[0,T]$. So $w = \pi$, and x, made of coordinates of w, is continuous with $x(0) = x_0$ and right derivative $f(w)_{e_i} = f(\pi)_{e_i} = p_i(x)$. □

With Corollary 15.30 this shows that the quadratization neither loses nor adds solutions: on $[0,T]$, solutions of $x' = p(x)$ from x_0 and solutions of the quadratized system from the monomials of x_0 correspond through $x \mapsto W(x)$ and $w \mapsto (w_{e_i})_i$.

Appendix I

The machine of Theorem 15.33

How many steps does it take a one-tape binary machine to add one to a number it keeps on its tape? For the machine of Theorem 15.33 the answer is exact. Suppose a counter holding 3 is kept on track 5 of the scratch area, and the head rests on the cell just left of the input. The program inc_5 of Lemma I.14 walks six cells left and then along track 5 until it meets the counter's first blank cell (62 units), writes a mark there, steps one row further and writes a blank (19 units), and walks back along the origin track to where it started (81 units): $162 = 36 \cdot 3 + 2 \cdot 5 + 44$ units in all, and the counter now holds 4. Every count in this appendix is of this kind: a program, the cells it reads and writes, and the exact or bounded number of units it takes.

Theorem 15.33 says that one control table H and one exponent λ serve every certified problem. Section 15.9 proves it from three lemmas and the stages of Table 15.1. This appendix constructs every stage and proves its bound, so that the proof of the theorem is complete.

The first six sections lay the foundation. They fix the layout of the tape (Section I.1), the language of programs and the rules that bound sequences and loops (Section I.2), and the small programs that every stage is built from: moving along the tape (Section I.3), counters and columns (Section I.4) and binary arithmetic (Section I.5). Section I.6 bounds every integer the machine stores.

The stages follow in the order in which they run; each section gives the programs, their contracts and their step bounds with fixed exponents. Section I.7 constructs the two stages that read the request, Parse and Decode. Sections I.8 and I.9 construct Schedule, which computes the problem's constants, the schedule and the width. Section I.10 constructs Initialize, which writes the first stored vector. Section I.11 constructs the coefficient table of a step, one rounded entry at a time, and Section I.12 its Taylor sum, which together make one stored step. Section I.13 repeats the step S times and selects the requested coordinate, Section I.14 rounds it to the precision m, and Section I.15 writes the answer word and erases the scratch area. Section I.16 composes the stages into the program of Theorem 15.33, computes its exponent λ and its constant K, and proves the theorem (Theorem I.209).

I.1 The tape: rows, tracks and marks

The machine has one tape of bits and no registers. Everything it remembers between instructions is written on the tape, and the input lies in the cells $0, 1, 2, \ldots$ until the machine has read it. The scratch area is the negative half, cut into rows of sixteen cells.

Definition I.1 (Cells, rows and tracks)**.** For a row $r \in \mathbb{N}$ and a track $k \in \{0, 1, \dots, 15\}$ put

$$\mathrm{cell}(r, k) = -2 - 16r - k.$$

Row r consists of the sixteen cells $\mathrm{cell}(r, 0), \dots, \mathrm{cell}(r, 15)$, that is, of $-2-16r$ down to $-17-16r$; track k consists of the cells $\mathrm{cell}(0, k), \mathrm{cell}(1, k), \dots$, sixteen apart. Cell -1 is the *root*. When no confusion is possible we write (r, k) for $\mathrm{cell}(r, k)$ and $\tau(r, k)$ for the bit a tape τ holds there.

Every cell $x \le -2$ is $\mathrm{cell}(r, k)$ for exactly one pair: write $-2 - x = 16r + k$ with $0 \le k < 16$. One step left from (r, k) reaches $(r, k+1)$ when $k < 15$; sixteen steps left reach $(r+1, k)$. A track is therefore a copy of the half-line $0, 1, 2, \dots$ read downwards with stride sixteen, and Lemma I.8 below runs ordinary one-tape programs on it.

Definition I.2 (Marks on tracks)**.** Let τ be a tape, k a track and $a, r, r_0, n \in \mathbb{N}$.

(a) Track k *carries the counter* a if $\tau(j, k) = 1$ for $j < a$ and $\tau(a, k) = 0$. The cell (a, k) is the counter's *hole*; nothing is said about the cells beyond it.

(b) Track k *holds the value* a if it carries the counter a and $\tau(j, k) = 0$ for every $j > a$.

(c) τ has *origin marks up to* r if $\tau(0, 1) = 0$ and $\tau(j, 1) = 1$ for $1 \le j \le r$.

(d) τ is a *workspace of* r *rows* if $\tau(-1) = 1$, $\tau(x) = 0$ for every $x \ge 0$, $\tau(j, 0) = 1$ for $j < r$, $\tau(r, 0) = 0$, and every cell of every row $j > r$ holds 0. Track 0 holds the row *headers* and row r is the *sentinel row*.

(e) Track 14 carries a *retained word of length* n *from row* r_0 if $\tau(r_0 + j, 14) = 1$ for $j < n$ and $\tau(r_0 + n, 14) = 0$.

A counter is a unary numeral that can be advanced by writing two cells. The same track may carry other marks beyond the hole; a value has none.

Definition I.3 (Streams, buffers and signed words)**.** Let $w = w_0 w_1 \cdots w_{\ell-1}$ be a word of bits.

(a) w lies *on the presence track* p *and the value track* v *from row* r_0 if $\tau(r_0 + j, p) = 1$ and $\tau(r_0 + j, v) = w_j$ for $j < \ell$ and $\tau(r_0 + \ell, p) = 0$. The *binary stream* is the word on tracks 6 and 7 from row 0; the *saved request* is the word on tracks 3 and 4 from row 0.

(b) The *output buffer holds* w *with capacity* R if track 11 carries the counter ℓ, $\tau(j, 12) = 1$ for $j < \ell$ and $\tau(j, 12) = 0$ for $\ell \le j \le R$, $\tau(j, 13) = w_j$ for $j < \ell$, τ has origin marks up to R, and $\ell \le R$.

(c) For an integer z and $W \in \mathbb{N}$, the *signed word* $\mathrm{sw}_W(z)$ is the bit $[z < 0]$ followed by the $W + 1$ lowest binary digits of $|z|$, least significant first: $W + 2$ bits. The integer z *fits* W if $|z| < 2^{W+1}$; then these digits are all the binary digits of $|z|$, and $\mathrm{sw}_W(z)$ determines z. For a list of integers, $\mathrm{sw}_W(z_1, \dots, z_d)$ is the concatenation of their signed words.

(d) For bits $b_0 \cdots b_{n-1}$ put $\mathrm{val}(b) = \sum_j b_j 2^j$ and $\mathrm{sval}_n(b) = \mathrm{val}(b) - 2^n b_{n-1}$ (the reading in two's complement); $\bar{b}$ is the word of complemented bits.

The answer word of Definition 15.32 is the frame of $\mathrm{sw}_{W_m}(a_m)$. Table I.1 lists what each track holds between stages; a stage that uses a track for scratch says so in its contract.

Tracks	Use
0	row headers of the workspace
1	origin marks: every walk back to the root follows this track
2	the step counter of the trajectory loop; scratch elsewhere
3, 4	the saved request: presence and bits of every frame's payload
5, 8, 9, 10	unary registers: after the schedule, σ, N, W_m and $\mathscr{B}(N)$ on 5, 8, 9 and 10 (with S on 6 and κ on 7); between steps, m, N, W_m and σ on 5, 8, 9 and 10
6, 7	the binary stream: the stored vector $\mathrm{sw}_{W_m}(Z_k)$, and at the end the answer word
11, 12, 13	the output buffer: the coefficient table of a step, and the arithmetic area of the coefficient stage
14	retained unary words, such as the step count S
15	a mark at the first row of every frame of the saved request after the first

Table I.1. The tracks of the scratch area and what they hold between stages.

Lemma I.4 (Where the marks are)**.** *Let τ be a workspace of r rows. Every cell holding* 1 *is the root or a cell of a row $j \le r$, and every counter carried by a track is at most $r + 1$.*

Proof. The first claim restates the definition: cells $x \ge 0$ and the cells of rows $j > r$ hold 0. If track k carried a counter $a \ge r + 2$, the cell $(r + 1, k)$ would hold 1. □

So a single walk over the rows marked on track 0 finds every cell the machine has written. The last stage does exactly that when it erases the scratch area.

I.2 Programs, counted runs and loops

Programs are the structured programs of Section 15.9: the primitives skip, $\mathsf{write}\,0$, $\mathsf{write}\,1$, left and right; sequences $P;Q$; branches $\mathsf{branch}(P_0, P_1)$, which run P_0 on a scanned 0 and P_1 on a scanned 1; and loops $\mathsf{loop}(P)$, which run P while the scanned bit is 1. Every primitive and every test costs one unit, including the final test of a loop. By Lemma 15.34, units are steps of the compiled control table.

A configuration is a pair (h, τ) of a head position and a tape. We write

$$(h, \tau) \xrightarrow[P]{t} (h', \tau')$$

when P has a counted execution in t units from (h, τ) to (h', τ'), and say that P runs from (h, τ) to (h', τ') *within b* units if it does so in some $t \le b$. Program names are set in sans serif, with tracks as subscripts.

Lemma I.5 (Moves and lists)**.** *Let left^n be n moves left followed by skip, and right^n likewise. For programs $P_1, \dots, P_k$ let $[P_1, \dots, P_k]$ be $P_1; (P_2; (\cdots; (P_k; \mathsf{skip}) \cdots))$.*

(a) *left^n runs from (h, τ) to $(h - n, \tau)$, and right^n from (h, τ) to $(h + n, \tau)$, in $n + 1$ units.*

(b) *If P_i runs in t_i units from the end of P_{i-1}, then $[P_1, \dots, P_k]$ runs in $t_1 + \cdots + t_k + 1$ units and $P_1; \cdots; P_k$ in $t_1 + \cdots + t_k$ units.*

Proof. Each move and the final skip cost one unit, and a sequence adds the units of its parts. □

Loops are bounded by an invariant that says, before each pass, where the head is and what the tape holds.

Lemma I.6 (Loops)**.** *Let P be a program, $n, b \in \mathbb{N}$, and $I_0, \dots, I_n$ sets of configurations. Suppose that for every $j < n$ each configuration in I_j scans a 1 and P runs from it within b units to a configuration in I_{j+1}, and that each configuration in I_n scans a 0. Then for every $j \le n$, $\mathsf{loop}(P)$ runs from each configuration in I_j within $(n-j)(b+1)+1$ units to a configuration in I_n.*

Proof. Induction on $n - j$. For $j = n$ the loop tests a 0 and stops: one unit. For $j < n$ the loop tests a 1 (one unit), runs P within b units to a configuration in I_{j+1}, and by the induction hypothesis finishes within $(n-j-1)(b+1)+1$ more units; in all $(n-j)(b+1)+1$. □

A stage of the machine is a program that starts and ends with the head on the root, together with a contract.

Definition I.7 (Stage contracts)**.** Fix a problem and write $X = m + n_0 + \kappa + 1$. A *contract* for a program P consists of two families of properties of tapes, Pre_r and $\mathrm{Post}_{r'}$ indexed by row counts, and a bound $K(X + r + 1)^g$. The program *meets* the contract if for every i, m, r and every tape τ satisfying Pre_r there are t, r' and τ' with

$$(-1, \tau) \xrightarrow[P]{t} (-1, \tau'), \qquad \tau' \text{ satisfies } \mathrm{Post}_{r'}, \qquad t + r' + 1 \le K(X + r + 1)^g.$$

The constant K may depend on the problem (the field, y_0, M, T and n_0) but is fixed before i, m, r and τ; the exponent g is a fixed natural number. When the rows do not change, a contract may bound t alone.

Lemma 15.36(c) composes two such contracts in sequence. The next two lemmas let one program written for a plain half-line run on a track, or on every other cell of a block, without being rewritten by hand.

Lemma I.8 (Running a program on a track)**.** *For a program P and $s \ge 1$ let $P^{\uparrow s}$ replace every left by left^s and every right by right^s. Fix $o \in \mathbb{Z}$, and say that (h, τ) carries (g, σ) if $h = o + sg$ and $\tau(o + si) = \sigma(i)$ for every $i \in \mathbb{Z}$. If $(g, \sigma) \xrightarrow[P]{t} (g', \sigma')$ and (h, τ) carries (g, σ), then $P^{\uparrow s}$ runs from (h, τ) within $(s+1)t$ units to a configuration (h', τ') that carries (g', σ'), with $\tau'(x) = \tau(x)$ for every x that is not of the form $o + si$.*

Proof. Induction on the counted execution of P. A write at virtual position g writes the cell $o + sg$, which is on the track, and costs one unit; a test reads $\tau(o + sg) = \sigma(g)$, so it takes the same branch or makes the same loop decision. A move becomes s moves and a skip, $s + 1$ units, and leaves the carried configuration moved by one. Sequences, branches and loops add the units of their parts, so every unit of P becomes at most $s + 1$ units of $P^{\uparrow s}$, and no cell off the track is written. □

Lemma I.9 (Mirror image). *Let $\overline{P}$ exchange* left *and* right *in P, and let the reflection of (g,σ) be $(-g,\, i \mapsto \sigma(-i))$. If $(g,\sigma) \xrightarrow[P]{t} (g',\sigma')$, then $\overline{P}$ runs in t units from the reflection of (g,σ) to the reflection of (g',σ'). Consequently, for $P^{\downarrow s} = (\overline{P})^{\uparrow s}$ and (h,τ) with $h = o - sg$ and $\tau(o - si) = \sigma(i)$ for all i, $P^{\downarrow s}$ runs within $(s+1)t$ units to (h',τ') with $h' = o - sg'$, $\tau'(o - si) = \sigma'(i)$, and $\tau'(x) = \tau(x)$ off the cells $o - si$.*

Proof. Induction on the execution: reflection exchanges a move left with a move right, preserves the scanned bit and turns a write at g into a write at $-g$. The second claim is Lemma I.8 applied to the reflected run. □

Track k is the descending sequence $\mathrm{cell}(j,k) = \mathrm{cell}(0,k) - 16j$. So a program P written for the half-line $0,1,2,\ldots$ runs on track k as $P^{\downarrow 16}$ with $o = \mathrm{cell}(0,k)$, within 17 times its units, and touches no other track. The arithmetic programs of Section I.5 are written for blocks of consecutive cells and used in this way.

I.3 Moving along the tape

The head finds its way by marks, never by addresses: control states are positions in the program, and a row number exists only as a counter on a track. Three scans do all the walking.

Lemma I.10 (Scans). *Let* $\mathsf{scanL} = \mathsf{loop}(\mathsf{left}^{16})$, $\mathsf{scanR} = \mathsf{loop}(\mathsf{right}^{16})$ *and* $\mathsf{scan}_1 = \mathsf{loop}(\mathsf{left})$.

(a) If $\tau(h-16j) = 1$ for $j < n$ and $\tau(h-16n) = 0$, then $(h,\tau) \xrightarrow[\mathsf{scanL}]{18n+1} (h-16n,\tau)$.

(b) If $\tau(h+16j) = 1$ for $j < n$ and $\tau(h+16n) = 0$, then $(h,\tau) \xrightarrow[\mathsf{scanR}]{18n+1} (h+16n,\tau)$.

(c) If $\tau(h-j) = 1$ for $j < n$ and $\tau(h-n) = 0$, then $(h,\tau) \xrightarrow[\mathsf{scan}_1]{2n+1} (h-n,\tau)$.

Proof. Lemma I.6 with $I_j = \{(h \mp 16j, \tau)\}$ (or $h - j$) and a body of 17 units (or 1): $n \cdot 18 + 1$ and $n \cdot 2 + 1$ units. □

Lemma I.11 (Going to a counter and back). *For tracks k and l put*

$$\mathsf{seek}_k = \mathsf{left}^{k+1};\mathsf{scanL}, \qquad \mathsf{home}_k = \mathsf{right}^{k-1};\mathsf{scanR};\mathsf{right}^2 \quad (k \geq 1),$$
$$\mathsf{pres}_k = [\mathsf{seek}_k, \mathsf{left}], \qquad \mathsf{val}_k = [\mathsf{seek}_k, \mathsf{left}^2],$$

and let $\mathsf{shift}_{k\to l}$ *be* left^{l-k} *if $k \leq l$ and* right^{k-l} *otherwise.*

(a) If track k carries the counter a, then seek_k *runs from $(-1,\tau)$ to $(\mathrm{cell}(a,k),\tau)$ in $18a+k+3$ units,* pres_k *to $(\mathrm{cell}(a,k+1),\tau)$ in $18a+k+5$ units and* val_k *to $(\mathrm{cell}(a,k+2),\tau)$ in $18a+k+7$ units.*

(b) If τ has origin marks up to a and $k \geq 1$, then home_k *runs from $(\mathrm{cell}(a,k),\tau)$ to $(-1,\tau)$ in $18a+k+4$ units.*

(c) $\mathsf{shift}_{k\to l}$ *runs from* $(\mathrm{cell}(r,k),\tau)$ *to* $(\mathrm{cell}(r,l),\tau)$ *in* $|k-l|+1$ *units.*

None of them writes.

Proof. (a) left^{k+1} takes $k+2$ units from -1 to $-2-k=\mathrm{cell}(0,k)$. The cells $\mathrm{cell}(0,k)-16j=\mathrm{cell}(j,k)$ hold 1 for $j<a$ and 0 for $j=a$, so scanL takes $18a+1$ units (Lemma I.10). One or two further moves and the final skip of the list give the other two counts. (b) right^{k-1} takes k units from $\mathrm{cell}(a,k)$ to $\mathrm{cell}(a,1)$. Going right along track 1 from row a the cells of rows $a,a-1,\dots,1$ hold 1 and that of row 0 holds 0, so scanR takes $18a+1$ units and stops at $\mathrm{cell}(0,1)=-3$; right^{2} takes 3 units to -1. (c) The two cells are $|k-l|$ apart in the same row. □

Lemma I.12 (Finding a mark, and writing a block)**.** *Let* $\mathsf{toggle}=\mathsf{branch}(\mathsf{write}\,1,\mathsf{write}\,0)$, $\mathsf{findL}=\mathsf{toggle};\mathsf{loop}(\mathsf{toggle};\mathsf{left};\mathsf{toggle});\mathsf{toggle}$*, and for bits* $b_0\cdots b_{\ell-1}$ *let* $\mathsf{put}(b_0\cdots b_{\ell-1})$ *be* $\mathsf{write}\,b_0;\mathsf{left};\mathsf{write}\,b_1;\mathsf{left};\cdots;\mathsf{write}\,b_{\ell-1};\mathsf{left};\mathsf{skip}$.

(a) toggle *complements the scanned cell in* 2 *units.*

(b) If $\tau(h-j)=0$ *for* $j<n$ *and* $\tau(h-n)=1$*, then* $(h,\tau)\xrightarrow[\mathsf{findL}]{6n+5}(h-n,\tau)$.

(c) $\mathsf{put}(b)$ *runs from* (h,τ) *in* $2\ell+1$ *units to* $(h-\ell,\tau')$*, where* $\tau'(h-j)=b_j$ *for* $j<\ell$ *and* $\tau'=\tau$ *elsewhere.*

Proof. (a) A branch and a write. (b) The first toggle complements the scanned cell, so the loop's test sees 1 exactly when the original bit was 0. A pass restores the current cell, moves left and complements the next cell: $1+2+1+2=6$ units with its test. After n passes the scanned cell is the complemented 1, the test fails (1 unit) and the last toggle restores it: $2+6n+1+2$ units, and the tape is unchanged. (c) Two units per bit and the skip. □

I.4 Counters, columns and rows

A counter is advanced by writing its hole and the cell below it. This section collects the programs that do this, copy and add counters, clear tracks and add rows, and it proves the rule by which a body is repeated once for every mark of a word.

Lemma I.13 (Advancing a counter)**.** *Let* $\mathsf{next}=[\mathsf{write}\,1,\mathsf{left}^{16},\mathsf{write}\,0]$. *It runs from* $(\mathrm{cell}(r,k),\tau)$ *in* 20 *units to* $(\mathrm{cell}(r+1,k),\tau')$*, where* τ' *is* τ *with* (r,k) *set to* 1 *and* $(r+1,k)$ *set to* 0.

Proof. $1+17+1+1$ units, by Lemma I.5. □

Lemma I.14 (Incrementing, resetting and marking)**.** *Let $2 \le k \le 15$ and let track k carry the counter a. Put*

$$\begin{aligned}
\mathsf{inc}_k &= \mathsf{seek}_k; \mathsf{write}\,1; \mathsf{left}^{16}; \mathsf{write}\,0; \mathsf{home}_k,\\
\mathsf{reset}_k &= [\mathsf{seek}_k, \mathsf{write}\,1, \mathsf{home}_k, \mathsf{left}^{k+1}, \mathsf{write}\,0, \mathsf{home}_k],\\
\mathsf{zero}_k &= \mathsf{left}^{k+1}; \mathsf{write}\,0; \mathsf{home}_k,\\
\mathsf{mark}_k &= [\mathsf{seek}_k, \mathsf{left}, \mathsf{write}\,1, \mathsf{right}, \mathsf{next}, \mathsf{home}_k] \quad (k \le 14),
\end{aligned}$$

and let inc_k^c be c copies of inc_k followed by skip. Each runs from $(-1,\tau)$ to $(-1,\tau')$:

(a) if τ has origin marks up to $a+1$, inc_k takes $36a+2k+44$ units and τ' is τ with (a,k) set to 1 and $(a+1,k)$ to 0, so track k carries $a+1$;

(b) if τ has origin marks up to $a+c$, inc_k^c takes $18c^2+(36a+2k+26)c+1$ units and leaves the counter $a+c$;

(c) if τ has origin marks up to a, reset_k takes $36a+4k+16$ units and τ' is τ with (a,k) set to 1 and $(0,k)$ to 0, so track k carries 0;

(d) if $\tau(0,1)=0$, zero_k takes $2k+7$ units and sets $(0,k)$ to 0, whatever track k held;

(e) if τ has origin marks up to $a+1$, mark_k takes $36a+2k+49$ units, sets $(a,k+1)$ to 1 and advances the counter on track k to $a+1$.

Track 1 is not written, so the origin marks are kept.

Proof. All counts come from Lemmas I.5, I.11 and I.13. (a) seek_k ($18a+k+3$) reaches the hole; $\mathsf{write}\,1$, left^{16} and $\mathsf{write}\,0$ (19) move the hole to row $a+1$; home_k from row $a+1$ takes $18(a+1)+k+4$. (b) The i-th increment starts at the counter $a+i$ and takes $36(a+i)+2k+44$ units; the sum over $i<c$ plus the final skip is $18c^2+(36a+2k+26)c+1$. (c) $(18a+k+3)+1+(18a+k+4)+(k+2)+1+(k+4)+1$: home_k from row 0 costs $k+4$. (d) $(k+2)+1+(k+4)$. (e) $(18a+k+3)+1+1+1+20+(18(a+1)+k+4)+1$. □

Lemma I.15 (Copying and adding counters)**.** *Let k, l and c be distinct tracks in $\{2,\dots,15\}$, let τ have origin marks up to R, and put*

$$\begin{aligned}
\mathsf{copy}_{k\to l} &= \mathsf{zero}_l; \mathsf{left}^{k+1}; \mathsf{loop}(\mathsf{shift}_{k\to l}; \mathsf{next}; \mathsf{shift}_{l\to k}); \mathsf{home}_k,\\
\mathsf{acc}^c_{k\to l} &= \mathsf{zero}_c; \mathsf{seek}_c; \mathsf{shift}_{c\to k}; \mathsf{loop}(\Gamma); \mathsf{home}_k,\\
\Gamma &= \mathsf{shift}_{k\to c}; \mathsf{next}; \mathsf{home}_c; \mathsf{inc}_l; \mathsf{seek}_c; \mathsf{shift}_{c\to k}.
\end{aligned}$$

(a) If track k carries $n \le R$, then $\mathsf{copy}_{k\to l}$ runs from $(-1,\tau)$ to $(-1,\tau')$ in $n(2|k-l|+41)+2k+2l+14 \le 100(n+1)$ units, where τ' is τ with (j,l) set to 1 for $j<n$ and (n,l) to 0: track l carries n.

(b) If track k carries b, track l carries a and $a+b \le R$, then $\mathsf{acc}^{c}_{k\to l}$ runs from $(-1,\tau)$ to $(-1,\tau')$ in

$$36b^2 + \big(36a + 2c + 2l + 2|k-c| + 92\big)b + 3c + k + |c-k| + 16 \le 500(a+b+1)^2$$

units; in τ' track l carries $a+b$, track c carries b, and only the cells (j,l), $a \le j \le a+b$, and (j,c), $j \le b$, have changed.

Proof. (a) zero_l $(2l+7)$ makes $(0,l)$ a hole, and left^{k+1} $(k+2)$ reaches cell$(0,k)$. Let I_j be the configuration at cell(j,k) in which $(i,l) = 1$ for $i < j$ and $(j,l) = 0$. From I_j with $j < n$ the body moves to cell(j,l), advances the hole there and returns to cell$(j+1,k)$: $2(|k-l|+1)+20$ units, so I_{j+1}. At I_n the scanned cell is the hole of track k. Lemma I.6 gives $n(2|k-l|+23)+1$ units, and home_k from row n takes $18n+k+4$. The sum is the stated count, and $2|k-l|+41 \le 67$ and $2k+2l+14 \le 74$ give the bound.

(b) zero_c, seek_c (counter 0) and $\mathsf{shift}_{c\to k}$ take $(2c+7)+(c+3)+(|c-k|+1)$ units and reach cell$(0,k)$. Let J_j be the configuration at cell(j,k) with j on track c and $a+j$ on track l. For $j < b$ the pass from J_j takes 1 unit for the test and

$$(|k-c|+1) + 20 + (18(j+1)+c+4) + (36(a+j)+2l+44) + (18(j+1)+c+3) + (|c-k|+1)$$

units, by Lemmas I.11, I.13 and I.14: $36(a+2j+1)+2c+2l+2|k-c|+74$ in all, and it ends in J_{j+1}. The final test at (b,k) costs 1 and home_k costs $18b+k+4$. Summing over $j < b$ gives the displayed count. With all tracks at most 15 and $|k-c| \le 13$, the count is at most $36(a+b)^2 + 178(a+b) + 89 \le 500(a+b+1)^2$. □

Lemma I.16 (Clearing tracks)**.** *Let $2 \le k \le 15$ and*

$$\mathsf{clear}_k = \mathsf{left}; \mathsf{loop}(\mathsf{left}^k; \mathsf{write}\,0; \mathsf{right}^k; \mathsf{left}^{16}); \mathsf{left}^k; \mathsf{write}\,0; \mathsf{home}_k,$$

and for tracks $k_1, \dots, k_s$ let $\mathsf{clear}_{k_1,\dots,k_s}$ be $\mathsf{clear}_{k_1}; \cdots; \mathsf{clear}_{k_s}; \mathsf{skip}$. If $\tau(j,0) = 1$ for $j < r$, $\tau(r,0) = 0$ and τ has origin marks up to r, then clear_k runs from $(-1,\tau)$ to $(-1,\tau')$ in $(2k+39)r + 2k + 8$ units, where τ' is τ with (j,k) set to 0 for every $j \le r$. So $\mathsf{clear}_{k_1,\dots,k_s}$ takes $\sum_i \big((2k_i+39)r + 2k_i + 8\big) + 1$ units.

Proof. left reaches the header $(0,0)$. A pass from the header $(j,0)$, $j < r$, clears (j,k), returns to the header and moves to $(j+1,0)$: $1 + (k+1) + 1 + (k+1) + 17 = 2k+21$ units with its test. The test at the sentinel $(r,0)$ fails (1 unit); left^k and $\mathsf{write}\,0$ clear (r,k) ($k+2$ units); and home_k from row r takes $18r+k+4$. □

Lemma I.17 (A new row)**.** *Let*

$$\mathsf{grow} = \mathsf{left}; \mathsf{scanL}; \mathsf{write}\,1; \mathsf{left}; \mathsf{scanR}; \mathsf{right}^2; \\ \mathsf{left}; \mathsf{scanL}; \mathsf{put}(\beta); \mathsf{right}^{15}; \mathsf{scanR}; \mathsf{right}^2,$$

where $\beta = \beta_0 \cdots \beta_{15}$ has $\beta_k = 1$ exactly for $k \in \{1,2,5,8,11,14\}$. If $\tau(j,0) = 1$ for $j < r$, $\tau(r,0) = 0$, $\tau(r+1,0) = 0$ and τ has origin marks up to r, then grow runs from $(-1,\tau)$ to $(-1,\tau')$ in $72r+99$ units, where τ' is τ with $(r,0)$ set to 1 and row $r+1$ overwritten by β (track k receiving β_k). In particular, if τ is a workspace of r rows with origin marks up to r, then τ' is a workspace of $r+1$ rows with origin marks up to $r+1$, and rows $j \le r$ are unchanged except for their header.

Proof. The first six parts promote the sentinel. left (1) reaches $(0,0)$, scanL $(18r+1)$ the sentinel header $(r,0)$, which is set to 1; left (1) reaches $(r,1)$, and scanR along the origin marks $(18r+1)$ and right^2 (3) return to the root: $36r+8$ units. The rest appends the block. Now the headers of rows $0,\dots,r$ hold 1 and $(r+1,0)$ holds 0, so left and scanL take $18(r+1)+2$ units to $(r+1,0)$; $\mathsf{put}(\beta)$ (33 units, Lemma I.12) writes β_k at $\mathrm{cell}(r+1,0)-k=(r+1,k)$ and stops at $(r+2,0)$; right^{15} (16) reaches $(r+1,1)$, which now holds $\beta_1=1$; and scanR $(18(r+1)+1)$ with right^2 (3) returns to the root. In all $36r+8+36r+91=72r+99$ units. The new row $r+1$ has header $\beta_0=0$ and origin mark $\beta_1=1$, every row below it is untouched and therefore blank, and row r now has header 1. □

The pattern β also fills tracks $2,5,8,11$ and 14 of the new row with 1. A counter on one of these tracks whose hole lies in an older row is unaffected, since only the cells below the hole matter.

The basic loop of the machine repeats a body once for every mark of a word. The step loop of the trajectory is of this kind: its body is one Taylor step, repeated once for each of the S marks of a retained word.

Lemma I.18 (Repeating a body along a word)**.** *Let $c\in\{2,12\}$ and put*

$$\mathsf{repeat}_c(P)=\big[\mathsf{seek}_c;\mathsf{left}^{14-c},\ \mathsf{loop}\big([\mathsf{home}_{14},P,\mathsf{seek}_c,\mathsf{next},\mathsf{left}^{14-c}]\big),\ \mathsf{home}_{14}\big].$$

Let $r_0,n,b\in\mathbb{N}$ and let $R_0,\dots,R_n$ be properties of tapes such that every tape with R_j has origin marks up to r_0+n. Suppose that for every $j<n$ and every tape τ with R_j on which track c carries r_0+j and track 14 a retained word of length n from row r_0, P runs from $(-1,\tau)$ within b units to some $(-1,\tau_1)$ such that τ_1 agrees with τ on the cells (i,c), $i\le r_0+n$, and $(r_0+i,14)$, $i\le n$, and the tape τ_2 obtained from τ_1 by setting (r_0+j,c) to 1 and (r_0+j+1,c) to 0 satisfies R_{j+1}. Then from every tape with R_0 on which track c carries r_0 and track 14 the retained word, $\mathsf{repeat}_c(P)$ runs to a tape with R_n, on which track c carries r_0+n and track 14 still carries the word, within

$$n\big(36(r_0+n)+b+58\big)+36r_0+18n+38$$

units.

Proof. The first part, seek_c followed by left^{14-c}, takes $(18r_0+c+3)+(15-c)=18r_0+18$ units and ends at $(r_0,14)$, the first mark of the word. Let I_j be the set of configurations at $(r_0+j,14)$ whose tape has R_j, carries r_0+j on track c and carries the word. A pass from I_j with $j<n$ scans the mark $(r_0+j,14)=1$, returns to the root $(18(r_0+j)+18$ units), runs P (at most b), goes to the hole of track c, which by hypothesis is still at row r_0+j $(18(r_0+j)+c+3)$, moves it by next (20), steps to $(r_0+j+1,14)$ $(15-c)$ and ends the list (1). The tape is then τ_2, which has R_{j+1}, carries r_0+j+1 on track c and still carries the word, because $c\neq 14$. So the pass ends in I_{j+1} within $36(r_0+j)+b+57$ units, at most $36(r_0+n)+b+57$. At I_n the scanned cell $(r_0+n,14)$ is the word's 0. Lemma I.6 bounds the loop by $n(36(r_0+n)+b+58)+1$, and home_{14} from row r_0+n and the final skip add $18(r_0+n)+19$. □

When the body has a polynomial bound and leaves the number of rows alone, repetition raises the exponent by one and moves the repetition count into the constant.

Lemma I.19 (Iterating a stage on fixed rows)**.** *In Lemma I.18 let $r_0 = 0$, let every tape with some R_j be a workspace of r rows with $n \le r$, and let $b = K_b Y^g$ with $Y \ge r + 1$. Then the number t of units of* $\mathsf{repeat}_c(P)$ *satisfies*

$$t + r + 1 \le \big(n(36n + K_b + 58) + 18n + 40\big)\, Y^{g+1}.$$

Proof. Since $Y \ge 1$, $Y^g \le Y^{g+1}$, $1 \le Y^{g+1}$ and $r + 1 \le Y \le Y^{g+1}$. So $t \le n(36n + 58) + nK_b Y^g + 18n + 38 \le (n(36n + K_b + 58) + 18n + 38)Y^{g+1}$, and adding $r + 1 \le Y^{g+1}$ gives the claim with room to spare. □

With $Y = X + r + 1$ this is the form of Definition I.7: the trajectory loop, whose body is one Taylor step on a fixed allocation of rows and whose count is the number S of steps, adds one to the exponent of the step and puts S into the constant only, whatever the precision.

I.5 Binary arithmetic in rows

The arithmetic programs work on a block of consecutive cells, cut into rows of six or twelve cells, with one presence cell per row. They are written for an ordinary tape and run where they are needed through Lemmas I.8 and I.9: on one track of the scratch area (stride sixteen, descending), or on the even cells of a block of twelve-cell rows (stride two), in which case the odd cells keep their contents. All the words are written least significant bit first.

Definition I.20 (Rows of a block)**.** Let σ be a tape, $q \ge 2$ and $h \in \mathbb{Z}$. The *q-cell rows at h* are the blocks $h + qj, \dots, h + qj + q - 1$, $j \in \mathbb{Z}$; cell $h + qj + c$ is *column c* of row j, and column 0 holds the *presence* bits. The block has *n marked rows* if $\sigma(h + qj) = 1$ for $0 \le j < n$ and $\sigma(h + qn) = 0$; it is *closed on the left* if also $\sigma(h - q) = 0$. Column c *holds* the word w if $\sigma(h + qj + c) = w_j$ for $j < |w|$. Row n, the first unmarked row, is the *end row*; some programs write in its columns.

Lemma I.21 (Ripple addition)**.** *In six-cell rows, let column* 1 *and column* 2 *hold the operands, column* 3 *the carries, column* 4 *the sum; column* 5 *is unused. Put*

$$\begin{aligned}
\mathsf{add} &= \mathsf{loop}(F), \qquad F = \mathsf{right};\mathsf{branch}(F_0, F_1),\\
F_a &= \mathsf{right};\mathsf{branch}(\mathsf{right};C_{a0},\ \mathsf{right};C_{a1}),\\
C_{ab} &= \mathsf{branch}\big(E(a \oplus b, \mathrm{maj}(a,b,0)),\ E(a \oplus b \oplus 1, \mathrm{maj}(a,b,1))\big),\\
E(u,v) &= \mathsf{right};\mathsf{write}\,u;\mathsf{right}^5;\mathsf{write}\,v;\mathsf{left}^3,
\end{aligned}$$

where maj *is the majority of three bits. Let the block at h have n marked rows, columns* 1 *and* 2 *hold words x and y of length n, and $c_0 = \sigma(h+3)$. Define $c_{j+1} = \mathrm{maj}(x_j, y_j, c_j)$ and $z_j = x_j \oplus y_j \oplus c_j$. Then* add *runs from (h, σ) to $(h + 6n, \sigma')$ in exactly $20n + 1$ units, where σ' is σ with column* 4 *of row j set to z_j for $j < n$ and column* 3 *of row j set to c_j for $1 \le j \le n$; and*

$$\mathrm{val}(z) + 2^n c_n = \mathrm{val}(x) + \mathrm{val}(y) + c_0.$$

Proof. Let I_j be the configuration at $h+6j$ in which the first j sums and carries have been written. From I_j, $j < n$, the presence bit is 1; F moves to column 1 and branches on x_j, moves to column 2 and branches on y_j, moves to column 3 and branches on c_j (this cell was written in the previous

pass, or is c_0); E writes z_j in column 4, moves five cells to column 3 of row $j+1$, writes c_{j+1} and returns to $h+6(j+1)$. With the test this is $1+(1+1)+(1+1)+(1+1)+(1+1+6+1+4) = 20$ units. At I_n the presence bit is 0. Lemma I.6 gives $20n+1$ units. The identity follows from $(a \oplus b \oplus c) + 2\,\mathrm{maj}(a,b,c) = a+b+c$ by induction on n. □

Corollary I.22 (Subtraction, comparison and signed sums)**.** *In Lemma I.21:*

(a) if column 2 holds $\bar{y}$ and $c_0 = 1$, then $\mathrm{val}(z) + 2^n c_n = \mathrm{val}(x) - \mathrm{val}(y) + 2^n$, so $c_n = 1$ exactly when $\mathrm{val}(y) \le \mathrm{val}(x)$, and then $\mathrm{val}(z) = \mathrm{val}(x) - \mathrm{val}(y)$;

(b) if $n \ge 1$, $u = \mathrm{sval}_n(x)$, $v = \mathrm{sval}_n(y)$ and $c_0 = 0$, then $\mathrm{sval}_n(z) = u + v$ whenever $-2^{n-1} \le u + v < 2^{n-1}$; with $\bar{y}$ in column 2 and $c_0 = 1$, $\mathrm{sval}_n(z) = u - v$ whenever $-2^{n-1} \le u - v < 2^{n-1}$;

(c) if $n \ge 1$, column 1 holds a word with $\mathrm{sval}_n = q$, column 2 holds 0^n, and $c_0 = g$, then $\mathrm{sval}_n(z) = q + g$ whenever $-2^{n-1} \le q + g < 2^{n-1}$. If $Z = 2^{k+1}q + 2^k g + \rho$ with $0 \le \rho < 2^k$, this is $\mathrm{near}(Z/2^{k+1})$.

Proof. (a) $\mathrm{val}(\bar{y}) = 2^n - 1 - \mathrm{val}(y)$, and $0 \le \mathrm{val}(z) < 2^n$. (b) $\mathrm{sval}_n(w) \equiv \mathrm{val}(w)$ modulo 2^n for every word, so $\mathrm{sval}_n(z) \equiv u + v + c_0$, and $\mathrm{sval}_n(\bar{y}) = -1 - v$. Both $\mathrm{sval}_n(z)$ and the target lie in $[-2^{n-1}, 2^{n-1})$, which contains one integer of each residue class. (c) The first claim is (b). For the second, $\mathrm{near}(Z/2^{k+1}) = \lfloor (Z + 2^k)/2^{k+1} \rfloor = q + \lfloor (2^k g + \rho + 2^k)/2^{k+1} \rfloor$, and $2^k g + \rho + 2^k$ lies in $[2^k, 2^{k+1})$ if $g = 0$ and in $[2^{k+1}, 2^{k+1} + 2^k)$ if $g = 1$. □

Lemma I.23 (Adding and subtracting one)**.** *Let* $\mathsf{carry} = \mathsf{loop}(\mathsf{write}\,0; \mathsf{right}); \mathsf{write}\,1$, $\mathsf{borrow} = \mathsf{toggle}; \mathsf{loop}(\mathsf{write}\,1; \mathsf{right}; \mathsf{toggle})$ *and* $\mathsf{borrow}^\circ = \mathsf{borrow}; \mathsf{left}; \mathsf{scan}_1; \mathsf{right}$.

(a) If $\sigma(h+j) = 1$ for $j < q$ and $\sigma(h+q) = 0$, carry *runs in $3q+2$ units to $h+q$, setting the cells $h, \dots, h+q-1$ to 0 and $h+q$ to 1.*

(b) If $\sigma(h+j) = 0$ for $j < q$ and $\sigma(h+q) = 1$, borrow *runs in $5q+3$ units to $h+q$, setting $h, \dots, h+q-1$ to 1 and $h+q$ to 0; if also $\sigma(h-1) = 0$,* borrow$^\circ$ *makes the same change and returns to h, in $7q+6$ units.*

Read as a word from h, (a) adds one to a word $1^q 0u$ and (b) subtracts one from a word $0^q 1u$.

Proof. (a) Each of the q passes costs 3 units with its test, the last test 1, and the final write 1. (b) The first toggle (2 units) makes the loop test see 1 exactly at the original 0s; each pass writes 1, moves right and complements the next cell (4 units, 5 with the test); at $h+q$ the complemented 1 reads 0 and the loop stops (1 unit). For borrow$^\circ$, left, a scan over the q new 1s up to the 0 at $h-1$ ($2q+1$) and right add $2q+3$ units. The values follow from $\mathrm{val}(0^q 1u) = \mathrm{val}(1^q 0u) + 1$. □

Lemma I.24 (Negation). *Let the two-cell rows at h have $\ell \geq 1$ marked rows whose column 1 holds a word w with $\mathrm{val}(w) > 0$, and let $\sigma(h-1) = 0$. Let*

$$\mathsf{neg} = \mathsf{right}; (\mathsf{borrow}^{\circ})^{\uparrow 2}; \mathsf{left}; \mathsf{loop}\big(\mathsf{right}; \mathsf{branch}(\mathsf{write}\,1, \mathsf{write}\,0); \mathsf{right}\big).$$

Then neg *runs from h to $h + 2\ell$ within $30(\ell+1)$ units and leaves in column 1 a word w' with $\mathrm{val}(w') \equiv -\mathrm{val}(w)$ modulo 2^{ℓ}; no other cell changes.*

Proof. Let $q < \ell$ be the position of the first 1 of w. The value cells $h+1+2i$ form a tape with stride two whose cell -1 is $h-1$. By Lemmas I.23 and I.8, $(\mathsf{borrow}^{\circ})^{\uparrow 2}$ subtracts one from w within $3(7q+6)$ units and returns to $h+1$. The last loop complements every value cell, 5 units a row and 1 for the final test. In all at most $1 + 3(7q+6) + 1 + 5\ell + 1 \leq 26\ell + 21$ units. Complementing ℓ bits maps the value v to $2^{\ell} - 1 - v$, so the result is $2^{\ell} - 1 - (\mathrm{val}(w) - 1) = 2^{\ell} - \mathrm{val}(w)$. □

The remaining programs use twelve-cell rows. Their columns are: 0 presence; 1 and 3 the original operands; 2 and 4 working words; 5 a row mark; 6, 8 and 10 the carry, sum and spare cells of the six-cell adder run on the even columns by $\mathsf{add}^{\uparrow 2}$; 9 a result.

Lemma I.25 (Walking over twelve-cell rows). *Let the twelve-cell rows at h have n marked rows and be closed on the left, and let $s, t < 12$. Put*

$$\begin{aligned}
\mathsf{back} &= \mathsf{left}^{12}; \mathsf{loop}(\mathsf{left}^{12}); \mathsf{right}^{12}, \qquad \mathsf{fwd} = \mathsf{loop}(\mathsf{right}^{12}),\\
\mathsf{cp}_{s\to t} &= \mathsf{loop}\big(\mathsf{right}^{s}; \mathsf{branch}(G_0, G_1)\big), \qquad G_b = \mathsf{left}^{s}; \mathsf{right}^{t}; \mathsf{write}\,b; \mathsf{left}^{t}; \mathsf{right}^{12},\\
\mathsf{cl}_t &= \mathsf{loop}(\mathsf{right}^{t}; \mathsf{write}\,0; \mathsf{left}^{t}; \mathsf{right}^{12}), \qquad \mathsf{z}_t = \mathsf{right}^{t}; \mathsf{write}\,0; \mathsf{left}^{t},\\
\mathsf{ret} &= \mathsf{right}^{5}; \mathsf{toggle}; \mathsf{loop}(\mathsf{toggle}; \mathsf{right}^{12}; \mathsf{toggle}); \mathsf{right}^{7}.
\end{aligned}$$

(a) For $k \leq n$, back *runs from $h + 12k$ to h in $14k + 27$ units, and* fwd *from h to $h + 12n$ in $14n + 1$ units.*

(b) From h, $\mathsf{cp}_{s\to t}$ copies column s into column t in $(2s + 2t + 20)n + 1$ units, cl_t sets column t to 0 in $(2t + 17)n + 1$ units, and both end at $h + 12n$; z_t sets column t of the current row to 0 in $2t + 3$ units.

(c) If column 5 holds 0 in rows $j < k$ and 1 in row $k < n$, then ret *runs from h to $h + 12(k+1)$ in $18k + 17$ units and sets column 5 of row k to 0.*

No other cells are written.

Proof. (a) left^{12} reaches row $k-1$; each marked row costs 14 units in the loop and the closed left end 1; right^{12} returns to row 0: $13 + 14k + 1 + 13$. (b) A pass of $\mathsf{cp}_{s\to t}$ costs $1+(s+1)+1+(s+1)+(t+1)+1+(t+1)+13$ units and one of cl_t costs $1+(t+1)+1+(t+1)+13$; the final test adds 1. (c) The first toggle complements the mark cell of row 0, so the loop runs exactly over the rows before k, restoring each and complementing the next (18 units a pass with its test); at row k the complemented mark reads 0. In all $6 + 2 + 18k + 1 + 8$ units, ending seven cells past the mark of row k, that is at $h + 12(k+1)$. □

Lemma I.26 (Doubling). *Let*

$$\mathsf{dbl} = \mathsf{loop}\big(\mathsf{right}^2; \mathsf{branch}(D_0, D_1)\big), \qquad D_u = \mathsf{right}^{20}; \mathsf{write}\, u; \mathsf{left}^{12}; \mathsf{branch}(D_0', D_1'),$$
$$D_b' = \mathsf{left}^8; \mathsf{write}\, b; \mathsf{right}^{10}.$$

If the twelve-cell rows at h have n marked rows, column 2 holds a and column 10 of row 0 holds e, then dbl *runs from h to $h + 12n$ in $62n + 1$ units and leaves in column 2 the word $e\, a_0 \cdots a_{n-2}$, whose value is $2\,\mathrm{val}(a) + e$ modulo 2^n; it writes only columns 2 and 10 (including column 10 of the end row).*

Proof. A pass from row j reads a_j in column 2, stores it in column 10 of row $j + 1$, reads the bit stored in column 10 of row j (the incoming bit: e for $j = 0$, a_{j-1} otherwise), writes it in column 2 and moves to row $j + 1$: $1 + 3 + 1 + 21 + 1 + 13 + 1 + 9 + 1 + 11 = 62$ units with its test. □

Lemma I.27 (Multiplication). *Let the twelve-cell rows at h have n marked rows and be closed on the left, with x in column 1 and y in column 3. Let*

$$\mathsf{mul} = \mathsf{cp}_{1\to 2}; \mathsf{back}; \mathsf{cl}_4; \mathsf{back}; \mathsf{cl}_5; \mathsf{back}; \mathsf{loop}(\Pi),$$
$$\Pi = \mathsf{right}^5; \mathsf{write}\, 1; \mathsf{left}^2; \mathsf{branch}\big(\mathsf{left}^3; \mathsf{back},\ \mathsf{left}^3; \mathsf{back}; \Sigma\big); \mathsf{z}_{10}; \mathsf{dbl}; \mathsf{back}; \mathsf{ret},$$
$$\Sigma = \mathsf{z}_6; \mathsf{add}^{\uparrow 2}; \mathsf{back}; \mathsf{cp}_{8\to 4}; \mathsf{back}.$$

Then mul *runs from h to $h + 12n$ within $240n^2 + 304n + 85 \le 400(n+1)^2$ units and leaves in column 4 the n lowest bits of $\mathrm{val}(x)\,\mathrm{val}(y)$. Columns 0, 1 and 3 are unchanged. If $n \ge 1$, $\mathrm{sval}_n(x) = u$, $\mathrm{sval}_n(y) = v$ and $-2^{n-1} \le uv < 2^{n-1}$, then column 4 reads uv in two's complement.*

Proof. The preparation copies x into column 2 and clears columns 4 and 5: $(26n + 1) + (25n + 1) + (27n + 1)$ units for the passes and $3(14n + 27)$ for the returns, by Lemma I.25. Let I_k ($k \le n$) be the configuration at row k in which column 2 holds the n lowest bits of $2^k\,\mathrm{val}(x)$, column 4 those of $\mathrm{val}(x) \cdot \big(\mathrm{val}(y) \bmod 2^k\big)$, column 5 is 0, and columns 0, 1, 3 are as given. A pass Π from I_k, $k < n$, marks row k in column 5 and reads y_k (10 units, then a branch). If $y_k = 1$, it returns to row 0 and runs Σ: z_6 clears the carry-in (15 units), $\mathsf{add}^{\uparrow 2}$ adds column 2 to column 4 into column 8 on the even columns within $3(20n + 1)$ units (Lemmas I.21 and I.8), and the copy of column 8 into column 4 with its two returns costs $(44n+1)+2(14n+27)$: at most $132n+73$. With left^3 and the return from row k the branch costs at most $14k + 132n + 105$. Then z_{10}, dbl and back double column 2 ($23 + (62n+1) + (14n+27)$ units), and ret removes the mark and moves to row $k + 1$ ($18k + 17$). The pass ends in I_{k+1} within $32k + 208n + 183 \le 240n + 183$ units. At I_n the presence bit is 0. Lemma I.6 bounds the loop by $n(240n + 184) + 1$, and the sum is $240n^2 + 304n + 85$. The two's complement claim follows as in Corollary I.22(b), since sval_n agrees with val modulo 2^n. □

Division is long division with restoring, one quotient bit per row, from the most significant bit down. Its single step is a subtraction that is undone when it would go negative.

Lemma I.28 (A restoring step)**.** *In six-cell rows at h, closed on the left, let column 1 hold x, column 2 hold $\bar{y}$, and $c_0 = 1$. Put* $\mathsf{rstep} = \mathsf{add}; \mathsf{right}^3; \mathsf{branch}(\beta_1, \beta_4)$ *with* $\beta_s = \mathsf{left}^3; \mathsf{left}^6; \mathsf{loop}(\mathsf{right}^s; \mathsf{branch}(\gamma_{s0}, \gamma_{s1})); \mathsf{right}^6$ *and* $\gamma_{sb} = \mathsf{right}^{4-s}; \mathsf{write}\, b; \mathsf{left}^{10}$*. Then* rstep *runs from h to h in exactly $40n + 25$ units. Afterwards the carry cell of the end row holds $e = [\mathrm{val}(y) \le \mathrm{val}(x)]$ and column 4 holds a word of value $\mathrm{val}(x) - e\,\mathrm{val}(y)$. If $\mathrm{val}(x) < 2\,\mathrm{val}(y)$, then $e = \lfloor \mathrm{val}(x)/\mathrm{val}(y) \rfloor$ and column 4 holds $\mathrm{val}(x) \bmod \mathrm{val}(y)$.*

Proof. By Corollary I.22(a), add ($20n + 1$ units, ending at the end row) leaves e in the end row's carry cell and, if $e = 1$, the difference in column 4. right^3 reads e (4 units and the branch 1). β_s moves to the last marked row and walks back to the closed left end copying column s into column 4: column 1 (restoring x) if $e = 0$, column 4 onto itself if $e = 1$. It costs $4 + 7 + 20n + 1 + 7$ units, a pass being $1 + (s + 1) + 1 + (5 - s) + 1 + 11 = 20$. The total is $(20n + 1) + 5 + (20n + 19)$. If $\mathrm{val}(x) < 2\,\mathrm{val}(y)$ the quotient is 0 or 1, and it is 1 exactly when $\mathrm{val}(y) \le \mathrm{val}(x)$. □

Lemma I.29 (Division)**.** *Let the twelve-cell rows at h have $n \ge 1$ marked rows and be closed on the left, column 1 hold x and column 4 hold $\bar{y}$, with $0 < \mathrm{val}(y) \le 2^{n-1}$. Let*

$$\begin{aligned}
\mathsf{div} &= \mathsf{cl}_2; \mathsf{back}; \mathsf{cl}_5; \mathsf{back}; \mathsf{fwd}; \mathsf{left}^{12}; \mathsf{loop}(\Delta); \mathsf{right}^{12},\\
\Delta &= \mathsf{right}^5; \mathsf{write}\ 1; \mathsf{left}^4; \mathsf{branch}(\Delta_0, \Delta_1),\\
\Delta_u &= \mathsf{left}; \mathsf{back}; \mathsf{right}^{10}; \mathsf{write}\, u; \mathsf{left}^{10}; \mathsf{dbl}; \mathsf{back};\\
&\qquad \mathsf{right}^6; \mathsf{write}\ 1; \mathsf{left}^6; \mathsf{rstep}^{\uparrow 2}; \mathsf{cp}_{8\to 2}; \mathsf{back};\\
&\qquad \mathsf{fwd}; \mathsf{right}^6; \mathsf{branch}(\Theta_0, \Theta_1),\\
\Theta_b &= \mathsf{left}^6; \mathsf{back}; \mathsf{ret}; \mathsf{left}^3; \mathsf{write}\, b; \mathsf{left}^{21}.
\end{aligned}$$

Then div *runs from h to h within $310n^2 + 389n + 84 \le 500(n + 1)^2$ units and leaves the quotient $\lfloor \mathrm{val}(x)/\mathrm{val}(y) \rfloor$ in column 9 and the remainder $\mathrm{val}(x) \bmod \mathrm{val}(y)$ in column 2; columns 0, 1 and 4 are unchanged.*

Proof. Write $y = \mathrm{val}(y)$. The preparation clears columns 2 and 5, walks to the end row and steps back to row $n - 1$: $(21n + 1) + (27n + 1) + 2(14n + 27) + (14n + 1) + 13$ units. For $k = n - 1, \dots, -1$ let I_k be the configuration at row k in which column 2 holds the remainder R_k of $\lfloor \mathrm{val}(x)/2^{k+1} \rfloor$ by y, column 9 holds the corresponding quotient bits in rows $k + 1, \dots, n - 1$, and column 5 is 0; $R_{n-1} = 0$. A pass Δ from I_k, $k \ge 0$, marks row k, reads x_k and returns to row 0 ($13 + 2 + (14k + 27)$ units). It writes x_k into column 10 of row 0 (23 units) and doubles column 2 with incoming bit x_k (Lemma I.26, $62n + 1$, and back, $14n + 27$): column 2 now holds $2R_k + x_k < 2y \le 2^n$, without overflow. It sets the carry-in (15) and runs rstep on the even columns, within $3(40n + 25)$ units (Lemma I.28): the end row's carry cell receives $e = \lfloor (2R_k + x_k)/y \rfloor$, and column 8 the remainder, which $\mathsf{cp}_{8\to 2}$ and back ($(40n+1)+(14n+27)$) move to column 2. Then Θ_e walks to the end row, reads e, returns, finds the marked row k with ret, writes e in its column 9 and steps to row $k - 1$ ($28n + 18k + 87$ units). The pass ends in I_{k-1} within $278n + 32k + 298 \le 310n + 298$ units: since $\lfloor \mathrm{val}(x)/2^k \rfloor = 2\lfloor \mathrm{val}(x)/2^{k+1} \rfloor + x_k$, the new remainder is R_{k-1} and e is the next quotient bit. At I_{-1} the scanned presence bit is the closed left end. Lemma I.6 bounds the loop by $n(310n + 299) + 1$; the final right^{12} costs 13. □

Lemma I.30 (Signed quotients)**.** *In Lemma I.29 let* $\mathrm{val}(x) = |z|$ *for an integer* z *with* $|z| < 2^n$*, and let the cell* $h-1$ *hold* $[z < 0]$*. There is a program* $\mathsf{sdiv} = \mathsf{div}; \mathsf{fix}$*, fixed once for all, that runs from* h *to* $h + 12n$ *within* $500(n+1)^2 + 270n + 175 \le 945(n+1)^2$ *units and leaves in the cell* $h-1$ *the bit* $[\lfloor z/y \rfloor < 0]$ *and in column* 8 *the* n *binary digits of* $|\lfloor z/y \rfloor|$*,* $y = \mathrm{val}(y)$*: the cell* $h-1$ *followed by column* 8 *is* $\mathrm{sw}_{n-1}(\lfloor z/y \rfloor)$*.*

Proof. Let q and ρ be the quotient and remainder of $|z|$ by y, left by div in columns 9 and 2. Then $\lfloor z/y \rfloor = q$ if $z \ge 0$ and $-(q + [\rho \ne 0])$ if $z < 0$, and the sign bit is unchanged: $z < 0$ forces $\lfloor z/y \rfloor \le -1$. The program fix has three parts. First it copies column 2 into column 4, returns, clears column 8 of row 0 and runs on the columns 0, 4 and 8 (stride four) a loop that writes into column 8 of each row the OR of the remainder bits of the earlier rows: $(32n+1) + (14n+27) + 19 + 5(11n+1)$ units, so at most $101n + 52$, and the end row's column 8 then holds $[\rho \ne 0]$. Second it reads that bit, returns to row 0, reads the sign in $h-1$, and writes $[z < 0] \wedge [\rho \ne 0]$ into the carry-in of row 0: $14n + 64$ units. Third it copies the quotient into column 2, clears column 4 and adds on the even columns: column 8 receives $q + [z < 0][\rho \ne 0]$, which is less than 2^n because $q + 1 \le |z|$ when $\rho \ne 0$; this costs $(42n+1) + (25n+1) + 2(14n+27) + 3(20n+1) \le 155n + 59$ units. The sum of the three parts is $270n + 175$. □

The last routine turns a binary number into a counter, one mark per unit of its value, so its cost grows with the value of the number and not only with its length.

Lemma I.31 (From binary to unary)**.** *There is a fixed program* $\mathsf{toUnary}$ *with the following property. Let the binary stream hold* w*, of length* ℓ *and value* n*, let track* 8 *carry the counter* r *and track* 9 *hold the value* r*, and let* τ *have origin marks up to* R *with* $\ell \le R$ *and* $r + n + 1 \le R$*. Then* $\mathsf{toUnary}$ *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $n\big(152\ell + 36(r+n) + 203\big) + 49\ell + 67 \le 1000(\ell + r + n + 1)^2$ *units; in* τ' *track* 8 *carries* $r + n$*, track* 9 *holds the value* $r + n$*, the origin marks are kept, and only tracks* 7*,* 8*,* 9 *and* 10 *have changed.*

Proof. The program is $\mathsf{Z}; \mathsf{loop}(\mathsf{home}_{10}; \mathsf{dec}; \mathsf{mark}_8; \mathsf{Z}); \mathsf{home}_{10}$. Here Z writes into the cell $(0, 10)$ the OR of the bits of the stream: it walks down the stream, carrying a running OR in track 10 one row ahead (30 or 31 units a row), and copies the final OR back to row 0; it costs at most $49\ell + 52$ units and ends at $(0, 10)$. $\mathsf{dec} = \mathsf{left}^8; (\mathsf{borrow})^{\downarrow 16}; \mathsf{home}_7$ subtracts one from the stream's bits on track 7 (Lemmas I.23 and I.9; the first 1 lies at a row $q < \ell$): at most $9 + 17(5q+3) + (18q+11) \le 103\ell + 71$ units. mark_8 ($36(r+j) + 65$ units in pass j) appends a mark to the value on track 9 and advances the counter on track 8. So a pass costs at most $14 + (103\ell + 71) + (36(r+j) + 65) + (49\ell + 52)$ units, and the flag it leaves is 1 exactly when the stream is still nonzero. Lemma I.6 with n passes, the first Z and the final home_{10} (14 units) give the bound. Every routine writes only tracks 7 to 10. □

I.6 The machine's own integers

Proposition 15.26 bounds the ratios of the procedure of Section 15.6. The machine computes differently: it keeps integer numerators over the fixed denominator 2^N, forms one integer numerator per new coefficient over a common denominator, and sums the Taylor series by Horner's rule on these integers, with one rounding at the end. The next proposition bounds

the integers it actually holds. Throughout, the problem has a coefficient field, $n = \max(m, n_0)$, $N = N(n)$, $W = W_m = 4\mathscr{B}(N) + 4$, and s, L and $\rho(N)$ are as in Section H.1. For a coordinate j let D_j be the product of the denominators of its coefficients (c_j, its A-coefficients and its B-coefficients), so that $D_j q$ is an integer for each of them.

Proposition I.32 (The machine's integers)**.**

(a) Let Z be an integer vector with $\|Z/2^N\| \le M$, and let $r_0 = Z, r_1, \dots, r_N$ be the integer rows of the table built from it as in Lemma 15.35. Every entry of every r_l fits W. In particular, under the region certificate, every stored vector Z_k, $k \le S$, and every row built from it fit W.

(b) Let Z be as in (a), $l < N$, $s_N = 2^N$, and let U be the integer with

$$c_j[l = 0] + (Af_l)_j + \sum_{i \le l} B(f_i, f_{l-i})_j = \frac{U}{D_j s_N^2}, \qquad f_i = r_i / s_N.$$

Then $r_{l+1,j} = \big\lfloor (2U + D_j s_N(l+1)) / (2D_j s_N(l+1)) \big\rfloor$, and both $|2U + D_j s_N(l+1)|$ and $2D_j s_N(l+1)$ are less than 2^{3W-1}.

(c) Let $z_0, \dots, z_N$ fit W, let $\sigma \ge 0$, $E = \sigma N$ and $H = W + \sigma N + N + 4$, and let $T_0 = z_0$ and $T_{k+1} = 2^\sigma T_k + z_{k+1}$ for $k < N$, the partial sums of Horner's rule. Then

$$|T_k| < (k+1)\, 2^{W+1+\sigma k} \quad \text{and} \quad |2^q T_k| < 2^{H-2} \qquad \text{whenever } k \le N \text{ and } \sigma k + q \le E;$$

and the rounded sum $\lfloor (2T_N + 2^E) / (2 \cdot 2^E) \rfloor$ fits $H - 1$.

(d) On a workspace of r rows every counter is at most $r + 1$.

(e) $W_m \le \big(4(q_P + l_P + c_P) + 4\big) X^2$ with $X = m + n_0 + \kappa + 1$.

Proof. (a) By Lemma 15.35, $r_l / 2^N$ is the coefficient a_l of the table at $Z/2^N$ with rounding $[\cdot]_N$, and by Lemma H.2 it has width $\rho(N)$ for $l \le N$, so $|r_l| \le 2^{\rho(N)}$. By (H.1), $\rho(N) \le \mathscr{B}(N) < W + 1$. The stored vectors lie in the ball by Theorem 15.20.

(b) Since $\mathrm{next}(f, l)$ is the displayed sum divided by $l + 1$, $r_{l+1,j} = \mathrm{near}(s_N \mathrm{next}(f,l)_j) = \mathrm{near}(U / (D_j s_N (l+1)))$, and $\mathrm{near}(u/v) = \lfloor (2u + v)/(2v) \rfloor$ for $v > 0$. Let w_j be the sum of $|D_j q|$ over the coefficients q of coordinate j. Clearing denominators,

$$U = [l = 0]\, D_j c_j s_N^2 + \sum_{(a,t)} D_j a\, r_{l,t}\, s_N + \sum_{i \le l} \sum_{(b,t,u)} D_j b\, r_{i,t}\, r_{l-i,u},$$

the sums running over the A-terms and B-terms of coordinate j. By (a) every $|r_{i,t}| < 2^{W+1}$, and $s_N \le 2^W$ because $N \le W$. So $|U| \le (l+1) w_j 2^{2W+2}$ and

$$|2U + D_j s_N (l+1)| \le (l+1)(2w_j + D_j) 2^{2W+2} < (l+2)(Q_j + 1) 2^{2W+2}, \qquad Q_j = 2w_j + 2D_j + 1,$$

and likewise $2D_j s_N(l+1) < (l+2)(Q_j+1)2^{2W+2}$. Each factor x is less than $2^{\mathrm{bl}(x)}$, so both integers are less than 2^β with $\beta = \mathrm{bl}(Q_j + 1) + \mathrm{bl}(l+2) + 2W + 2$. Now D_j is a product of denominators e whose binary lengths sum to at most s, so $D_j < 2^s$; each $|D_j q| = |u| D_j / e \le 2^{2s}$ for $q = u/e$; and coordinate j has at most $L + 1$ coefficients. Hence $Q_j + 1 = 2w_j + 2D_j + 2 \le (2L + 6) 2^{2s}$

and $\mathrm{bl}(Q_j + 1) \le 2s + 2L + 6$. Also $\mathrm{bl}(l + 2) \le l + 2 \le N + 1$. By (H.1), $\mathscr{B}(N) \ge s + L + N + 3$, since $v^*(N) \ge L$. Therefore $\beta \le 2W + 2s + 2L + N + 9 \le 2W + 2\mathscr{B}(N) + 3 \le 3W - 1$.

(c) This is Lemma I.158(d), where the machine's use of these integers is described; the argument is short. $|T_0| = |z_0| < 2^{W+1}$, and

$$|T_{k+1}| \le 2^{\sigma}|T_k| + |z_{k+1}| < (k+1)2^{W+1+\sigma(k+1)} + 2^{W+1} \le (k+2)2^{W+1+\sigma(k+1)}.$$

If $\sigma k + q \le E$, then $|2^q T_k| < (k+1)2^{W+1+E} \le 2^{H-3}$, because $k+1 \le N+1 \le 2^N$. For an integer x, $|\lfloor x/2^E \rfloor| \le |x|$, so the rounded sum, which is $\lfloor T_N/2^E \rfloor$ or that number plus one (Lemma I.158(c)), has absolute value at most $2^{H-2} < 2^H$.

(d) is Lemma I.4. (e) By Proposition 15.26, $\mathscr{B}(N) \le (q_P + l_P + c_P)X^2$, and $4 \le 4X^2$. □

So the coefficient stage works with words of $3W_m$ bits and the Taylor sum with words of $W_m + \sigma N + N + 4$ bits, both at most a constant depending on the problem times X^2, since σ depends only on the problem and $N < X$; and every unary number the machine writes is bounded by the rows in use, which each stage bound controls through Definition I.7. The coefficients and the initial point are read in binary from the saved request, whose length is at most a constant depending on the problem times X.

I.7 Reading the request

The request for a problem of dimension $d = 2$ begins with the frame 1110010: three unary marks, a separator and the three binary digits 0, 1, 0 of 2, least significant first. The first stage of the machine spends exactly 965 units on these seven cells. It turns the three marks into three rows of the scratch area (475 units), copies the digits into rows 0, 1 and 2 of tracks 3 and 4 (490 units), and leaves a single mark on cell 6, the last cell of the frame, to show where reading resumes. Every later frame is read in the same way, and the row at which its bits begin is marked on track 15.

So the request does not stay where it was written. The stage Parse consumes the input cells one by one and moves the bits of every frame into tracks 3 and 4 of the rows, with the frame starts on track 15 (Theorem I.42). When it ends, the only 1 left in the cells $0, 1, 2, \ldots$ is that mark, on the last cell of the request. The stage Decode erases the mark, reads the saved frames back and writes every natural number of the request in unary on tracks 9 and 10 (Theorem I.58). The signed integers of the payload stay in binary on tracks 3 and 4, where the later stages read them.

I.7.1 The raw marker

The machine reads the request from left to right. One mark on the input cells separates what has been read from what has not: the cells before it have been erased, the cell under it is the last one consumed, and the cells after it are still the request.

Definition I.33 (Raw marker)**.** A tape τ has a *raw marker at* $c \in \mathbb{N}$ if $\tau(-1) = 1$, $\tau(c) = 1$ and $\tau(x) = 0$ for $0 \le x < c$. For a word v, the cells *after the marker hold* v if $\tau(c + 1 + j) = v_j$ for $j < |v|$ and $\tau(c + 1 + j) = 0$ for $j \ge |v|$.

Lemma I.34 (Following the marker)**.** *Let* $\overline{\mathsf{scan}}_1 = \mathsf{loop}(\mathsf{right})$ *and* $\mathsf{findR} = \overline{\mathsf{findL}}$ *be the mirror images (Lemma I.9) of* scan_1 *and* findL*, and put*

$$\mathsf{raw} = [\mathsf{right}, \mathsf{findR}], \qquad \mathsf{unraw} = [\mathsf{left}, \mathsf{findL}], \qquad \mathsf{home}_0 = \mathsf{left}; \mathsf{scanR}; \mathsf{right}^2,$$
$$\mathsf{adv} = \mathsf{write}\,0; \mathsf{right}; \mathsf{write}\,1; \mathsf{left}; \mathsf{findL},$$
$$\mathsf{rd}(P_0, P_1) = \mathsf{right}; \mathsf{branch}\big(\mathsf{left}; \mathsf{adv}; P_0,\ \mathsf{left}; \mathsf{adv}; P_1\big).$$

(a) If $\tau(h + j) = 1$ *for* $j < n$ *and* $\tau(h + n) = 0$*, then* $\overline{\mathsf{scan}}_1$ *runs from* (h, τ) *to* $(h + n, \tau)$ *in* $2n + 1$ *units. If* $\tau(h + j) = 0$ *for* $j < n$ *and* $\tau(h + n) = 1$*, then* findR *runs from* (h, τ) *to* $(h + n, \tau)$ *in* $6n + 5$ *units.*

(b) Let τ *have a raw marker at* c*. Then* raw *runs from* $(-1, \tau)$ *to* (c, τ)*, and* unraw *from* (c, τ) *to* $(-1, \tau)$*, each in* $6c + 7$ *units. The program* adv *runs from* (c, τ) *to* $(-1, \tau^+)$ *in* $6c + 15$ *units, where* τ^+ *is* τ *with the cell* c *set to* 0 *and the cell* $c + 1$ *set to* 1*; so* τ^+ *has a raw marker at* $c + 1$*. If* $b = \tau(c + 1)$ *and* P_b *runs from* $(-1, \tau^+)$ *in* t *units to a configuration* γ*, then* $\mathsf{rd}(P_0, P_1)$ *runs from* (c, τ) *to* γ *in* $6c + 18 + t$ *units.*

(c) If τ *has origin marks up to* k*, then* home_0 *runs from* $(\mathrm{cell}(k, 0), \tau)$ *to* $(-1, \tau)$ *in* $18k + 5$ *units.*

Apart from adv*, and* P_b *inside* rd*, none of these programs writes.*

Proof. (a) Reflection exchanges left and right, so by Lemma I.9 the two programs take the units of scan_1 and findL on the reflected tape: $2n + 1$ and $6n + 5$ (Lemmas I.10(c) and I.12(b)). (b) right takes one unit to cell 0; the cells $0, \dots, c - 1$ hold 0 and c holds 1, so findR takes $6c + 5$; with the final skip, $6c + 7$. For unraw, left reaches $c - 1$ and findL passes the c zeros $c - 1, \dots, 0$ to the root, which holds 1: again $1 + (6c + 5) + 1$. The first four primitives of adv write the two cells and return to c (4 units); now the cells $c, c - 1, \dots, 0$ hold 0 and the root holds 1, so findL takes $6(c + 1) + 5$. In rd, right, the test of $\tau(c + 1) = b$ and left take 3 units, adv takes $6c + 15$, and P_b takes t. (c) left moves from $\mathrm{cell}(k, 0)$ to $\mathrm{cell}(k, 1)$; along track 1 the rows $k, \dots, 1$ hold 1 and row 0 holds 0, so scanR takes $18k + 1$ units to $\mathrm{cell}(0, 1) = -3$, and right^2 three more. □

I.7.2 Rows for the first frame

The first frame of the request is $1^L 0 b$ with b the binary digits of d and $L = |b| \ge 1$. Before the scratch area has rows, the machine has no counters; it uses the unary length of the frame instead, and makes one row for each mark. Three sixteen-bit patterns are written as rows: β^{first} has 1 exactly on tracks 0 and 14, β^{next} on tracks $0, 1, 2, 5, 8, 11, 14$, and β^{sent} on tracks $1, 2, 5, 8, 11, 14$; the last is the pattern β of Lemma I.17. For a pattern β put

$$\mathsf{block}(\beta) = \mathsf{left}; \mathsf{scanL}; \mathsf{put}(\beta); \mathsf{right}^{15}; \mathsf{scanR}; \mathsf{right}^2,$$

the second half of grow, and

$$\begin{aligned}
&\mathsf{alloc} = \mathsf{pre}; \mathsf{loop}(\mathsf{hdr}); \mathsf{epi},\\
&\mathsf{pre} = \overline{\mathsf{scan}}_1; \mathsf{write}\,1; \mathsf{left}; \mathsf{write}\,0; \mathsf{left}; \mathsf{scan}_1; \mathsf{left}; \mathsf{put}(\beta^{\mathrm{first}}); \mathsf{right}^{17}; \mathsf{right},\\
&\mathsf{hdr} = \mathsf{cut}; \mathsf{block}(\beta^{\mathrm{next}}); \mathsf{right}, \qquad \mathsf{cut} = \overline{\mathsf{scan}}_1; \mathsf{left}; \mathsf{write}\,0; \mathsf{left}; \mathsf{scan}_1,\\
&\mathsf{epi} = \mathsf{left}; \mathsf{block}(\beta^{\mathrm{sent}}); \mathsf{write}\,1.
\end{aligned}$$

Lemma I.35 (Allocating the first rows)**.**

(a) Let $k \geq 1$, $\tau(j,0) = 1$ for $j < k$, $\tau(k,0) = 0$, $\tau(0,1) = 0$ and $\tau(j,1) = 1$ for $1 \leq j < k$, and let β be a pattern with $\beta_1 = 1$. Then block(β) *runs from $(-1,\tau)$ to $(-1,\tau')$ in $36k + 55$ units, where τ' is τ with row k overwritten by β (track t receiving β_t).*

(b) Let b be a word of length $L \geq 1$ and v a word. From the head on cell 0 of the input tape of $1^L 0 bv$, alloc *runs to $(-1,\tau_A)$ in $20L^2 + 80L + 55$ units, where $\tau_A(-1) = 1$, $\tau_A(x) = 0$ for $0 \leq x < L$, $\tau_A(L) = 1$, the cells after L hold bv, row 0 holds β^{first}, rows $1, \ldots, L-1$ hold β^{next}, row L holds β^{sent}, and every cell of a row $j > L$ holds 0.*

So τ_A has a raw marker at L, headers 1 in rows $j < L$, sentinel row L and origin marks up to L, and tracks 2, 5, 8 and 11 carry the counter 0.

Proof. (a) left (1 unit) reaches $(0,0)$ and scanL the first blank header $(k,0)$ $(18k+1)$; put(β) (33) writes β_t at cell$(k,0) - t = (k,t)$ and stops at $(k+1,0)$; right^{15} (16) reaches $(k,1)$, which now holds $\beta_1 = 1$. Along track 1 the rows $k, \ldots, 1$ hold 1 and row 0 holds 0, so scanR and right^2 return to the root in $18k+4$ units. In all $36k + 55$.

(b) While marks remain the root holds 0; it is set to 1 at the end. pre: $\overline{\mathsf{scan}}_1$ runs over the L marks to the separator at L $(2L+1)$, which write 1 turns into the marker; left; write 0; left (3) erase the mark $L-1$; scan$_1$ runs left over the remaining marks $L-2, \ldots, 0$ to the root $(2(L-1)+1)$; left, put(β^{first}) and right^{17} $(1+33+18)$ write row 0 and come back to the root, and right reaches cell 0: $4L + 57$ units. For $j \leq L-1$ let I_j be the configuration at cell 0 in which the cells $0, \ldots, L-2-j$ hold 1 (so $m = L-1-j$ marks remain), the cells $L-1-j, \ldots, L-1$ and the root hold 0, cell L holds 1, rows $0, \ldots, j$ hold $\beta^{\mathrm{first}}, \beta^{\mathrm{next}}, \ldots, \beta^{\mathrm{next}}$, and every cell of a row $> j$ holds 0. After pre the configuration lies in I_0. From I_j with $j < L-1$ the scanned cell holds 1. cut runs right over the m marks $(2m+1)$, erases the mark $m-1$ (3) and runs left over the other $m-1$ to the root $(2(m-1)+1)$: $4m+3$ units. Then block(β^{next}) writes row $j+1$ by (a), whose hypotheses hold with $k = j+1$ $(36(j+1)+55)$, and right returns to cell 0. With its test the pass takes $4(L-1-j) + 36j + 96$ units and ends in I_{j+1}. At I_{L-1} cell 0 holds 0, so the loop makes exactly $L-1$ passes (Lemma I.6), and

$$\sum_{j<L-1} \big(4(L-1-j) + 36j + 96\big) + 1 = 20(L-1)^2 + 80(L-1) + 1.$$

epi returns to the root, writes row L by (a) with $k = L$ $(1 + 36L + 55)$ and sets the root (1). The total is $(4L+57) + 20(L-1)^2 + 80(L-1) + 1 + (36L+57) = 20L^2 + 80L + 55$. The patterns give the last sentence: track 1 holds 0 in row 0 and 1 in rows $1, \ldots, L$, and tracks $2, 5, 8, 11$ hold 0 in row 0. □

The bits b are then copied into the rows, one per row, with track 2 as the counter of copied bits. Put

$$\begin{aligned}\mathsf{emit}_b &= \mathsf{left}^3;\mathsf{scanL};\mathsf{write}\,1;\mathsf{left};\mathsf{write}\,1;\mathsf{left};\mathsf{write}\,b;\mathsf{left}^{14};\mathsf{write}\,0;\mathsf{right}^2,\\ \mathsf{pk} &= \mathsf{home}_0;\mathsf{right};\mathsf{findR};\mathsf{rd}(\mathsf{emit}_0,\mathsf{emit}_1),\\ \mathsf{pack} &= \mathsf{left};\mathsf{loop}(\mathsf{pk});\mathsf{home}_0, \qquad \mathsf{boot} = \mathsf{alloc};\mathsf{pack}.\end{aligned}$$

Lemma I.36 (Copying the first frame)**.**

(a) *If track 2 carries the counter s, then emit_b runs from $(-1,\tau)$ to $(\mathrm{cell}(s+1,0),\tau')$ in $18s+29$ units, where τ' is τ with $(s,2)$ and $(s,3)$ set to 1, $(s,4)$ set to b and $(s+1,2)$ set to 0: the counter on track 2 advances to $s+1$.*

(b) *In Lemma I.35(b), pack runs from $(-1,\tau_A)$ to $(-1,\tau_B)$ in $36L^2+53L+7$ units, where τ_B is τ_A with the cells $L,\dots,2L-1$ set to 0, the cell $2L$ set to 1, the cells $(j,2)$ and $(j,3)$ set to 1 and $(j,4)$ set to b_j for $j<L$, and $(L,2)$ set to 0. So boot runs from cell 0 of the input tape of 1^L0bv to $(-1,\tau_B)$ in $56L^2+133L+62$ units.*

Proof. (a) left^3 (4) reaches $(0,2)$ and scanL the hole $(s,2)$ ($18s+1$); the next six primitives write $(s,2)$, $(s,3)$, $(s,4)$ (5 units), left^{14} reaches $(s+1,2)$ (15), and $\mathsf{write}\,0;\mathsf{right}^2$ (4) clears it and stops at $(s+1,0)$.

(b) For $k\le L$ let J_k be the configuration at $(k,0)$ whose tape is τ_A with the marker moved to $L+k$, the bits $b_0,\dots,b_{k-1}$ copied as stated and track 2 carrying k. The first left (1 unit) enters J_0. From J_k, $k<L$, the header $(k,0)$ holds 1; pk returns to the root ($18k+5$, Lemma I.34(c)), steps to cell 0 and finds the marker ($1+6(L+k)+5$), reads $b_k=\tau(L+k+1)$ and moves the marker by rd ($6(L+k)+18$ plus the continuation), and emit_{b_k} copies it ($18k+29$, by (a)): $36k+12(L+k)+58$ units, ending in J_{k+1}. At J_L the header $(L,0)$ holds 0. The loop takes $\sum_{k<L}(36k+12(L+k)+59)+1 = 36L^2+35L+1$ units and home_0 from row L takes $18L+5$; with the first left, $36L^2+53L+7$. Adding Lemma I.35 gives $56L^2+133L+62$. □

For $d=2$, $L=3$: $475+490=965$ units, as in the example that opens this section.

I.7.3 Reading one frame

Every later frame is read into the binary stream (tracks 6 and 7) and then appended to the saved word on tracks 3 and 4. The state of the tape between two frames is the following.

Definition I.37 (Reader state)**.** Let $c,R\in\mathbb{N}$ and let w be a word. A tape τ is a *reader state* (c,R,w) if

(a) τ has a raw marker at c;

(b) track 5 carries the counter 0 and track 2 the counter $|w|$, and $|w|\le R$;

(c) w lies on tracks 3 and 4 from row 0;

(d) τ has origin marks up to R, $\tau(j,0)=1$ for $j<R$ and $\tau(R,0)=0$;

(e) $\tau(x) = 0$ for every $x \le \mathrm{cell}(R+1, 0)$, that is, every cell of every row $j > R$ holds 0.

By Lemma I.36, τ_B is a reader state $(2L, L, b)$ whose cells after the marker hold v, and tracks 6, 7, 9, 10, 12, 13 and 15 hold 0 in every row. Reading a frame uses the programs

$$\begin{aligned}
\mathsf{hmark} &= [\mathsf{left}, \mathsf{adv}, \mathsf{mark}_5, \mathsf{raw}, \mathsf{right}],\\
\mathsf{ghmark} &= \mathsf{left}; \mathsf{unraw}; \mathsf{grow}; \mathsf{raw}; \mathsf{right}; \mathsf{hmark},\\
\mathsf{store}_b &= [\mathsf{seek}_5, \mathsf{left}^2, \mathsf{write}\, b, \mathsf{right}^2, \mathsf{next}, \mathsf{left}], \qquad \mathsf{cut}_6 = \mathsf{pres}_5; \mathsf{write}\, 0; \mathsf{home}_6,\\
\mathsf{pbit} &= [\mathsf{home}_6, \mathsf{raw}, \mathsf{rd}(\mathsf{store}_0, \mathsf{store}_1)],\\
\mathsf{xfer} &= [\mathsf{raw}, \mathsf{right}, \mathsf{loop}(\mathsf{ghmark}), \mathsf{left}, \mathsf{adv}, \mathsf{cut}_6, \mathsf{reset}_5,\\
&\qquad \mathsf{pres}_5, \mathsf{loop}(\mathsf{pbit}), \mathsf{home}_6],
\end{aligned}$$

which read the length of a frame (one new row per mark) and then its bits, and the programs

$$\begin{aligned}
\mathsf{fa}_b &= \mathsf{home}_7; \mathsf{emit}_b; \mathsf{home}_0; \mathsf{inc}_5; \mathsf{pres}_5, \qquad \mathsf{fa} = \mathsf{left}; \mathsf{branch}(\mathsf{fa}_0, \mathsf{fa}_1),\\
\mathsf{seal} &= \mathsf{seek}_2; \mathsf{left}; \mathsf{write}\, 0; \mathsf{home}_3, \qquad \mathsf{app} = \mathsf{pres}_5; \mathsf{loop}(\mathsf{fa}); \mathsf{home}_6; \mathsf{seal}; \mathsf{reset}_5,\\
\mathsf{start} &= \mathsf{seek}_2; \mathsf{left}^{13}; \mathsf{write}\, 1; \mathsf{home}_{15}, \qquad \mathsf{save} = \mathsf{xfer}; \mathsf{reset}_5; \mathsf{app},
\end{aligned}$$

which mark the first row of the frame on track 15 and append its bits to the saved word.

Lemma I.38 (Reading the length and the bits of a frame)**.** *Let τ have a raw marker at c whose cells after the marker hold $1^n 0 f v$ with $|f| = n \ge 1$; let track 5 carry 0, let τ have origin marks up to R, $\tau(j, 0) = 1$ for $j < R$ and $\tau(R, 0) = 0$, and let $\tau(x) = 0$ for $x \le \mathrm{cell}(R+1, 0)$. Then* xfer *runs from $(-1, \tau)$ to $(-1, \tau')$ in*

$$102n^2 + (36c + 72R + 298)n + 12c + 104$$

units. The tape τ' has a raw marker at $c + 2n + 1$ and the cells after it hold v; f lies on tracks 6 and 7 from row 0; track 5 carries n; τ' has origin marks up to $R + n$, $\tau'(j, 0) = 1$ for $j < R + n$, $\tau'(R + n, 0) = 0$, and every cell of a row $j > R + n$ holds 0. In rows $j \le R$ the tracks other than 0, 5, 6 and 7 are unchanged, and track 15 is unchanged in every row.

Proof. raw and right ($6c + 8$) reach the first mark $c + 1$. For $j \le n$ let H_j be the configuration at $c + 1 + j$ whose tape has the marker at $c + j$ followed by $n - j$ marks and a 0, carries j on track 5, has $R + j$ rows in the sense of the hypothesis, and has $(i, 6) = 1$ for $i < j$. From H_j, $j < n$, the scanned cell is a mark. ghmark returns to the root ($1 + 6(c + j) + 7$), adds a row ($72(R + j) + 99$, Lemma I.17), comes back past the marker ($6(c + j) + 7 + 1$), and hmark moves the marker onto the mark (Lemma I.34(b)), sets $(j, 6)$ to 1 and advances the counter on track 5 by mark_5 ($36j + 59$, Lemma I.14(e)), and returns to $c + j + 2$: $12(c + j) + 36j + 90$ units. The pass takes $24(c + j) + 36j + 72(R + j) + 205$ units and ends in H_{j+1}; the loop takes $\sum_{j<n}(24c + 72R + 206 + 132j) + 1 = 66n^2 + (24c + 72R + 140)n + 1$ units. At H_n the scanned cell is the separator. left and adv ($1 + 6(c + n) + 15$) consume it; cut_6 ($36n + 21$) writes the terminator $(n, 6) = 0$; reset_5 ($36n + 36$) and pres_5 (10) reach $(0, 6)$. For $k \le n$ let G_k be the configuration at $(k, 6)$ with the marker at $c + n + 1 + k$, track 5 carrying k and $(i, 7) = f_i$ for $i < k$. From G_k, $k < n$, the presence cell holds 1; pbit returns to the root ($18k + 10$), finds the marker ($6(c + n + 1 + k) + 7$), reads f_k and moves the marker ($6(c + n + 1 + k) + 18$), and store_{f_k} writes

$(k, 7)$, advances the counter and stops at $(k+1, 6)$ $(18k+37)$: $36k + 12(c+n+1+k) + 73$ units, ending in G_{k+1}. At G_n the terminator stops the loop, which took $24n^2 + (12(c+n+1)+50)n+1$ units, and home_6 and the final skip add $18n + 11$. The sum is the stated count. The writes are on tracks 0 (headers of the new rows), 5, 6 and 7, and in the new rows $R+1, \dots, R+n$, whose pattern β^{sent} has 0 on track 15. □

Lemma I.39 (Appending a frame to the saved word)**.** *Let τ have origin marks up to R, and let track 2 carry s.*

(a) If track 5 carries k and $s+1, k+1 \le R$, then fa_b runs from $(\mathrm{cell}(k,7), \tau)$ to $(\mathrm{cell}(k+1,6), \tau')$ in $72k + 36s + 145$ units, where τ' is τ changed as by emit_b in Lemma I.36(a) and with the counter on track 5 advanced to $k+1$.

(b) If a word f of length n lies on tracks 6 and 7 from row a, track 5 carries a, and $s+n, a+n \le R$, then app runs from $(-1, \tau)$ to $(-1, \tau')$ in

$$54n^2 + (72a + 36s + 184)n + 72a + 36s + 71$$

units, where in τ' the cells $(s+j, 3)$ hold 1 and $(s+j, 4)$ hold f_j for $j < n$, $(s+n, 3)$ holds 0, track 2 carries $s+n$, track 5 carries 0, and only tracks 2, 3, 4 and 5 have changed. So if w of length s lies on tracks 3 and 4 from row 0, afterwards wf does.

(c) If $s \le R$, then seal runs from -1 to -1 in $36s + 14$ units and sets $(s, 3)$ to 0, and start runs from -1 to -1 in $36s + 39$ units and sets $(s, 15)$ to 1.

Proof. (a) home_7 from row k $(18k+11)$, emit_b $(18s+29$, ending at $(s+1, 0))$, home_0 from row $s+1$ $(18s+23)$, inc_5 $(36k+54)$ and pres_5 from the new hole $(18k+28)$. (b) pres_5 $(18a+10)$ reaches $(a, 6)$. Let F_j, $j \le n$, be the configuration at $(a+j, 6)$ in which the first j bits of f have been appended and tracks 2 and 5 carry $s+j$ and $a+j$. A pass from F_j, $j < n$, tests the presence 1, moves to $(a+j, 7)$, branches on f_j and runs fa_{f_j}: $72(a+j) + 36(s+j) + 148$ units with the test, ending in F_{j+1}. At F_n the terminator $(a+n, 6) = 0$ stops the loop, which took $54n^2 + (72a + 36s + 94)n + 1$ units. home_6 $(18(a+n)+10)$, seal $(36(s+n)+14$, by (c)) and reset_5 $(36(a+n)+36$, Lemma I.14(c)) complete the count. (c) seek_2 $(18s+5)$, one move, one write and home_3 $(18s+7)$ for seal; for start, seek_2, left^{13} (14), the write and home_{15} $(18s+19)$. □

Lemma I.40 (Reading one frame)**.** *Let τ be a reader state (c, R, w) with $s = |w|$ whose cells after the marker hold $1^n 0 f v$, $|f| = n \ge 1$. Put $\mathsf{raw}^+ = \mathsf{raw}; \mathsf{right}$, $\mathsf{unraw}^+ = \mathsf{left}; \mathsf{unraw}$,*

$$\mathsf{rf} = \mathsf{unraw}^+; \mathsf{start}; \mathsf{save}; \mathsf{raw}^+,$$
$$X(c, R, s, n) = 156n^2 + (36c + 72R + 36s + 518)n + 12c + 36s + 211.$$

(a) save runs from $(-1, \tau)$ in $X(c, R, s, n)$ units, and rf runs from $(c+1, \tau)$ to $(c+2n+2, \tau')$ in

$$(6c + 8) + (36s + 39) + X(c, R, s, n) + \big(6(c + 2n + 1) + 8\big)$$

units.

(b) τ' *is a reader state* $(c + 2n + 1, R + n, wf)$ *whose cells after the marker hold* v.

(c) $\tau'(r, 15) = \tau(r, 15)$ *for every row* $r \neq s$, *and* $\tau'(s, 15) = 1$.

Proof. unraw^+ takes $1 + (6c + 7)$ units from $c + 1$ to the root, and start $(36s + 39)$ sets $(s, 15)$. Then xfer takes $102n^2 + (36c + 72R + 298)n + 12c + 104$ units (Lemma I.38; its hypotheses are parts (a), (b), (d) and (e) of the reader state). It leaves f on tracks 6 and 7 from row 0 and the counter n on track 5, and it does not touch tracks 2, 3, 4 in rows $j \leq R$, which hold w, its terminator and the counter $s \leq R$. reset_5 $(36n + 36)$ sets track 5 to 0, and app with $a = 0$ $(54n^2 + (36s + 184)n + 36s + 71$, Lemma I.39) appends f to w, which fits since $s + n \leq R + n$. The three counts add up to X. Finally raw^+ $(6(c + 2n + 1) + 8)$ finds the moved marker and steps past it. Part (b) collects the conclusions of Lemmas I.38 and I.39; part (c) holds because only start writes on track 15. □

I.7.4 The stage Parse

Fix a problem with a coefficient field of dimension d, a level n_0, a coordinate $i < d$ and a precision m, and let u be the request of Definition 15.32. It is a concatenation of frames,

$$u = 1^{|f_0|}0 f_0\, 1^{|f_1|}0 f_1 \cdots 1^{|f_F|}0 f_F,$$

where f_0 is the $\mathrm{bl}(d) + 1$ lowest binary digits of d, followed by one frame for every natural number of the shape, the frame of the number q of payload integers, one frame for each of these q signed integers, and the frames of M, T, n_0, i and m. Every f_k is nonempty. Put $l_1 = |f_0|$ and $n_k = |f_k|$, and

$$w_u = f_0 f_1 \cdots f_F, \qquad s_k = l_1 + n_1 + \cdots + n_{k-1} \quad (1 \leq k \leq F + 1),$$

so that s_k is the position in w_u of the first bit of f_k, and $s_{F+1} = |w_u|$.

Definition I.41 (The saved request)**.** A tape τ *carries the saved request* of u if w_u lies on tracks 3 and 4 from row 0 (Definition I.3(a)) and, for every row r, $\tau(r, 15) = 1$ if r is one of $s_1, \ldots, s_F$ and $\tau(r, 15) = 0$ otherwise.

The saved request keeps the whole request: every bit of every frame, in order, and the first row of every frame after the first. The first frame starts at row 0 and needs no mark. The program of the stage is

$$\mathsf{Parse} = \mathsf{boot}; \mathsf{frames}, \qquad \mathsf{frames} = \mathsf{raw}^+; \mathsf{loop}(\mathsf{rf}); \mathsf{unraw}^+.$$

Theorem I.42 (Parse)**.** *Let* $c_k = 2l_1 + \sum_{1 \leq j < k}(2n_j + 1)$ *for* $1 \leq k \leq F + 1$, *so that* $c_{F+1} = |u| - 1$, *and let*

$$B_k = (6c_k + 8) + (36s_k + 39) + X(c_k, s_k, s_k, n_k) + \big(6(c_k + 2n_k + 1) + 8\big).$$

Then Parse *runs from the head on cell* 0 *of the input tape of* u *to* $(-1, \tau_P)$ *in exactly*

$$C_P(u) = 56l_1^2 + 133l_1 + 62 + (12l_1 + 8) + \sum_{k=1}^{F}(1 + B_k) + 1 + (6|u| + 2)$$

units, and:

(a) τ_P *is a reader state* $(|u|-1, |w_u|, w_u)$ *and* $\tau_P(x) = 0$ *for every* $x \geq |u|$*; so the only cell* $x \geq 0$ *that holds* 1 *is* $|u|-1$*, the last cell of the request;*

(b) τ_P *carries the saved request of* u*;*

(c) $C_P(u) \leq 100000(|u|+1)^3 \leq 100000(c_{\mathrm{req}}+2)^3 X^3$*, where* $X = m + n_0 + \kappa + 1$ *and* c_{req} *is the length of the request without its last two frames (those of* i *and* m*), plus* $2d+7$*.*

The exponent of the stage is 3*; its constant* $100000(c_{\mathrm{req}}+2)^3$ *depends only on the problem and* n_0*.*

Proof. By Lemma I.36, boot takes $56l_1^2 + 133l_1 + 62$ units and leaves a reader state $(2l_1, l_1, f_0)$ whose cells after the marker hold $1^{n_1}0\,f_1 \cdots 1^{n_F}0\,f_F$, with track 15 blank. raw^+ $(12l_1+8)$ steps past the marker. For $1 \leq k \leq F+1$ let P_k be the set of configurations at $c_k + 1$ whose tape is a reader state $(c_k, s_k, f_0 \cdots f_{k-1})$, whose cells after the marker hold $1^{n_k}0\,f_k \cdots 1^{n_F}0\,f_F$, and whose track 15 holds 1 exactly in the rows $s_1, \ldots, s_{k-1}$. The configuration after raw^+ is in P_1, since $c_1 = 2l_1$ and $s_1 = l_1$. From P_k, $k \leq F$, the scanned cell is the first mark of the frame of f_k, and by Lemma I.40 with $R = s = s_k$ the body rf takes exactly B_k units and ends in P_{k+1}. At P_{F+1} the scanned cell is $c_{F+1} + 1 = |u|$, which holds 0. So the loop makes exactly F passes and takes $\sum_k (1 + B_k) + 1$ units, and unraw^+ from $|u|$ takes $6(|u|-1)+8$. The final tape is in P_{F+1}, which gives (a) and (b).

(c) Put $N = |u| + 1$ and $K = 4l_1 + 4(n_1 + \cdots + n_F) + 4F + 1$; since $|u| = 2l_1 + 1 + \sum_k (2n_k + 1)$, $K \leq 4N$. For every k, $c_k + 2s_k + n_k + 1 \leq K$, and $c_k, F \leq K$. With $x = c + 2s + n + 1$,

$$X(c,s,s,n) = 156n^2 + (36c + 108s + 518)n + 12c + 36s + 211 \leq 1000x^2,$$

since each of n, $c + 2s$ and 1 is at most x. Hence $B_k \leq 1000K^2 + 36K + 61 \leq 1100K^2$, the loop takes at most $F(1100K^2 + 1) + 1 \leq (1101F + 1)K^2$ units, and the part frames at most $(6K + 8) + (1101K + 1)K^2 + (6K + 8) \leq 1200K^3 \leq 76800N^3$. As $l_1 \leq N$, boot takes at most $251N^3$. So $C_P(u) \leq 100000N^3$. For the second inequality, the frame of a natural number n has $2\,\mathrm{bl}(n) + 3 \leq 2n + 3$ cells, $i \leq d - 1$ and $m \leq X$, so $|u| + 1 \leq c_{\mathrm{req}} + 2m \leq (c_{\mathrm{req}} + 2)X$. □

I.7.5 Reading a saved frame

The second stage reads the saved word back, one frame at a time. Track 5 counts the saved bits already read, and the marks on track 15 tell where a frame ends.

Definition I.43 (Frames on the saved tracks)**.** Let $a \in \mathbb{N}$ and let $g_1, \ldots, g_p$ be nonempty words; put $a_1 = a$ and $a_{j+1} = a_j + |g_j|$. A tape τ *lays out* $g_1, \ldots, g_p$ *from row* a if, for every $j \leq p$, $\tau(a_j + i, 3) = 1$ and $\tau(a_j + i, 4) = (g_j)_i$ for $i < |g_j|$, $\tau(a_j + i, 15) = 0$ for $0 < i < |g_j|$, and $\tau(a_j + |g_j|, 3) = 0$ or $\tau(a_j + |g_j|, 15) = 1$; and if $\tau(a_{p+1}, 3) = 0$.

The condition reads only tracks 3, 4 and 15, so a program that leaves these tracks unchanged keeps every layout. A tape that lays out $g_1, \ldots, g_p$ from row a lays out $g_2, \ldots, g_p$ from row $a + |g_1|$.

Lemma I.44 (The saved request as frames)**.** *A tape that carries the saved request of u lays out $f_0, f_1, \dots, f_F$ from row 0.*

Proof. The word $w_u = f_0 \cdots f_F$ lies on tracks 3 and 4 from row 0, which gives the presence and value cells and $\tau(|w_u|, 3) = 0$. Inside f_k, the rows $s_k + i$ with $0 < i < n_k$ lie strictly between s_k and s_{k+1}, so they carry no mark on track 15; the same holds for the rows $1, \dots, l_1 - 1$ inside f_0. The row after f_k is s_{k+1}, which is marked if $k < F$; for $k = F$ it is $|w_u|$, whose presence cell holds 0. □

Copying a frame needs a test that tells, at a row a, whether the current frame goes on: whether $(a, 3)$ holds 1 and $(a, 15)$ holds 0. Put

$$\begin{aligned}
\mathsf{src} &= \mathsf{seek}_5; \mathsf{right}^2, \qquad \mathsf{sealb} = \mathsf{seek}_8; \mathsf{right}^2; \mathsf{write}\,0; \mathsf{home}_6,\\
\mathsf{probe} &= \mathsf{branch}\big(\mathsf{left}^7; \mathsf{write}\,0; \mathsf{right}^5; \mathsf{left}^5,\\
&\qquad\qquad \mathsf{left}^{12}; \mathsf{branch}(\mathsf{right}^5; \mathsf{write}\,1,\ \mathsf{right}^5; \mathsf{write}\,0)\big),\\
\mathsf{cpy}_b &= \mathsf{left}^2; \mathsf{write}\,1; \mathsf{left}; \mathsf{write}\,b; \mathsf{left}; \mathsf{next}; \mathsf{right}^5,\\
\mathsf{bin}_b &= \mathsf{seek}_8; \mathsf{right}^4; \mathsf{cpy}_b; \mathsf{home}_3, \qquad \mathsf{cs}_b = \mathsf{home}_4; \mathsf{bin}_b; \mathsf{inc}_5; \mathsf{src},\\
\mathsf{cs} &= \mathsf{left}; \mathsf{branch}(\mathsf{cs}_0, \mathsf{cs}_1), \qquad \mathsf{fc} = \mathsf{right}^7; \mathsf{cs}; \mathsf{probe},\\
\mathsf{fetch} &= \mathsf{src}; \mathsf{cs}; \mathsf{probe}; \mathsf{loop}(\mathsf{fc}); \mathsf{home}_{10}; \mathsf{sealb}.
\end{aligned}$$

probe starts at $(a, 3)$, writes the answer into the flag cell $(a, 10)$ and stops there, in 22 units on either branch. The first bit of a frame is copied without a test: the first row of every frame after the first carries a mark on track 15.

Lemma I.45 (Copying a saved frame)**.** *Let τ have origin marks up to R, let track 5 carry a and track 8 carry o, and let τ lay out g (and possibly further frames) from row a, with $n = |g|$, $a + n \le R$ and $o + n \le R$. Then* fetch *runs from $(-1, \tau)$ to $(-1, \tau')$ in*

$$F(a, o, n) = 54(n-1)^2 + (72a + 36o + 306)(n-1) + 108a + 72o + 294 \le 1000(a + o + n + 1)^2$$

units. In τ', g lies on tracks 6 and 7 from row o, track 5 carries $a + n$ and track 8 carries $o + n$. Only tracks 5, 6, 7, 8 and 10 have changed, and only in rows $j \le R$.

Proof. cpy_b runs from $(o, 4)$ to $(o + 1, 3)$ in 33 units, writing $(o, 6) = 1$ and $(o, 7) = b$ and advancing the counter on track 8; so bin_b takes $(18o + 11) + 5 + 33 + (18o + 25) = 36o + 74$ units. From $(k, 3)$ with tracks 5 and 8 carrying k and o', cs reads $(k, 4)$ and copies it: $2 + (18k + 8) + (36o' + 74) + (36k + 54) + (18k + 29) = 72k + 36o' + 167$ units, ending at $(k + 1, 3)$ with both counters advanced. So src $(18a + 11)$, cs and probe (22) copy g_0 and set the flag of row $a + 1$. For $1 \le i \le n$ let C_i be the configuration at $(a + i, 10)$ in which $g_0, \dots, g_{i-1}$ lie on tracks 6, 7 from row o (without terminator), tracks 5 and 8 carry $a + i$ and $o + i$, and the flag holds 1 exactly when $i < n$; this is what the layout says about the rows $a + 1, \dots, a + n$. A pass from C_i, $i < n$, moves to $(a + i, 3)$ (8 units), copies g_i and sets the next flag: $72(a + i) + 36(o + i) + 198$ units with its test. So the loop takes $\sum_{1 \le i < n} (72(a + i) + 36(o + i) + 198) + 1 = 54(n-1)^2 + (72a + 36o + 252)(n-1) + 1$ units. home_{10} from row $a + n$ $(18(a + n) + 14)$ and sealb, which writes the terminator $(o + n, 6) = 0$ $(36(o + n) + 25)$, complete the count. Each of $n - 1$, a, o and 1 is at most $a + o + n + 1$, which gives the bound. □

A frame of the payload is skipped rather than copied:

$$\mathsf{sp} = \mathsf{next};\mathsf{right}^2;\mathsf{probe}, \qquad \mathsf{sb} = \mathsf{right}^5;\mathsf{sp},$$
$$\mathsf{skipf} = \mathsf{seek}_5;\mathsf{sp};\mathsf{loop}(\mathsf{sb});\mathsf{home}_{10}.$$

Lemma I.46 (Skipping a saved frame)**.** *If track* 5 *carries* a*,* τ *has origin marks up to* R *and lays out* g *from row* a*, and* $a+|g| \le R$*, then* skipf *runs from* -1 *to* -1 *in* $36a+70|g|+16 \le 200(a+|g|+1)^2$ *units; afterwards track* 5 *carries* $a+|g|$*, and only tracks* 5 *and* 10 *have changed, only in rows* $j \le R$*.*

Proof. seek_5 ($18a+8$) reaches the hole; sp advances it (20), steps to $(a+1,3)$ (3) and probes (22): 45 units. Each of the $|g|-1$ passes moves from the flag to the hole (6) and runs sp: 52 units with the test. The final test and home_{10} add $1+18(a+|g|)+14$. □

I.7.6 Appending a unary word

Every natural number read from the saved request is appended, in unary, to a temporary record on tracks 13 (presence) and 14 (values), with track 11 as its length. For a number n write $\langle n\rangle = 1^n0$, and for numbers $n_1,\dots,n_k$ write $\langle n_1,\dots,n_k\rangle = \langle n_1\rangle\cdots\langle n_k\rangle$.

Definition I.47 (Reading configuration)**.** Let w be a word and $a, R \in \mathbb{N}$. A tape τ is a *reading configuration* (w,a,R) if

(a) track 11 carries the counter $|w|$; $\tau(j,13)=1$ and $\tau(j,14)=w_j$ for $j<|w|$, and $\tau(j,13)=0$ for every $j \ge |w|$; and $|w| \le R$;

(b) τ has origin marks up to R, $\tau(j,0)=1$ for $j<R$, $\tau(R,0)=0$, and $\tau(x)=0$ for every $x \le \mathrm{cell}(R+1,0)$;

(c) track 5 carries the counter a, track 8 the counter 0, and track 9 holds the value 0.

By (b), a reading configuration whose root holds 1 and whose cells $x \ge 0$ hold 0 is a workspace of R rows; none of the programs below writes a cell $x \ge -1$. Appending uses the programs

$$\mathsf{rec}_b = \mathsf{seek}_{11};\mathsf{left}^2;\mathsf{write}\ 1;\mathsf{left};\mathsf{write}\ b;\mathsf{right}^3;\mathsf{next};\mathsf{home}_{11},$$
$$\mathsf{grec}_b = \mathsf{grow};\mathsf{rec}_b, \qquad \mathsf{at}_9 = \mathsf{seek}_8;\mathsf{left},$$
$$\mathsf{ub} = \mathsf{write}\ 0;\mathsf{home}_9;\mathsf{grec}_1;\mathsf{inc}_8;\mathsf{at}_9,$$
$$\mathsf{word} = \mathsf{reset}_8;\mathsf{at}_9;\mathsf{loop}(\mathsf{ub});\mathsf{home}_9;\mathsf{grec}_0;\mathsf{reset}_8.$$

Lemma I.48 (Appending to the record)**.**

(a) If track 11 *carries* r *and* τ *has origin marks up to* $r+1$*,* rec_b *runs from* -1 *to* -1 *in* $36r+77$ *units, setting* $(r,13)$ *to* 1 *and* $(r,14)$ *to* b *and advancing the counter on track* 11*.*

(b) If τ *satisfies (a) and (b) of Definition I.47 with* w *and* R*, then* grec_b *runs from* -1 *to* -1 *in* $72R+36|w|+176$ *units to a tape that satisfies (a) and (b) with* wb *and* $R+1$*; in rows* $j \le R$ *only tracks* 0, 11, 13 *and* 14 *change.*

(c) *If τ satisfies (a) and (b) with w and R, track* 8 *carries n and track* 9 *holds the value n, with $n \le R$, then* word *runs from* -1 *to* -1 *in*

$$W(|w|,R,n) = 90n^2 + n(72R + 36|w| + 389) + 72R + 36|w| + 298 \le 1000(R + |w| + n + 1)^2$$

units to a tape that satisfies (a) and (b) with $w\langle n\rangle$ and $R + n + 1$, on which track 9 *holds the value* 0 *and track* 8 *carries* 0*. Tracks* 3, 4 *and* 15 *are unchanged, and tracks* 2, 5 *and* 12 *are unchanged in rows $j \le R$.*

Proof. (a) seek_{11} ($18r + 14$), five primitives and right^3 that write the two cells and return to the hole ($3 + 3 + 4$), next (20) and home_{11} from row $r + 1$ ($18r + 33$). (b) grow ($72R + 99$, Lemma I.17) adds row $R + 1$; its pattern has 0 on track 13, so (a) persists, and then rec_b ($36|w| + 77$) appends b. (c) reset_8 ($36n + 48$) makes track 8 carry 0 and at_9 (12) reaches $(0, 9)$. For $j \le n$ let U_j be the configuration at $(j, 9)$ in which track 9 holds 1 exactly in the rows $j, \dots, n-1$, track 8 carries j, and (a), (b) hold with $w1^j$ and $R+j$. A pass from U_j, $j < n$, clears $(j, 9)$ (1), returns to the root ($18j + 13$), appends a 1 ($72(R + j) + 36(|w| + j) + 176$), advances track 8 ($36j+60$) and returns to $(j+1, 9)$ ($18j+30$): with the test, $72R+36|w|+180j+281$ units, ending in U_{j+1}. At U_n the cell $(n, 9)$ holds 0, and the loop has taken $90n^2 + n(72R + 36|w| + 191) + 1$ units. Then home_9 ($18n + 13$), grec_0 ($72(R + n) + 36(|w| + n) + 176$) and reset_8 ($36n + 48$). The writes lie on tracks 0, 8, 9, 11, 13, 14 and in new rows, whose pattern has 0 on tracks 3, 4, 15; the bound follows termwise as in Lemma I.45. □

A number arrives in binary, from a saved frame; it is turned into unary by the program toUnary of Lemma I.31, with one difference: the rows its counter needs do not exist yet, so every pass first adds one. With Z and dec the programs of the proof of Lemma I.31, put

$$\mathsf{toUnary}^{+} = \mathsf{Z}; \mathsf{loop}\big(\mathsf{home}_{10}; \mathsf{grow}; \mathsf{left}^{11}; \mathsf{home}_{10}; \mathsf{dec}; \mathsf{mark}_8; \mathsf{Z}\big); \mathsf{home}_{10}.$$

Lemma I.49 (From binary to unary with new rows)**.** *Let the binary stream hold a word b of length ℓ and value n, let track* 8 *carry r and track* 9 *hold the value r, and let τ satisfy (b) of Definition I.47 with R, where $\ell, r \le R$. Then* $\mathsf{toUnary}^{+}$ *runs from* -1 *to* -1 *within*

$$n\big(152\ell + 36(r + n) + 72(R + n) + 328\big) + 49\ell + 67 \le 1000(\ell + r + R + n + 1)^2$$

units to a tape on which the binary stream holds 0^ℓ, track 8 *carries $r + n$, track* 9 *holds the value $r + n$, and (b) holds with $R + n$. Tracks* 3, 4, 13 *and* 15 *are unchanged, and in rows $j \le R$ only tracks* 0, 7, 8, 9 *and* 10 *change.*

Proof. This is the proof of Lemma I.31 with three more parts in each pass. Z ($49\ell + 52$ at most) writes the OR of the stream into $(0, 10)$; the loop runs once for each unit of n. In pass j the program returns to the root (14), adds row $R + j + 1$ ($72(R + j) + 99$), steps to $(0, 10)$ (12) and runs the old body: home_{10} (14), dec (at most $103\ell + 71$), which subtracts one from the stream, mark_8 ($36(r + j) + 65$), which appends a mark to the value on track 9 and advances track 8, and Z. The new row lies beyond the holes of the counters on tracks 8 and 9, and its pattern has 0 on track 9. So a pass costs at most $152\ell + 36(r + j) + 72(R + j) + 327$ units, the n passes and the last test at most $n(152\ell + 36(r + n) + 72(R + n) + 328) + 1$, and the final home_{10} 14. Only the stream values (track 7), the counters and the OR cells (tracks 8, 9, 10) and the headers of the new rows are written in rows $j \le R$. □

One natural number of the request is read by

$$\mathsf{nat} = \mathsf{fetch}; \mathsf{reset}_8; \mathsf{toUnary}^+; \mathsf{word}.$$

Lemma I.50 (Reading one natural number)**.** *Let τ be a reading configuration (w, a, R) that lays out* $\mathrm{bits}(n)$ *from row a (possibly followed by further frames), where* $\mathrm{bits}(n)$ *is the word of the $\ell = \mathrm{bl}(n) + 1$ lowest binary digits of n, and let $a + \ell \le R$. Then* nat *runs from -1 to -1 within*

$$F(a, 0, \ell) + (36\ell + 48) + n\big(152\ell + 36n + 72(R + n) + 328\big) + 49\ell + 67 + W(|w|, R + n, n) \le 10000\,\sigma^2$$

units, $\sigma = a + \ell + R + |w| + n + 1$, to a reading configuration $(w\langle n\rangle, a + \ell, R + 2n + 1)$. Tracks 3, 4 *and* 15 *are unchanged, tracks* 2 *and* 12 *are unchanged in rows $j \le R$, the cells $(j, 13)$ and $(j, 14)$ with $j < |w|$ are unchanged, and so is every cell $x \ge -1$.*

Proof. fetch with $o = 0$ (Lemma I.45) copies $\mathrm{bits}(n)$ onto the binary stream, advances track 5 to $a + \ell$ and leaves ℓ on track 8, which reset_8 ($36\ell + 48$) sets back to 0. Track 9 holds 0, so Lemma I.49 applies with $r = 0$: the value n moves to tracks 8 and 9 and the rows become $R + n$. Neither program touches tracks 11, 13 and 14 in rows $j \le R$, nor track 5 beyond its own advance, so the record w and the counter $a + \ell$ survive. Then word (Lemma I.48(c) with $R + n$ rows) appends $\langle n\rangle$ and clears tracks 8 and 9. The bound adds $F(a, 0, \ell) \le 1000\sigma^2$, $36\ell + 48 \le 84\sigma^2$, the conversion $\le 1000\sigma^2$ and $W(|w|, R + n, n) \le 1000(2\sigma)^2$. □

Lemma I.51 (Reading several natural numbers)**.** *Let τ be a reading configuration (w, a, R) that lays out* $\mathrm{bits}(c_1), \dots, \mathrm{bits}(c_k), g_1, \dots, g_p$ *from row a, and let $a + \Lambda \le R$, where Λ is the total length of these frames. Let $\lambda = |\,\mathrm{bits}(c_1) \cdots \mathrm{bits}(c_k)|$ and*

$$\sigma = a + \Lambda + R + |w| + 4(c_1 + \cdots + c_k) + 3k + 1.$$

Then the list $[\mathsf{nat}, \dots, \mathsf{nat}]$ *of k copies runs from -1 to -1 within*

$$k \cdot 10000\,\sigma^2 + 1$$

units to a reading configuration $(w\langle c_1, \dots, c_k\rangle, a + \lambda, R + 2(c_1 + \cdots + c_k) + k)$ that lays out $g_1, \dots, g_p$ from row $a + \lambda$; tracks 3, 4, 15 *and every cell $x \ge -1$ are unchanged, and tracks* 2 *and* 12 *are unchanged in rows $j \le R$.*

Proof. Induction on k, by Lemma I.50; the final skip of the list is the $+1$. The layout of the remaining frames survives because tracks 3, 4 and 15 do. The scale does not grow: after the first number, a, R and $|w|$ grow by ℓ_1, $2c_1 + 1$ and $c_1 + 1$, while Λ, $4\sum c$ and $3k$ fall by ℓ_1, $4c_1$ and 3; and the scale $a + \ell_1 + R + |w| + c_1 + 1$ of the first number is at most σ. □

I.7.7 Rows, groups and the payload

The shape of the field is a group of d rows for the A-terms and a group of d rows for the B-terms. Row i of a group is the number n of terms of coordinate i followed by their $n\alpha$ indices, with arity $\alpha = 1$ for A-terms and $\alpha = 2$ for B-terms. The number n just read is the count of

the loop that reads the rest of the row, and the dimension, the first word of the record, is the count of the loop over rows. Put

$$\mathsf{row}_\alpha = [\mathsf{copy}_{11\to12}, \mathsf{nat}, \mathsf{repeat}_{12}([\mathsf{nat}, \dots, \mathsf{nat}])] \quad (\alpha \text{ copies of } \mathsf{nat}),$$
$$\mathsf{skips} = [\mathsf{copy}_{11\to12}, \mathsf{nat}, \mathsf{repeat}_{12}(\mathsf{skipf})].$$

$\mathsf{copy}_{11\to12}$ puts on track 12 the row where the next word of the record begins; after nat that word is $\langle n\rangle$, which is a retained word of length n on track 14, and repeat_{12} (Lemma I.18) runs its body once for each of its marks.

Lemma I.52 (One row of the shape). *Let $\alpha \in \{1, 2\}$ and let τ be a reading configuration (w, a, R) that lays out* $\mathrm{bits}(n)$*, then* $\mathrm{bits}(e_1), \dots, \mathrm{bits}(e_{n\alpha})$*, then $g_1, \dots, g_p$ from row a, with $a + \Lambda \le R$ as in Lemma I.51. Let $\ell_n = |\mathrm{bits}(n)|$ and let σ' be the scale of Lemma I.51 for the record $w\langle n\rangle$, the row $a + \ell_n$, $R + 2n + 1$ rows and the numbers $e_1, \dots, e_{n\alpha}$. Then row_α runs from -1 to -1 within*

$$100(|w| + 1) + 10000(a + \ell_n + R + |w| + n + 1)^2 + n\big(36(|w| + n) + 10000\alpha\sigma'^2 + 59\big) + 36|w| + 18n + 39$$

units to a reading configuration $(w\langle n, e_1, \dots, e_{n\alpha}\rangle, a', R+2(n+\sum e)+n\alpha+1)$ that lays out $g_1, \dots, g_p$ from the row a' after these frames. Tracks 3, 4, 15 *and the cells $x \ge -1$ are unchanged, and track* 2 *is unchanged in rows $j \le R$.*

Proof. $\mathsf{copy}_{11\to12}$ (Lemma I.15(a)) takes at most $100(|w| + 1)$ units and makes track 12 carry $|w|$. nat (Lemma I.50) appends $\langle n\rangle$, leaving track 12 alone in rows $j \le R$; now track 14 carries a retained word of length n from row $r_0 = |w|$. In Lemma I.18 with $c = 12$, let R_j say that j entries of the row have been read: the tape is a reading configuration with $w\langle n, e_1, \dots, e_{j\alpha}\rangle$ that lays out the remaining frames. The body, α copies of nat, runs within $\alpha \cdot 10000\sigma'^2 + 1$ units (Lemma I.51, whose scale for the remaining numbers is at most σ'); it does not change track 12 in rows $j \le R$, nor the cells of the record already written, which include the word $\langle n\rangle$. Lemma I.18 gives $n(36(r_0 + n) + b + 58) + 36r_0 + 18n + 38$ with $b = 10000\alpha\sigma'^2 + 1$, and the list adds one unit. □

Lemma I.53 (A group of rows). *Let τ be a reading configuration (w, a, R) with $d + 1 \le |w|$, on which track* 14 *carries a retained word of length d from row* 0 *and track* 2 *carries* 0*, and which lays out the frames of d rows of arity α followed by $g_1, \dots, g_p$ from row a, with $a + \Lambda \le R$. Let S be the scale of Lemma I.51 for all the numbers of the d rows. Then $\mathsf{repeat}_2(\mathsf{row}_\alpha)$ runs from -1 to -1 within*

$$d\big(36d + 10^6S^3 + 58\big) + 18d + 38$$

units to a reading configuration whose record is w followed by the unary words of all numbers of the d rows, which lays out $g_1, \dots, g_p$ from the row after these frames, and on which track 2 *carries d and track* 14 *still carries the retained word; tracks* 3, 4, 15 *and the cells $x \ge -1$ are unchanged.*

Proof. Lemma I.18 with $c = 2$, $r_0 = 0$, $n = d$ and the body row_α, whose cost is at most 10^6S^3: in Lemma I.52 each of $|w_j| + 1$, the first scale, σ' and the count n is at most S, and $\alpha \le 2$, so the count there is at most $100S + 10000S^2 + S(72S + 20000S^2 + 59) + 54S + 39 \le 10^6S^3$. The body keeps track 2 in rows $j \le R$ and the cells of the record already written, which contain the retained word. □

Lemma I.54 (Skipping the payload). *Let τ be a reading configuration (w, a, R) that lays out* bits(q)*, then q nonempty words $z_1, \dots, z_q$, then $g_1, \dots, g_p$ from row a, with $a + \Lambda \le R$; put $\ell_q = |\,\mathrm{bits}(q)|$ and $\zeta = |z_1 \cdots z_q|$. Then* skips *runs from -1 to -1 within*

$$100(|w|+1) + 10000(a + \ell_q + R + |w| + q + 1)^2 + q\big(36(|w|+q) + 200(a+\ell_q+\zeta+1)^2 + 58\big) + 36|w| + 18q + 39$$

units to a reading configuration $(w\langle q\rangle, a + \ell_q + \zeta, R + 2q + 1)$ that lays out $g_1, \dots, g_p$ from row $a + \ell_q + \zeta$; tracks 3, 4, 15 *and the cells $x \ge -1$ are unchanged.*

Proof. As for Lemma I.52, with the body skipf (Lemma I.46), which reads the next z_j from row $a_j \le a + \ell_q + \zeta$ within $200(a + \ell_q + \zeta + 1)^2$ units, changes only tracks 5 and 10 and adds no row. The signed integers are never converted: their bits stay on tracks 3 and 4. □

I.7.8 The numeric record

When every number has been read, the record on tracks 13 and 14 holds $\langle c_1, \dots, c_L\rangle$. The last part of the stage copies it to tracks 9 and 10, preceded by the unary word of its number L of words, which it counts on the way. With track 5 as the reading counter of the record and track 8 as the writing counter put

$$\begin{aligned}
\mathsf{tpres} &= \mathsf{seek}_5; \mathsf{left}^8, \qquad \mathsf{tadv} = \mathsf{right}^8; \mathsf{next}; \mathsf{left}^8,\\
\mathsf{tskip} &= \mathsf{right}^9; \mathsf{next}; \mathsf{left}^8,\\
\mathsf{femit}_b &= \mathsf{seek}_8; \mathsf{left}; \mathsf{write}\,1; \mathsf{left}; \mathsf{write}\,b; \mathsf{right}^2; \mathsf{next}; \mathsf{home}_8,\\
\mathsf{temit}_b &= \mathsf{home}_{14}; \mathsf{femit}_b; \mathsf{tpres}; \mathsf{tadv},\\
\mathsf{fseal} &= \mathsf{seek}_8; \mathsf{left}; \mathsf{write}\,0; \mathsf{home}_9; \mathsf{reset}_8,\\
\mathsf{scan}(V_0, V_1) &= \mathsf{tpres}; \mathsf{loop}\big(\mathsf{left}; \mathsf{branch}(V_0, V_1)\big); \mathsf{home}_{13},\\
\mathsf{fin} &= \mathsf{scan}(\mathsf{temit}_1, \mathsf{tskip}); \mathsf{femit}_0; \mathsf{reset}_5;\\
&\qquad \mathsf{scan}(\mathsf{temit}_0, \mathsf{temit}_1); \mathsf{fseal}.
\end{aligned}$$

Lemma I.55 (Writing the numeric record). *Let $c_1, \dots, c_L$ be numbers and $v = \langle c_1, \dots, c_L\rangle$. Let $\tau(j, 13) = 1$ and $\tau(j, 14) = v_j$ for $j < |v|$ and $\tau(|v|, 13) = 0$, let tracks* 5 *and* 8 *carry* 0*, let τ have origin marks up to R, and let $|v| + L + 1 \le R$. Then* fin *runs from -1 to -1 within $2000(R+1)^2$ units to a tape τ' with $\tau'(0, 8) = 0$ on which the word $\langle L, c_1, \dots, c_L\rangle$ lies on tracks* 9 *and* 10 *from row* 0*. Tracks* 3, 4, 13, 14 *and* 15 *are unchanged, and if τ is a workspace of R rows, so is τ'.*

Proof. femit_b appends b to tracks 9 and 10 at the counter o on track 8 and advances it, in $36o + 68$ units. In $\mathsf{scan}(V_0, V_1)$ the head stands at $(k, 13)$, where k is the counter on track 5; while the presence cell holds 1 the body reads the value v_k and runs V_{v_k}, which ends at $(k+1, 13)$ with track 5 advanced: tskip in 39 units, temit_b in $36k + 36o + 141$ units. So each pass costs at most $72R + 144$ units with its test. The first scan emits one 1 for each 0 of v, that is, 1^L; femit_0 completes $\langle L\rangle$; reset_5 $(36|v| + 36)$ rewinds the record; the second scan copies v after it; fseal $(72o + 74)$ writes the terminator at $o = L + 1 + |v|$ and resets track 8, so that $(0, 8) = 0$. With the two walks tpres and home_{13} of each scan and $|v|, L \le R$, the total is at most $2000(R+1)^2$. Only tracks 5, 8, 9 and 10 of rows $j \le R$ are written. □

I.7.9 The stage Decode

Let $c_1, \dots, c_L$ be the natural numbers of the request u in order: d; for each coordinate the number of its A-terms and their indices; for each coordinate the number of its B-terms and their index pairs; the number q of payload integers; and M, T, n_0, i, m. The *value size* of the request is

$$V(u) = |u| + c_1 + \cdots + c_L + 1.$$

It counts the unary length of every number, because Decode writes every number in unary. It is still linear in X: if $c_{\mathrm{num}} = c_{\mathrm{req}} + \Sigma_0 + d + 3$, where Σ_0 is the sum of the numbers c_j other than i and m, then $V(u) \le c_{\mathrm{num}} X$, since $|u| + 1 \le c_{\mathrm{req}} + 2m$, $i \le d$ and $m \le X - 1$.

Definition I.56 (The decoded request)**.** A tape τ is a *decoded request* of u with r rows if

(a) τ carries the saved request of u (Definition I.41);

(b) $\tau(0, 8) = 0$, and the word $\langle L, c_1, \dots, c_L \rangle$ lies on tracks 9 and 10 from row 0;

(c) τ is a workspace of r rows.

The program of the stage is

$$\begin{aligned} \mathsf{Decode} &= \big(\mathsf{erase}; (\mathsf{init}; \mathsf{walk})\big); (\mathsf{reset}_5; \mathsf{fin}), \qquad \mathsf{erase} = \mathsf{raw}; \mathsf{write}\,0; \mathsf{unraw}, \\ \mathsf{init} &= \mathsf{clear}_9; \mathsf{clear}_{13}; \mathsf{zero}_2; \mathsf{zero}_5; \mathsf{zero}_8; \mathsf{zero}_{11}; \mathsf{zero}_{12}; \mathsf{skip}, \\ \mathsf{walk} &= [\mathsf{zero}_2, \mathsf{zero}_{11}, \mathsf{nat}, \mathsf{repeat}_2(\mathsf{row}_1), \mathsf{zero}_2, \mathsf{repeat}_2(\mathsf{row}_2), \\ &\qquad \mathsf{skips}, [\mathsf{nat}, \mathsf{nat}, \mathsf{nat}, \mathsf{nat}, \mathsf{nat}]]. \end{aligned}$$

It reads d, then the group of A-rows and the group of B-rows, each counted by the first word of the record, then q and the q frames of the payload, which it skips, and finally M, T, n_0, i and m.

Lemma I.57 (Preparing the scratch area and reading d)**.** *Let $R = |w_u|$. From $(-1, \tau_P)$ the program* erase; init; [zero$_2$, zero$_{11}$, nat] *runs to $(-1, \tau_1)$ in t_1 units with $t_1 + (R + 2d + 1) + 1 \le 200000\, V(u)^2$, and τ_1 is a reading configuration $(\langle d \rangle, l_1, R + 2d + 1)$ that lays out $f_1, \dots, f_F$ from row l_1, carries the saved request of u, carries 0 on tracks 2 and 12, and is a workspace of $R + 2d + 1$ rows.*

Proof. By Theorem I.42(a), erase finds the marker at $c = |u| - 1$, erases it and returns ($12c + 15$ units, Lemma I.34); the tape is now a workspace of R rows. init clears tracks 9 and 13 in rows $j \le R$ ($57R + 26$ and $65R + 34$, Lemma I.16); they are 0 in the rows beyond. It then puts the hole of tracks $2, 5, 8, 11, 12$ in row 0 (112 units, Lemma I.14(d)). The result is a reading configuration $(\varnothing, 0, R)$, with $\varnothing$ the empty record, that carries 0 on tracks 2 and 12 and, by Lemma I.44, lays out $f_0, \dots, f_F$ from row 0. As $c \le |u|$ and $R \le |u|$, these two parts take at most $309V(u)$ units. zero$_2$ and zero$_{11}$ (11 and 29 units) change nothing. nat reads $f_0 = \mathrm{bits}(d)$ within $10000(l_1 + R + d + 1)^2 \le 160000V(u)^2$ units (Lemma I.50). It keeps tracks 3, 4 and 15, tracks 2 and 12 in rows $j \le R$, and the cells $x \ge -1$. Adding the final skip of the list and $R + 2d + 2 \le 3V(u)$ gives the bound. □

Theorem I.58 (Decode). *From $(-1,\tau_P)$, the program* Decode *runs to $(-1,\tau_D)$ in some number t of units, where τ_D is a decoded request of u with*

$$r' = |w_u| + 2(c_1 + \cdots + c_L) + L$$

rows, and

$$t + r' + 1 \le K_d\, V(u)^8, \qquad K_d = 10^{16} + 400082.$$

Consequently $t + r' + 1 \le K_d\, c_{\mathrm{num}}^8 X^8$. With Pre_r the tape τ_P left by Parse *on a request (with $r = |w_u|$ rows) and $\mathrm{Post}_{r'}$ the decoded requests with r' rows,* Decode *meets a contract in the sense of Definition I.7 with exponent 8 and constant $K_d\, c_{\mathrm{num}}^8$, which depends only on the problem and n_0.*

Proof. Write $V = V(u)$ and $R = |w_u|$; note $R \le |u|$ and $1 \le V$. The program $\mathsf{erase};(\mathsf{init};\mathsf{walk})$ is the program of Lemma I.57 followed by the list

$$[\mathsf{repeat}_2(\mathsf{row}_1), \mathsf{zero}_2, \mathsf{repeat}_2(\mathsf{row}_2), \mathsf{skips}, [\mathsf{nat}, \mathsf{nat}, \mathsf{nat}, \mathsf{nat}, \mathsf{nat}]],$$

up to the final skip of the first list, which the joint list does not repeat; so it takes at most $t_1 + t_2$ units, where t_2 is the count of this list from τ_1. Every scale that occurs below is at most $12V$, by the same count as in Lemma I.51: the reading row plus the remaining frames is $R \le V$, the rows are at most $2V$, the record is at most V, and the numbers still to be read with their count are at most V.

First group. On τ_1 the record is $\langle d\rangle$, so track 14 carries a retained word of length d from row 0, and track 2 carries 0. Lemma I.53 with $\alpha = 1$ reads the d rows of A-terms within $d(36d + 10^6(12V)^3 + 58) + 18d + 38 \le 10^{12}V^4$ units, as $d \le V$.

zero_2 (11 units) returns the hole of track 2 to row 0; the retained word on track 14 is part of the record and has not changed. Lemma I.53 with $\alpha = 2$ reads the d rows of B-terms within $10^{12}V^4$ units.

Payload. Lemma I.54 reads q and skips the q signed frames. There the record has length $|w| \le V$, $q \le V$, and the rows are at most $2V$, so the first scale of Lemma I.54 is at most $6V$ and $a+\ell_q+\zeta+1 \le R+1 \le 2V$; its count is at most $100(V+1)+10000(6V)^2+V(72V+800V^2+58)+54V+39 \le 10^{12}V^4$.

Last numbers. Lemma I.51 with $k = 5$ reads M, T, n_0, i and m within $5\cdot 10000(12V)^2+1 \le 10^{12}V^4$ units.

With the final skip, $t_2 \le 4 \cdot 10^{12}V^4 + 12 \le 10^{16}V^4$, and the tape is a reading configuration $(\langle c_1, \dots, c_L\rangle, R, r')$ that carries the saved request and is a workspace of r' rows: each number c added $2c + 1$ rows. Since $t_1 \le 200000V^2$,

$$t_1 + t_2 \le (10^{16} + 200000)V^6.$$

Then reset_5 ($36R + 36 \le 72V$ units) sets the reading counter to 0, and fin (Lemma I.55) writes $\langle L, c_1, \dots, c_L\rangle$ on tracks 9 and 10 within $2000(r'+1)^2$ units. Its hypothesis $|\langle c_1, \dots, c_L\rangle|+L+1 \le r'$ holds because $|\langle c_1, \dots, c_L\rangle| = c_1 + \cdots + c_L + L$ and $L + 1 \le R + c_1 + \cdots + c_L$. It keeps tracks 3, 4, 15 and the workspace. As $r' + 1 \le 2V \le 10V$,

$$t + r' + 1 \le (10^{16} + 200000)V^6 + 72V + 200000V^2 + 10V \le (10^{16} + 400082)V^8.$$

The last claim follows from $V(u) \le c_{\mathrm{num}}X$ and $X \le X + r + 1$. □

After Decode every cell $x \geq 0$ holds 0 again (part (c) of Definition I.56): the request now exists only in the rows, as the saved request on tracks 3, 4 and 15 and as the numeric record on tracks 9 and 10. The exponent 8 arises as $4 + 2 + 2$: the traversal of the request is bounded in the fourth power of the value size, and each of the two compositions around it, with the first number and with the final copy, raises the exponent by two while keeping the bound in one variable.

Corollary I.59 (Reading the request in sequence)**.** *The program* Parse; Decode *runs from the head on cell* 0 *of the input tape of* u *to* $(-1, \tau_D)$*, a decoded request of* u *with* r' *rows, in* $t_P + t_D$ *units, where* $t_P = C_P(u)$ *and* t_D *is the count of Theorem I.58, and*

$$t_P + t_D + r' + 1 \leq A\, X^{11}, \qquad A = 100000(c_{\mathrm{req}} + 2)^3 + K_d\, c_{\mathrm{num}}^8.$$

Proof. By Theorem I.42(c), $t_P \leq 100000(c_{\mathrm{req}} + 2)^3 X^3$, and by Theorem I.58, $t_D + r' + 1 \leq K_d\, c_{\mathrm{num}}^8 X^8$. Since $X \geq 1$, both powers are at most X^{11}. Add. □

The bound has the form of the hypothesis of Lemma 15.36(a) with $N = X$ and $e = 11$, so the stages after Decode compose with it directly. The constant A depends on the problem and n_0 only; the exponent $11 = 8 + 3$ is a fixed number.

I.8 The problem's constants: preparing the request and folding the field

Where does the machine find the number β of a field? Take $y' = -y^2$ with $y_0 = \frac{1}{2}$. Its request (Definition 15.32) has the shape $d = 1$, no A-term, one B-term with indices $(0, 0)$, then the payload count 6 and the six integers $1, 2$ (the numerator and denominator of y_0), $0, 1$ (of c_0) and $-1, 1$ (of the coefficient of the B-term), followed by M, T, n_0, i and m. After the request has been read (Section I.7), the bits of every frame lie on tracks 3 and 4 of the scratch area, with a mark on track 15 at the first bit of each frame after the first. By Definition 15.24, β is the largest, over the coordinates, of the sum of $\lceil |b| \rceil$ over the B-terms of the coordinate; here $\beta = \lceil |-1/1| \rceil = 1$. The machine finds it in four moves: it writes $|-1| = 1$ and the denominator 1 in unary, divides the first by the second with rounding up, adds the result over the B-terms of the coordinate, and keeps the largest row sum. The number 1 is then appended to a list kept on the tape, the *archive*. The same pattern, a number for each coordinate and then the largest of them, gives γ, α, the capacity s of the field, the row length L and the capacity s_0 of the initial point (Section H.1); the capacities count binary digits, which the machine reads off the lengths of the frames. For this request the archive ends as

$$(p, \gamma, \alpha, \beta, s, L, s_0) = (11, 0, 0, 1, 3, 1, 3),$$

where $p = 11$ is the row of the saved request at which the payload begins: the frames before it are those of $d = 1$ (2 bits), of the shape numbers 0, 1, 0, 0 ($1 + 2 + 1 + 1$ bits) and of $q = 6$ (4 bits).

This section constructs the first half of the stage "Schedule" of Table 15.1: from the decoded request to the archive of these seven numbers. Section I.9 computes σ, S, κ, N, the capacity polynomial and the width from the archive. The three programs of this section are

$$\begin{aligned} \mathsf{Prepare} &= \mathsf{norm};\mathsf{grow};\mathsf{norm};\mathsf{prec};\mathsf{clear}_{2,5,6,7,12,13,14},\\ \mathsf{MetaBank} &= \mathsf{Meta};\mathsf{Bank},\\ \mathsf{Summ} &= \mathsf{clear}_9;\mathsf{Gam};\mathsf{pass}(\mathsf{row}_A,2);\mathsf{pass}(\mathsf{row}_B,3);\\ &\qquad \mathsf{pass}(\mathsf{row}_W,4);\mathsf{pass}(\mathsf{row}_L,5);\mathsf{Ini}, \end{aligned}$$

run in this order. Prepare (Section I.8.1) reads the precision m into unary and blanks the scratch tracks. Meta archives the payload row p and Bank writes in unary the magnitude of every integer of the request (Section I.8.3). Summ archives γ (Gam), then the four row folds for α, β, s and L, then s_0 (Ini) (Section I.8.7). Every routine they use that the foundation sections do not prove is constructed and counted below, from the routines of Sections I.3 to I.5.

The objects on the tape

Throughout, ω is the saved request of Definition I.41: the bits of d followed by the bits of every later frame of the request, on track 3 (presence) and track 4 (bits) from row 0, with the frame-start marks on track 15. The payload integers are $z_1, \dots, z_q$, in the order of Definition 15.32: the numerators and denominators of y_0, of c, of the A-coefficients coordinate by coordinate, and of the B-coefficients. In this section a *frame of* ω means the bits of a frame of the request as they lie in ω: the unary length and the separator are not stored, and the first bit of every frame after the first carries the frame-start mark. The frame of an integer z has $\mathrm{bl}(|z|)+2$ bits: the bit $[z<0]$ and the $\mathrm{bl}(|z|)+1$ lowest binary digits of $|z|$. We write p for the row of ω at which the frame of z_1 begins, and p_j for the row at which the frame of z_j begins, so that $p_1 = p$ and $p_{j+1} = p_j + \mathrm{bl}(|z_j|) + 2$. For $n \in \mathbb{N}$ let $u(n) = 1^n 0$, and for numbers $n_1, \dots, n_k$ let $\mathrm{rec}(n_1, \dots, n_k) = u(k)\,u(n_1)\cdots u(n_k)$; the *numeric record* of Definition I.56 is this word on tracks 9 (presence) and 10 (values) from row 0, with $\tau(0,8) = 0$.

Definition I.60 (Bank, archive and gather state)**.** Fix a problem, i and m, and let τ be a tape and $R \in \mathbb{N}$.

(a) The *bank list* is $\mathbf{b} = (d,\ \text{the shape numbers},\ q,\ |z_1|, \dots, |z_q|,\ M,\ T,\ n_0,\ i,\ m)$: the control numbers of the request in their order, with the magnitude of every payload integer inserted after q. The tape carries the *bank* if the word $\mathrm{rec}(\mathbf{b})$ lies on tracks 9 and 10 from row 0 and $\tau(0,8) = 0$. It has a *bank view* within R rows if there are a tape τ_0 that carries the bank and is a workspace of at most R rows, and $\tau(j,10) = \tau_0(j,10)$ for every j: only the values of the bank are kept, and track 9 is free.

(b) For numbers $v_1, \dots, v_k$, τ holds the *archive* $(v_1, \dots, v_k)$ *within* R *rows* if ω lies on tracks 3 and 4 from row 0 (so $\tau(|\omega|,3) = 0$), the word $u(v_1)\cdots u(v_k)$ lies on tracks 3 and 4 from row $|\omega|+1$, and

$$|\omega| + 1 + \sum_{j \le k} (v_j + 1) \le R.$$

In particular every v_j is at most R.

(c) τ is in the *gather state* with archive $(v_1, \dots, v_k)$ and R rows if it holds that archive within R rows, has a bank view within R rows, has on track 15 the frame-start marks of the saved request, is a workspace of R rows with origin marks up to R, and $v_1 = p$.

The archive is an extension of the saved request: its words follow ω on the same two tracks, after the blank cell $(|\omega|, 3)$ that ends ω. So ω and the archive together are one finite stream, and the final erase of Section I.15 clears both with the rest of the rows.

The contracts

The stage results are stated here and proved at the ends of Sections I.8.1 and I.8.7. A *prepared request with r rows* is a decoded request with r rows (Definition I.56) that has origin marks up to r, holds the value m on track 11, and has 0 in every cell of tracks 2, 5, 6, 7, 12, 13 and 14.

Lemma I.61 (Preparing the request)**.** *From every decoded request with r rows,* Prepare *runs from the root to the root in some t units to a prepared request with $r+1$ rows, and $t \le 4000(r+2)^2$. The saved request and the numeric record are kept.*

Theorem I.62 (The archive of the seven constants)**.** *Fix a problem. There are constants K_1 and K_2, depending only on the problem, with the following properties for every i, m, r and tape τ.*

(a) If τ is a prepared request with r rows, then MetaBank *runs from the root to the root in some t units to a tape that holds the archive (p) within r' rows, carries the bank on tracks 9 and 10, keeps the saved request, is a workspace of r' rows with origin marks up to r', and satisfies*

$$t + (r' + m) + 2 \le K_1(r + m + 2)^{24}.$$

(b) If τ is in the gather state with archive (p) and r rows, then Summ *runs from the root to the root in some t units to a tape in the gather state with archive*

$$(p,\ \gamma,\ \alpha,\ \beta,\ s,\ L,\ s_0)$$

and $r + \rho_S$ rows, where ρ_S depends only on the problem, and

$$t + (r + \rho_S + m) + 2 \le K_2(r + m + 2)^3.$$

(c) If τ is a prepared request with r rows, then MetaBank; Summ *runs from the root to the root in some t units to a tape that holds the archive $(p, \gamma, \alpha, \beta, s, L, s_0)$ within r'' rows, keeps the saved request, is a workspace of r'' rows with origin marks up to r'', and*

$$t + (r'' + m) + 2 \le (K_1 + K_2K_1^3)(r + m + 2)^{72}.$$

Here γ, α and β are the bounds of Definition 15.24, and s, L and s_0 those of Section H.1.

I.8.1 Preparing the request

A decoded request leaves the scratch tracks in an unknown state, and it need not have origin marks. The first routine writes them from the row headers.

Lemma I.63 (The origin corridor)**.** *Let*

$$\mathsf{corr} = \mathsf{left}^2;\mathsf{write}\,0;\mathsf{right}^1;\mathsf{branch}(\mathsf{right}^1,\ \mathsf{corr}^+),$$
$$\mathsf{corr}^+ = \mathsf{left}^{16};\mathsf{loop}(\mathsf{left};\mathsf{write}\,1;\mathsf{left}^{15});\mathsf{left};\mathsf{write}\,1;\mathsf{home}_1,$$

and $\mathsf{norm} = \mathsf{corr};\mathsf{clear}_{2,5,6,7,11,12,13,14}$*. If τ is a workspace of r rows, then* corr *runs from $(-1,\tau)$ to $(-1,\tau')$ in 9 units if $r=0$ and in $37r+13$ units if $r\ge 1$, where τ' is τ with $(0,1)$ set to 0 and $(j,1)$ set to 1 for $1\le j\le r$. So τ' is a workspace of r rows with origin marks up to r. Then* norm *runs from $(-1,\tau)$ to the root within $489r+218$ units, and in addition sets every cell of tracks 2, 5, 6, 7, 11, 12, 13 and 14 to 0; no other track changes.*

Proof. left^2, $\mathsf{write}\,0$ and right^1 ($3+1+2$ units) clear $(0,1)=-3$ and stop on the header $(0,0)$. If $r=0$ the header is 0, and the branch and right^1 return to the root: 9 units. If $r\ge 1$, left^{16} (17 units) reaches $(1,0)$. Let I_j, for $1\le j\le r$, be the configuration at $(j,0)$ in which $(i,1)=1$ for $1\le i<j$. A pass from I_j with $j<r$ scans the header 1, writes the origin mark of row j and moves to $(j+1,0)$: 19 units with its test. At I_r the header is the sentinel 0. Lemma I.6 gives $19(r-1)+1$ units. Then left and $\mathsf{write}\,1$ mark row r, and home_1 from row r costs $18r+5$ (Lemma I.11). In all $7+17+19(r-1)+1+2+18r+5=37r+13$. Only track 1 is written, in rows $j\le r$, so τ' is again a workspace. For norm, Lemma I.16 applies to τ' and adds $\sum_k\big((2k+39)r+2k+8\big)+1=452r+205$ units over the eight tracks, whose numbers sum to 70; cells of rows $j>r$ are 0 already. The total is at most $489r+218$. □

The precision m is the last word of the numeric record. The next routine reads a unary word backwards, from its last mark to the blank cell before it, and counts its marks on track 11; it serves twice in this section.

Lemma I.64 (Reading a word backwards)**.** *Let*

$$\mathsf{tail} = \mathsf{loop}(\mathsf{home}_{10};\mathsf{inc}_{11};\mathsf{seek}_2;\mathsf{right}^{16};\mathsf{write}\,0;\mathsf{left}^8);\mathsf{home}_{10}.$$

Let $s,n,R\in\mathbb{N}$ with $s+n\le R$, and let τ have origin marks up to R, carry the counter $s+n$ on track 2 and the counter 0 on track 11, and satisfy $\tau(s,10)=0$ and $\tau(s+j,10)=1$ for $1\le j\le n$. Then tail *runs from $(\mathrm{cell}(s+n,10),\tau)$ to $(-1,\tau')$ in exactly*

$$n\big(36(s+n)+113\big)+1+18s+14$$

units. In τ' track 2 carries s and track 11 carries n; only the cells $(j,2)$, $s\le j<s+n$, and $(j,11)$, $j\le n$, differ from τ.

Proof. For $j\le n$ let I_j be the configuration at $\mathrm{cell}(s+n-j,10)$ in which track 2 carries $s+n-j$ and track 11 carries j. From I_j with $j<n$ the scanned cell is a mark. Put $h=s+n-j$. The pass returns to the root ($18h+14$ units), advances the counter on track 11 ($36j+66$, Lemma I.14; the origin marks reach $j+1\le R$), goes to the hole $(h,2)$ ($18h+5$), steps to $(h-1,2)$ and writes 0 there (18), so that track 2 now carries $h-1$, and moves to $(h-1,10)$ (9). With its test it costs $36h+36j+113=36(s+n)+113$ units and ends in I_{j+1}. At I_n the scanned cell is $(s,10)=0$. Lemma I.6 gives $n(36(s+n)+113)+1$ units, and home_{10} from row s costs $18s+14$. □

Lemma I.65 (The precision). *Let* $\mathsf{last} = \mathsf{acc}^{14}_{9\to 2}; \mathsf{seek}_2; \mathsf{right}^{32}; \mathsf{write}\,0; \mathsf{left}^{8}$ *and* $\mathsf{prec} = \mathsf{last}; \mathsf{tail}$. *Let τ be a workspace of R rows with origin marks up to R that carries the numeric record $w = \mathrm{rec}(n_1, \dots, n_k)$, $k \geq 1$, with $|w| \leq R$, and let track 2 carry the counter 0 and track 11 hold the value 0. Then* prec *runs from the root to the root within $1000(R+1)^2$ units to a tape on which track 11 holds the value n_k; only tracks 2, 11 and 14 change, so the workspace and the origin marks are kept.*

Proof. Put $\ell = |w|$. Track 9 carries the counter ℓ, so by Lemma I.15(b) $\mathsf{acc}^{14}_{9\to 2}$ makes track 2 carry ℓ in $36\ell^2 + 134\ell + 72$ units, writing only tracks 2 and 14. seek_2 reaches $(\ell, 2)$ $(18\ell + 5)$, right^{32} moves two rows back to $(\ell - 2, 2)$ (33), $\mathsf{write}\,0$ makes track 2 carry $\ell - 2$, and left^{8} reaches $(\ell - 2, 10)$ (9). The last word $u(n_k)$ of w occupies the rows $\ell - n_k - 1, \dots, \ell - 1$ of track 10, and the word before it, which exists because $k \geq 1$, ends with its blank cell at row $s = \ell - n_k - 2$. So Lemma I.64 applies with this s and $n = n_k$, and takes $n_k(36(\ell - 2) + 113) + 1 + 18s + 14$ units; track 11, blank before, now holds the value n_k. Since $n_k \leq \ell \leq R$ the total is at most $72\ell^2 + 211\ell + 135 \leq 1000(R+1)^2$. □

Proof of Lemma I.61. Let τ be a decoded request with r rows. Its control numbers end with m, so its numeric record is $\mathrm{rec}(n_1, \dots, n_k)$ with $n_k = m$, $k \geq 1$. The five parts of $\mathsf{Prepare}$ act as follows.

(i) norm writes the origin marks up to r and blanks the eight scratch tracks, within $489r + 218$ units (Lemma I.63).

(ii) grow makes a workspace of $r + 1$ rows with origin marks up to $r + 1$ in $72r + 99$ units (Lemma I.17). It writes the header $(r, 0)$ and the new row $r + 1$, which was blank and receives 0 on tracks 3, 4, 9, 10 and 15.

(iii) norm on $r + 1$ rows, within $489(r + 1) + 218$ units, blanks the marks that grow left on tracks 2, 5, 11 and 14 of row $r + 1$.

(iv) The numeric record has length at most $r + 1$, because its presence marks lie in rows $j \leq r$; track 2 carries 0 and track 11 holds 0. Lemma I.65 with $R = r + 1$ writes the value m on track 11 within $1000(r + 2)^2$ units.

(v) $\mathsf{clear}_{2,5,6,7,12,13,14}$ on $r + 1$ rows costs $391(r + 1) + 175$ units (Lemma I.16).

No part writes tracks 3, 4, 9, 10 or 15 outside the blank row $r + 1$, nor the cell $(0, 8)$, so the saved request and the numeric record are kept, and the result is a prepared request with $r + 1$ rows. The total is at most $1441r + 1590 + 1000(r + 2)^2 \leq 4000(r + 2)^2$. □

I.8.2 Counters, growth and the archive

Most routines of the schedule move a unary number from one track to another, or step a counter back by one. In this subsection and the rest of the section, "within R rows" includes that the tape is a workspace of R rows with origin marks up to R.

Lemma I.66 (Clean copies and steps back). *For distinct tracks $k, l \in \{2, \dots, 15\}$ put $\mathsf{cc}_{k\to l} = \mathsf{clear}_l; \mathsf{copy}_{k\to l}$ and $\mathsf{retr}_k = \mathsf{seek}_k; \mathsf{right}^{16}; \mathsf{write}\,0; \mathsf{home}_k$.*

(a) If τ is a workspace of R rows with origin marks up to R and track k carries a counter $n \le R$, then $\mathsf{cc}_{k\to l}$ runs from the root to the root within $(2l+39)R+2l+9+100(n+1) \le 300(R+1)$ units, and afterwards track l holds the value n; only track l changes.

(b) If track k carries the counter $j+1$ and τ has origin marks up to j, then retr_k runs from the root to the root in $36j + 2k + 43$ units and sets (j, k) to 0, so that track k carries j.

Proof. (a) clear_l followed by the final skip costs $(2l + 39)R + 2l + 9$ units and leaves track l blank in every row (Lemma I.16; rows beyond R are blank already). $\mathsf{copy}_{k\to l}$ costs at most $100(n + 1)$ and writes 1 in (j, l) for $j < n$ and 0 in (n, l) (Lemma I.15(a)), so track l holds the value n. With $l \le 15$ the count is at most $169R + 139$. (b) seek_k reaches the hole $(j + 1, k)$ in $18(j + 1) + k + 3$ units, right^{16} and $\mathsf{write}\,0$ (18) clear (j, k), and home_k from row j costs $18j + k + 4$ (Lemma I.11). □

New rows are added by the count held on track 12, one grow per unit, with track 2 as the loop counter.

Lemma I.67 (Growing by a count). *Let $\mathsf{rdc} = \mathsf{seek}_2; \mathsf{shift}_{2\to 12}$ and*

$$\mathsf{alloc} = \mathsf{grow}; \mathsf{rdc}; \mathsf{loop}(\mathsf{home}_{12}; \mathsf{grow}; \mathsf{inc}_2; \mathsf{rdc}); \mathsf{home}_{12}.$$

Let τ be a workspace of R rows with origin marks up to R on which track 2 carries the counter 0 and track 12 holds the value c. Then alloc runs from the root to the root within $2000(R + c + 2)^2$ units to a workspace of $R + 1 + c$ rows with origin marks up to $R + 1 + c$ on which track 12 still holds c. Besides the new rows and the headers of the rows $R, \dots, R + c$, only track 2 is written.

Proof. The marks of the value c lie in rows $j \le R$, so $c \le R + 1$. The first grow ($72R + 99$ units, Lemma I.17) gives a workspace of $R + 1$ rows; its new row has 0 on track 12 and track 2 still carries 0. rdc ($5 + 11$ units) reaches $(0, 12)$. For $j \le c$ let I_j be the configuration at $(j, 12)$ whose tape is a workspace of $R + 1 + j$ rows with origin marks up to $R + 1 + j$, carries j on track 2 and holds c on track 12. A pass from I_j, $j < c$, scans the mark $(j, 12)$, returns to the root $(18j + 16)$, adds a row $(72(R + 1 + j) + 99)$, advances track 2 $(36j + 48)$ and reads $(j + 1, 12)$ $(18j + 34)$: $72(R+1)+144j+198$ units with its test, ending in I_{j+1}. At I_c the scanned cell is the blank $(c, 12)$. With the final home_{12} $(18c+16)$ the total is $72R+132+72Rc+72c^2+216c \le 2000(R+c+2)^2$. □

The archive of Definition I.60 is read and written through a cursor on track 13. The routines are

$$\begin{aligned}
\mathsf{start} &= \mathsf{cc}_{3\to 13}; \mathsf{inc}_{13}, \qquad \mathsf{rv} = \mathsf{seek}_{13}; \mathsf{shift}_{13\to 4},\\
\mathsf{rd} &= \mathsf{clear}_{12}; \mathsf{rv}; \mathsf{loop}(\mathsf{home}_4; \mathsf{inc}_{12}; \mathsf{inc}_{13}; \mathsf{rv}); \mathsf{home}_4; \mathsf{inc}_{13},\\
\mathsf{term} &= \mathsf{seek}_{13}; \mathsf{shift}_{13\to 3}; \mathsf{write}\,0; \mathsf{home}_3, \qquad \mathsf{init} = \mathsf{grow}; \mathsf{grow}; \mathsf{start}; \mathsf{term},\\
\mathsf{load}_{k,l} &= \mathsf{start}; \mathsf{rd}^k; \mathsf{rd}; \mathsf{cc}_{12\to l}, \qquad \mathsf{prefix}_k = \mathsf{start}; \mathsf{rd}^k,\\
\mathsf{trunc}_k &= \mathsf{start}; \mathsf{rd}^k; \mathsf{term},
\end{aligned}$$

where rd^k is k copies of rd followed by skip; and, for appending,

$$\begin{aligned}\mathsf{sbuf} &= \mathsf{cc}_{13\to 2};\mathsf{cc}_{11\to 6};\mathsf{inc}_6;\mathsf{cc}_{11\to 7};\mathsf{zero}_5,\\ \mathsf{append} &= \mathsf{cc}_{11\to 12};\mathsf{zero}_2;\mathsf{alloc};\mathsf{sbuf};\mathsf{fapp};\mathsf{cc}_{2\to 13},\\ \mathsf{tc} &= \mathsf{right};\mathsf{write}\,0;\mathsf{right};\mathsf{loop}(\mathsf{right}^{16};\mathsf{left};\mathsf{write}\,1;\mathsf{right});\mathsf{right}^2,\\ \mathsf{end} &= \mathsf{seek}_{13};\mathsf{shift}_{13\to 3};\mathsf{scanL};\mathsf{tc};\mathsf{cc}_{2\to 13}, \qquad \mathsf{push} = \mathsf{start};\mathsf{end};\mathsf{append}.\end{aligned}$$

Here fapp is the frame-append routine of Lemma I.39(b), named app there and used here with $a = 0$: from a tape on which track 2 carries w, track 5 carries 0 and a word x lies on the binary stream (tracks 6 and 7 from row 0), with origin marks up to $w + |x|$, it writes x on tracks 3 and 4 from row w, writes 0 in $(w + |x|, 3)$, leaves track 2 carrying $w + |x|$ and track 5 carrying 0, changes no other track and no row before w of tracks 3 and 4, and takes $54|x|^2 + (36w + 184)|x| + 36w + 71$ units.

Lemma I.68 (The archive routines)**.** *Let τ be within R rows and let ω lie on tracks 3 and 4 from row 0. Each routine runs from the root to the root.*

(a) If $|\omega| + 1 \le R$, start makes track 13 hold the value $|\omega| + 1$, within $1000(R + 1)$ units; only track 13 changes.

(b) If track 13 carries a, $\tau(a + j, 4) = 1$ for $j < n$, $\tau(a + n, 4) = 0$ and $a + n + 1 \le R$, then rd makes track 12 hold the value n and track 13 carry $a + n + 1$, within $10000(R + 1)^2$ units; only tracks 12 and 13 change. So rd^k passes k consecutive words $u(n_1)\cdots u(n_k)$ of track 4 within $(k + 1)\cdot 10000(R + 1)^2$ units.

(c) If τ holds an archive within R rows whose entries, numbered from 0, are $v_0, v_1, \ldots$, if it has an entry v_k, and if $5 \le l \le 11$, then $\mathsf{load}_{k,l}$ makes track l hold the value v_k, within $(k + 3)\cdot 20000(R + 1)^2$ units; only tracks 12, 13 and l change.

(d) If track 13 carries $a \le R$, term sets $(a, 3)$ to 0 in $36a + 35$ units.

(e) init leaves the archive $()$ within $R + 2$ rows, with the value $|\omega| + 1$ on track 13; every track $k \ge 4$, $k \ne 13$, that carried a counter at most R still carries it; and its count t satisfies $t + (R + 2) + 2 \le 3000(R + 3)$.

(f) If track 13 carries $w \le R$ and track 11 carries $n \le R$, then append writes the word $u(n)$ on tracks 3 and 4 from row w followed by 0 in $(w + n + 1, 3)$, leaves the rows before w of tracks 3 and 4 and all of track 15 unchanged, makes track 13 hold $w + n + 1$, ends within $R + 1 + n$ rows, keeps every counter at most R on tracks 8 to 11, and takes at most $100000(R + w + n + 3)^2$ units.

(g) If track 13 carries a and a word of length ℓ lies on tracks 3 and 4 from row a, with $a + \ell \le R$, then end makes track 13 hold the value $a + \ell$ within $2000(R + 1)$ units; only tracks 2 and 13 change.

(h) If τ holds the archive $(v_1, \ldots, v_k)$ within R rows, track 11 carries $n \le R$ and track 9 carries $c \le R$, then push leaves the archive $(v_1, \ldots, v_k, n)$ within $R + 1 + n$ rows, track 9 still carrying c, track 10 and track 15 unchanged, within $10^6(R + n + 2)^2$ units.

(i) If τ holds the archive $(v_1, \dots, v_k, w_1, \dots, w_l)$ within R rows, then prefix_k makes track 13 carry $e = |\omega| + 1 + \sum_{j \le k}(v_j + 1)$ and changes only tracks 12 and 13; trunc_k moreover writes 0 in $(e, 3)$, so that the tape holds the archive $(v_1, \dots, v_k)$ within R rows, with the value e on track 13. Each takes at most $(k+3) \cdot 20000(R+1)^2$ units.

Proof. (a) Track 3 carries $|\omega|$. $\mathsf{cc}_{3\to 13}$ costs at most $65R + 35 + 100(|\omega| + 1)$ (Lemma I.66) and inc_{13} costs $36|\omega| + 70$; the sum is at most $201R + 135$. The new hole of track 13 is at row $|\omega| + 1$, and the cells beyond it were blank.

(b) clear_{12} costs $63R + 33$ and rv, from the counter a, $18a + 26$, ending at $(a, 4)$. For $j \le n$ let I_j be the configuration at $(a + j, 4)$ on which track 13 carries $a + j$ and track 12 holds the value j. A pass from I_j, $j < n$, scans a mark, returns to the root $(18(a + j) + 8)$, advances tracks 12 and 13 ($36j + 68$ and $36(a + j) + 70$) and reads the next cell ($18(a + j) + 44$): $72(a + j) + 36j + 191$ units with its test. At I_n the scanned cell is $(a + n, 4) = 0$; home_4 and inc_{13} add $54(a + n) + 78$. Since $a + n < R$ the total is at most $108R^2 + 326R + 138 \le 10000(R + 1)^2$. For rd^k, each copy starts at the first cell of the next word.

(c) start puts the cursor at the first word $u(v_0)$ of the archive, rd^k passes $u(v_0), \dots, u(v_{k-1})$, the next rd leaves v_k on track 12, and $\mathsf{cc}_{12\to l}$ copies it. The archive inequality gives the hypotheses of (a) and (b). The total is at most $1000(R + 1) + (k + 2) \cdot 10000(R + 1)^2 + 300(R + 1)$.

(d) $(18a + 16) + 11 + 1 + (18a + 7)$.

(e) Two rows are added ($144R + 270$ units). The marks of ω lie in rows $j \le R$, so $|\omega| + 1 \le R + 2$, and start ($\le 1000(R + 3)$) and term at row $|\omega| + 1$ ($\le 36(R + 2) + 35$) write the empty word at row $|\omega| + 1$. The sum plus $(R + 2) + 2$ is at most $1181R + 3381$. A counter at most R has its hole in an old row, which grow does not write, and start and term write only track 13 and $(|\omega| + 1, 3)$.

(f) $\mathsf{cc}_{11\to 12}$ and zero_2 prepare Lemma I.67 with $c = n$, which gives $R' = R + 1 + n$ rows; the new rows do not disturb counters whose holes lie in old rows, so track 13 still carries w and track 11 carries n. sbuf makes track 2 hold w, track 6 hold $n + 1$, track 7 hold n and track 5 carry 0: the binary stream is the word $u(n)$ of length $n + 1$. Then fapp writes $u(n)$ from row w with its terminator, and $\mathsf{cc}_{2\to 13}$ copies the new end $w + n + 1 \le R'$. The parts cost at most $300(R+1)+11$, $2000(R+n+2)^2$, $900(R'+1)+36n+73$, $54(n+1)^2+(36w+184)(n+1)+36w+71$ and $300(R' + 1)$, together less than $100000(R + w + n + 3)^2$. Tracks 8 to 11 and 15 are written only in the new rows, and tracks 3 and 4 only from row w.

(g) seek_{13} and $\mathsf{shift}_{13\to 3}$ ($18a + 27$) reach $(a, 3)$; scanL ($18\ell + 1$) reaches the blank $(a + \ell, 3)$. With $h = a + \ell$, tc moves to $(h, 2)$ and blanks it, moves to $(h, 1)$, and then, while the origin mark of the current row is 1, steps to the previous row, writes 1 on track 2 and returns to track 1 (21 units a pass); at the blank $(0, 1)$ it stops and right^2 reaches the root. It costs $21h + 7$ units and leaves track 2 carrying h. $\mathsf{cc}_{2\to 13}$ copies it. The total is at most $204R + 170$.

(h) By (a) and (g), $\mathsf{start}; \mathsf{end}$ puts on track 13 the end $e = |\omega| + 1 + \sum_j (v_j + 1) \le R$ of the archive within $3000(R + 1)$ units, and (f) with $w = e$ appends $u(n)$ there within $100000(2R + n + 3)^2 \le 400000(R + n + 2)^2$ units. The new end is $e + n + 1 \le R + 1 + n$, and the word ω and the old entries, which lie before row e, are kept. Track 9 is a counter of tracks 8 to 11, and no part writes track 10 or 15 outside the new blank rows.

(i) By (a) and (b), within $1000(R+1)+(k+1)\cdot 10000(R+1)^2$ units. term adds $36e+35$ and cuts the archive after its k-th entry; the span only shrinks. $\square$

I.8.3 The payload address and the magnitude bank

The decoding stage of Section I.7 reads the frames of the saved request in order and appends each control number, in unary, to a temporary record on tracks 13 and 14. The front of the schedule runs the same traversal twice more: once over the frames before the payload, to find the payload row p, and once over all frames, writing the magnitude of each payload integer instead of skipping it. We recall the routines and their contracts. A tape is in the *traversal state* $T(v,s,R)$ if it is a workspace of R rows with origin marks up to R, the word v lies on tracks 13 (presence) and 14 (values) from row 0, track 13 is blank from row $|v|$ on, $|v|\le R$, track 11 carries $|v|$, track 5 (the reading cursor) carries s, track 9 is blank and track 8 carries 0. We say that the frame of a natural number n *begins at row* s if the saved request carries the $\mathrm{bl}(n)+1$ bits of n on rows $s,\dots,s+\mathrm{bl}(n)$, with no frame-start mark on rows $s+1,\dots,s+\mathrm{bl}(n)$, followed by a frame-start mark or the end of ω.

Lemma I.69 (The decoding routines)**.** *Let*

$$\mathsf{ini}=\mathsf{clear}_9;\mathsf{clear}_{13};\mathsf{zero}_2;\mathsf{zero}_5;\mathsf{zero}_8;\mathsf{zero}_{11};\mathsf{zero}_{12};\mathsf{skip},$$

and let app, row_a *(*$a=1,2$*) and* fin *be the routines* nat, row_α *and* fin *of Section I.7. Let the tape keep the saved request.*

(a) On a workspace of R rows with origin marks up to R, ini *runs from the root to the root in $122R+172$ units to a tape in $T(\langle\rangle,0,R)$ on which tracks 2 and 12 carry 0.*

(b) If the tape is in $T(v,s,R)$, the frame of n begins at row s and $s+\mathrm{bl}(n)+1\le R$, then app *runs from the root to the root, within $10000\big(s+\mathrm{bl}(n)+1+R+|v|+n+1\big)^2$ units, to a tape in $T\big(vu(n),\ s+\mathrm{bl}(n)+1,\ R+2n+1\big)$ that keeps the saved request, the cells of tracks 2 and 12 in rows $j\le R$ and those of tracks 13 and 14 in rows $j<|v|$.*

(c) Let $a\in\{1,2\}$, and let the frames of ω from row s begin with, for each of d coordinates in turn, the frame of a count k followed by ak frames of natural numbers; let $c_1,\dots,c_g$ be the numbers of these frames and $s'=s+\sum_j(\mathrm{bl}(c_j)+1)$. If the tape is in $T(v,s,R)$, carries on track 14 a retained word of length d from row r_0 with $r_0+d+1\le|v|$, and carries r_0 on track 2, then $\mathsf{repeat}_2(\mathsf{row}_a)$ *runs from the root to the root to a tape in $T\big(vu(c_1)\cdots u(c_g),\ s',\ R+\sum_j(2c_j+1)\big)$ that keeps the saved request and the retained word, with r_0+d on track 2, within*

$$d\big(36(r_0+d)+10^6Z^3+58\big)+36r_0+18d+38$$

units, where $Z=|\omega|+R+|v|+4\sum_j c_j+3g+1$.

(d) If the word $u(n_1)\cdots u(n_k)$ lies on tracks 13 and 14 from row 0, tracks 5 and 8 carry 0, the tape is within R rows and $\sum_j(n_j+1)+k+1\le R$, then fin *runs from the root to the root within $2000(R+1)^2$ units to a tape within R rows that carries $\mathrm{rec}(n_1,\dots,n_k)$ on tracks 9 and 10, with $\tau(0,8)=0$, and keeps tracks 3, 4, 13, 14 and 15.*

Proof. (a) Lemmas I.16 and I.14(d): $(57R+26)+(65R+34)+(11+17+23+29+31)+1$. Track 9 and track 13 are then blank, and tracks 2, 5, 8, 11 and 12 carry 0, which is $T((),0,R)$.

The other parts are results of Section I.7 in the notation of this section. A tape in $T(v,s,R)$ is a reading configuration (v,s,R) (Definition I.47) that is a workspace, and a frame of n that begins at row s is the layout of bits(n), possibly followed by further frames, from row s (Definition I.43). Part (b) is Lemma I.50, whose scale is the one displayed in (b); the tape stays a workspace, since nat writes no cell $x \geq -1$. Part (c) is Lemma I.53 with the retained word and the counter of track 2 starting at row r_0 instead of 0: its proof, Lemma I.18 with $c=2$ from row r_0 and the body bound of Lemma I.52, gives the stated count, and the scale of the numbers read there is at most Z, because the frames read lie in ω. Part (d) is Lemma I.55 with $v = u(n_1)\cdots u(n_k)$ and $L=k$, since $\mathrm{rec}(n_1,\dots,n_k) = u(k)\,u(n_1)\cdots u(n_k)$. □

The magnitude of a payload integer is read by skipping its sign bit.

Lemma I.70 (A signed frame read as its magnitude)**.** *Let* $\mathsf{sapp} = \mathsf{inc}_5;\mathsf{app}$*. If the frame of the payload integer z begins at row s of ω, the tape is in $T(v,s,R)$ and keeps the saved request, and $s+\mathrm{bl}(|z|)+2 \leq R$, then* sapp *runs from the root to the root, within* $10100\,Y^2$ *units with* $Y = s+\mathrm{bl}(|z|)+2+R+|v|+|z|+1$*, to a tape in* $T\big(vu(|z|),\ s+\mathrm{bl}(|z|)+2,\ R+2|z|+1\big)$ *with the same preservation as in Lemma I.69(b).*

Proof. inc_5 ($36s+54$ units) moves the reading cursor to $s+1$ and writes only track 5. The frame of z consists of $[z<0]$ at row s and the $\mathrm{bl}(|z|)+1$ binary digits of $|z|$ on the rows after it, with no frame-start mark before the next frame. So the frame of the natural number $|z|$, in the sense above, begins at row $s+1$, and Lemma I.69(b) applies. Since $36s+54 \leq 100Y^2$, the total is at most $10100Y^2$. □

Lemma I.71 (The payload row)**.** *Let*

$$\mathsf{paddr} = \mathsf{ini};\mathsf{app};\mathsf{repeat}_2(\mathsf{row}_1);\mathsf{zero}_2;\mathsf{repeat}_2(\mathsf{row}_2);\mathsf{app};\mathsf{cc}_{14\to9};\mathsf{cc}_{9\to14},$$
$$\mathsf{Meta} = \mathsf{paddr};\mathsf{cc}_{5\to11};\mathsf{init};\mathsf{append}.$$

Let τ keep the saved request and be within R rows. Let D be the numeric size of the request ($|u|$ plus the sum of the control numbers plus 1*, as in Theorem I.58) and $N = R+D+1$.*

(a) paddr *runs from the root to the root in some t units to a tape within S rows, $R \leq S \leq 2N$, that keeps the saved request, carries the counter p on track* 5 *and holds the value d on track* 14*, and $t+S+1 \leq 4\cdot 10^{12}N^4$. No cell of tracks* 3*,* 4 *and* 15 *changes.*

(b) Meta *runs from the root to the root in some t units to a tape that holds the archive (p) within $R_1 = S+3+p$ rows and keeps the saved request, and $t+R_1+1 \leq 10^{32}N^8$.*

Proof. Every frame of ω is a frame of the request, so $|\omega| \leq |u| \leq D$; there are at most $|u|$ control numbers, and each is at most D. Let $c_1, c_2, \dots$ be the numbers of the frames before the payload: d, the shape numbers and q. Their sum Σ and their count satisfy $2\Sigma + (\text{count}) \leq 2D$.

(a) ini ($122R+172 \leq 300N$ units) gives $T((),0,R)$. The frame of d begins at row 0; app appends $u(d)$, within $10000(R+2D+1)^2 \leq 40000N^2$ units. The record now begins with the retained

word $u(d)$ of length d from row 0, and track 2 carries 0. The next frames are the linear shape group, for each of the d coordinates the count of its A-terms and their indices, so Lemma I.69(c) applies with $a = 1$ and $r_0 = 0$. Throughout the traversal of the prefix the capacity is at most $R + 2\Sigma + (\text{count}) \le R + 2D$, the record has length at most $2D$, and $|\omega| \le D$, so $Z \le 14N$ and the group costs at most $d(36d + 10^6(14N)^3 + 58) + 18d + 38 \le 3.1 \cdot 10^9 N^4$ units. zero_2 (11 units) resets track 2, and the bilinear group is read in the same way with $a = 2$. The last app reads q, within $10000(8N)^2$ units; the reading cursor now stands at the first payload frame, row p. In all at most $7 \cdot 10^9 N^4$ units, and the final capacity is $S = R + 2\Sigma + (\text{count}) \le 2N$, and $S \ge R$. The record begins with $u(d)$, so track 14 carries the counter d; $\mathsf{cc}_{14\to 9}$ and $\mathsf{cc}_{9\to 14}$ ($\le 600(S+1)$ units, Lemma I.66) make it a value. The bound follows. The parts ini, zero_2 and the two copies write only tracks 2, 5, 8, 9, 11, 12, 13 and 14, and app and $\mathsf{repeat}_2(\mathsf{row}_a)$ keep tracks 3, 4 and 15 (Lemmas I.50 and I.53), so no cell of these tracks changes.

(b) $p \le |\omega| \le S$, so $\mathsf{cc}_{5\to 11}$ ($\le 300(S+1)$) puts the value p on track 11. init leaves the archive $()$ within $S + 2$ rows with $|\omega| + 1$ on track 13 and keeps the counter p on track 11, and append with $w = |\omega| + 1$ and $n = p$ leaves the archive (p) within $S + 3 + p$ rows (Lemma I.68(e), (f)). These three parts and the $3 + p$ new rows cost at most $10^6(S+3)^2$. With (a), $t + R_1 + 1 \le 4 \cdot 10^{12} N^4 + 10^6(2N+3)^2 \le 10^{32} N^8$. □

Lemma I.72 (The magnitude bank)**.** *Let*

$$\begin{aligned}\mathsf{Bank} &= \mathsf{grow};\mathsf{ini};\mathsf{app};\big[\mathsf{repeat}_2(\mathsf{row}_1),\mathsf{zero}_2,\mathsf{repeat}_2(\mathsf{row}_2),\mathsf{pay},\\ &\qquad \mathsf{app},\mathsf{app},\mathsf{app},\mathsf{app},\mathsf{app}\big];\mathsf{reset}_5;\mathsf{fin},\\ \mathsf{pay} &= \big[\mathsf{copy}_{11\to 12},\ \mathsf{app},\ \mathsf{repeat}_{12}(\mathsf{sapp})\big].\end{aligned}$$

There is a constant c_B, depending only on the problem, with the following property. If τ keeps the saved request and is within R rows, then Bank *runs from the root to the root in some t units to a tape within $R' = R + 1 + 2\sum_j \mathbf{b}_j + |\mathbf{b}|$ rows that carries the bank, keeps tracks* 3, 4 *and* 15*, and*

$$t + R' + 1 \le c_B(R + m + 1)^3.$$

Proof. grow and ini give $T((), 0, R+1)$ and tracks 2 and 12 carrying 0. The first app and the two group traversals proceed as in Lemma I.71, appending d and the shape numbers. In pay, $\mathsf{copy}_{11\to 12}$ puts on track 12 the current length ℓ of the record (Lemma I.15(a)), and app appends $u(q)$, which is a retained word of length q on track 14 from row ℓ. Lemma I.18 with $c = 12$, $r_0 = \ell$, $n = q$, and R_j the traversal state after $u(|z_1|)\cdots u(|z_j|)$ with the reading cursor at row p_{j+1}, runs sapp once for each payload integer (Lemma I.70): sapp does not change track 12 in the rows of the capacity, nor the retained word, which lies in rows $j < |\nu|$, as the repeat rule requires. The five app read M, T, n_0, i and m. The record is now $u(\mathbf{b}_1)\cdots u(\mathbf{b}_K)$, $K = |\mathbf{b}|$, the capacity is R', and reset_5 ($36|\omega| + 36$ units) returns the reading cursor to 0. There is one frame per bank number, so $K \le |\omega| \le R + 1$, and Lemma I.69(d) applies: fin writes $\mathrm{rec}(\mathbf{b})$ on tracks 9 and 10. No part writes tracks 3, 4 or 15.

For the count let G be $|\mathbf{b}|$ plus the sum of the bank numbers other than m plus the number of bits of the frames of ω other than that of m; G depends only on the problem, and $|\omega| \le G + m + 1$. During the traversal every reading position is at most $|\omega|$, every record length at most $G+m+1$, every capacity at most $R + 1 + 3G + 2m$ and every appended number at most $G + m$. Hence

the argument Y of each of the at most G appends (Lemma I.69(b) and Lemma I.70) is at most $c(R+m+1)$ with $c = 7G+6$, and each costs at most $10100c^2(R+m+1)^2$; in each group traversal $Z \le c'(R+m+1)$ with $c' = 12G+8$, so each costs at most $(10^6c'^3d+72d^2+76d+38)(R+m+1)^3$; the repeat over the payload adds at most $q(36(2G+q)+58)+72G+18q+38$ besides its bodies; and grow, ini, zero_2, $\mathsf{copy}_{11\to12}$, reset_5 and fin, together with $R'+1$, cost at most $3000(R'+1)^2 \le 3000c^2(R+m+1)^2$, because $R'+1 \le R+2+3G+2m$. All these coefficients depend only on the problem, and $(R+m+1)^2 \le (R+m+1)^3$; their sum is the constant c_B. □

Two bounds of this shape compose with a product of exponents.

Lemma I.73 (Composing schedule bounds)**.** *Let $a, b \ge 1$ and $x, y, z, t, u, K, L \in \mathbb{N}$. If $t+y+2 \le K(x+2)^a$ and $u+z+2 \le L(y+2)^b$, then*

$$t+u+z+2 \le (K+LK^b)(x+2)^{ab}.$$

Proof. $y+2 \le K(x+2)^a$, so $(y+2)^b \le K^b(x+2)^{ab}$ and $u+z+2 \le LK^b(x+2)^{ab}$. Also $t \le K(x+2)^a \le K(x+2)^{ab}$, because $a \le ab$ and $x+2 \ge 1$. Add. □

The variable x will be the rows in use plus the precision m: the bound of a stage is then a polynomial in $r+m+2$, and m enters only there.

Proof of Theorem I.62(a). Let τ be a prepared request with r rows. It keeps the saved request and is within r rows. By Lemma I.71(b), Meta ends within r_1 rows with the archive (p) and $t_1 + r_1 + 1 \le 10^{32}N^8$, $N = r + D + 1$. By Theorem I.58, $D \le c_{\mathrm{num}}X$ with a constant c_{num} depending only on the problem, and $X = m + n_0 + \kappa + 1 \le (n_0+\kappa+2)(r+m+2)$; so $N \le c_M(r+m+2)$ with $c_M = c_{\mathrm{num}}(n_0+\kappa+2)+1$. Since $m+1 \le (r+m+2)^8$,

$$t_1 + (r_1+m) + 2 \le A(r+m+2)^8, \qquad A = 10^{32}c_M^8 + 2.$$

Bank starts within r_1 rows and keeps tracks 3, 4 and 15, so the archive (p) and the saved request survive, and by Lemma I.72 it ends within r' rows with the bank on tracks 9 and 10 and $t_2 + (r'+m) + 2 \le B(r_1+m+2)^3$, $B = c_B + 2$. Lemma I.73 with $x = r+m$, $y = r_1+m$, $z = r'+m$, $a = 8$ and $b = 3$ gives the bound with $K_1 = A + BA^3$ and exponent 24. □

I.8.4 Reading the bank

Many loops of the folds run a body once for each unit of a counter and count the counter down. One lemma covers them.

Lemma I.74 (Counting a counter down)**.** *For a track $k \in \{2, \dots, 15\}$ and a program P put*

$$\mathsf{down}_k(P) = \mathsf{left}^{k+1}; \mathsf{loop}(\mathsf{home}_k; P; \mathsf{retr}_k; \mathsf{left}^{k+1}); \mathsf{home}_k,$$
$$\mathsf{down}_k^{\circ}(P) = \mathsf{left}^{k+1}; \mathsf{loop}(\mathsf{home}_k; \mathsf{retr}_k; P; \mathsf{left}^{k+1}); \mathsf{home}_k.$$

Let $n \in \mathbb{N}$, let $J_0, \dots, J_n$ be properties of tapes such that every tape with J_j has origin marks up to n and carries the counter j on track k, and let $b_1, \dots, b_n \in \mathbb{N}$.

(a) *Suppose that for $1 \le j \le n$, from every tape τ with J_j, P runs from the root within b_j units to the root and a tape that agrees with τ on the cells (i,k), $i \le j$, and has J_{j-1} once $(j-1,k)$ is set to 0. Then $\mathsf{down}_k(P)$ runs from every tape with J_n to a tape with J_0 within $\sum_{j\le n}(b_j + 36n + 4k + 14) + 2k + 7$ units.*

(b) *Suppose that for $1 \le j \le n$, from every tape τ with J_j, P runs from the root and τ with $(j-1,k)$ set to 0 within b_j units to the root and a tape with J_{j-1}. Then $\mathsf{down}^\circ_k(P)$ has the same bound.*

Proof. left^{k+1} ($k+2$ units) reaches $(0,k)$, which holds 1 exactly when the counter is positive. Let I_j be the configurations at $(0,k)$ whose tape has J_{n-j}. A pass from I_j, $j < n$, tests the mark (1), returns to the root ($k+4$), runs P ($\le b_{n-j}$) and retr_k ($36(n-j-1)+2k+43$, Lemma I.66(b)) in the order of the program, and goes back to $(0,k)$ ($k+2$): at most $b_{n-j} + 36n + 4k + 14$ units, ending in I_{j+1}. At I_n the counter is 0 and the test fails (1). Lemma I.6, with the final home_k ($k+4$), gives the bound. □

The bank word $\mathrm{rec}(\mathbf{b}) = u(K)\,u(\mathbf{b}_1)\cdots u(\mathbf{b}_K)$, $K = |\mathbf{b}|$, is read on track 10 with a cursor on track 2. Put $e_0 = K$ and $e_j = e_{j-1} + \mathbf{b}_j + 1$: the word $u(\mathbf{b}_j)$ occupies the rows $e_{j-1}+1, \dots, e_j$ and ends with the blank $(e_j, 10)$. The cursor stands *after entry j* if track 2 carries e_j. With a bank view within R rows, $|\mathrm{rec}(\mathbf{b})| = e_K + 1 \le R + 1$, so every e_j is at most R. The entries are, in order: $\mathbf{b}_1 = d$; the linear shape group, for each coordinate i the count k_i^A of its A-terms followed by their k_i^A indices; the bilinear shape group, for each i the count k_i^B followed by $2k_i^B$ indices; q; the magnitudes $|z_1|, \dots, |z_q|$; and M, T, n_0, i, m. The *weight* of a list of rows of a shape group is the sum of $k+1$ over its rows; let w_A and w_B be the weights of the two groups.

Lemma I.75 (Words of the bank)**.** *Let*

$$\begin{aligned}
\mathsf{fprobe} &= \mathsf{seek}_2;\mathsf{shift}_{2\to10}, \qquad \mathsf{fstep} = \mathsf{home}_{10};\mathsf{inc}_{11};\mathsf{inc}_2;\mathsf{fprobe},\\
\mathsf{fword} &= \mathsf{clear}_{11};\mathsf{inc}_2;\mathsf{fprobe};\mathsf{loop}(\mathsf{fstep});\mathsf{home}_{10},\\
\mathsf{head} &= \mathsf{clear}_{2,11};\mathsf{fprobe};\mathsf{loop}(\mathsf{fstep});\mathsf{home}_{10}, \qquad \mathsf{dim} = \mathsf{head};\mathsf{fword},\\
\mathsf{wskip} &= \mathsf{down}_{14}(\mathsf{fword}), \qquad \mathsf{eskip}^a = \mathsf{down}_{14}(\mathsf{fword}^a),\\
\mathsf{srow}^{g,a} &= \mathsf{fword};\mathsf{gacc}^g;\mathsf{cc}_{11\to14};\mathsf{eskip}^a,\\
\mathsf{srows}^{g,a} &= \mathsf{down}_{13}(\mathsf{srow}^{g,a}), \qquad \mathsf{blk}^a = \mathsf{cc}_{6\to13};\mathsf{srows}^{0,a},
\end{aligned}$$

where fword^a is a copies of fword and skip, $\mathsf{gacc}^1 = \mathsf{acc}^6_{11\to5}$ and $\mathsf{gacc}^0 = \mathsf{skip}$. Let τ be within R rows with a bank view. All routines run from the root to the root.

(a) *If the cursor carries x, $(x+1+i, 10) = 1$ for $i < n$, $(x+1+n, 10) = 0$ and $x+n+1 \le R$, then fword leaves the value n on track 11 and the cursor at $x+n+1$, within $10000(R+1)^2$ units; only tracks 2 and 11 change. So from the cursor after entry j it reads $\mathbf{b}_{j+1}$ and leaves the cursor after entry $j+1$; fword^a reads a entries within $(a+1)\cdot 11000(R+1)^2$ units.*

(b) head *leaves the cursor after entry 0 and K on track 11 within $10000(R+1)^2$ units;* dim *leaves it after entry 1 and the value d on track 11, within $20000(R+1)^2$ units.*

(c) *If the cursor stands after entry j, track 14 carries c and $j + c \le K$, then wskip leaves the cursor after entry $j+c$ and the counter 0 on track 14, within $(c+1)\cdot 12000(R+1)^2$ units; only tracks 2, 11 and 14 change.*

(d) Let $a \in \{1,2\}$, let the entries after entry j begin with n rows of a shape group of arity a, with counts $k_1, \dots, k_n$ and weight $w = \sum_i (k_i + 1)$, let track 13 carry n, and if $g = 1$ let track 5 carry s with $s + \sum_i k_i \le R$. Then $\mathsf{srows}^{g,a}$ *leaves the cursor after these rows, the counter 0 on track 13 and, if $g = 1$, the counter $s + \sum_i k_i$ on track 5, within $(w+1)(a+1)\cdot 60000(R+1)^2$ units; only tracks 2, 11, 13, 14, and if $g = 1$ also 5 and 6, change. If track 6 carries n,* blk^a *does the same with $g = 0$, within $((w+1)(a+1)\cdot 60000 + 1000)(R+1)^2$ units.*

Proof. (a) clear_{11} $(61R+31)$, inc_2 $(36x+48)$ and fprobe $(18x+32)$ reach $(x+1, 10)$ with track 11 blank. For $i \le n$ let I_i be the configuration at $(x+1+i, 10)$ on which the cursor carries $x+1+i$ and track 11 holds i. A pass from I_i, $i < n$, scans a mark and costs $72(x+1+i) + 36i + 161$ units with its test (Lemmas I.11 and I.14), ending in I_{i+1}; at I_n the cell is blank, and home_{10} adds $18(x+1+n) + 14$. With $x + 1 + n \le R$ the total is at most $108R^2 + 294R + 126 \le 10000(R+1)^2$. The counter on track 2 ends at the blank $x+n+1$, as claimed. For fword^a, $a \cdot 10000(R+1)^2 + 1$.

(b) $\mathsf{clear}_{2,11}$ $(104R + 43)$ and fprobe (14) reach $(0, 10)$, and the same loop counts the K marks of $u(K)$; the total is at most $108R^2 + 283R + 72$. dim adds one fword.

(c) Lemma I.74(a) with $k = 14$, $n = c$, J_j the tapes with the cursor after entry $j_0 + c - j$ (j_0 the initial entry) and j on track 14, and $b_j = 10000(R+1)^2$, since fword does not write track 14: at most $c(10000(R+1)^2 + 36c + 70) + 35$ units.

(d) By (a), fword^a reads one entry of a row; eskip^a skips the k entries of a row of arity a by Lemma I.74(a), within $k((a+1)11000(R+1)^2 + 36k + 70) + 35 \le (k+1)(a+1)13000(R+1)^2$ units. $\mathsf{srow}^{g,a}$ reads the count k of a row (fword), adds it to track 5 when $g = 1$ ($\mathsf{acc}^6_{11\to 5}$, at most $500(R+1)^2$ by Lemma I.15(b), since $s + \sum_i k_i \le R$), puts it on track 14 ($\mathsf{cc}_{11\to 14}$) and skips the row's entries: at most $(k+1)(a+1)\cdot 40000(R+1)^2$ units, leaving the cursor after the row and track 13 untouched. Lemma I.74(a) with $k = 13$ and $b_i = (k_i+1)(a+1)40000(R+1)^2$ gives at most $\sum_i \big((k_i+1)(a+1)40000(R+1)^2 + 36n + 66\big) + 33$, which is at most $(w+1)(a+1)60000(R+1)^2$ because $n \le w$. blk^a adds $\mathsf{cc}_{6\to 13}$. □

A *row* of the field is a list of coefficients that the folds treat together: the A-coefficients of a coordinate j, its B-coefficients, its constant c_j, or all the constants $c_0, \dots, c_{d-1}$. Its k coefficients are consecutive in the payload: they are the integers $z_{o+1}, \dots, z_{o+2k}$, numerator and denominator in turn, with

$$o = 4d + 2P_j^A, \quad o = 4d + 2P_j^B, \quad o = 2d + 2j, \quad o = 2d$$

respectively, where $P_j^A = \sum_{i<j} k_i^A$ and $P_j^B = \sum_i k_i^A + \sum_{i<j} k_i^B$ count the coefficients that precede the row in the A-block and in the B-block. Let $h = 2 + \sum_i (1 + k_i^A) + \sum_i (1 + 2k_i^B)$ be the index of the entry q; the magnitudes of the row are the entries $h + o + 1, \dots, h + o + 2k$. The pairs of a row are *ready* if tracks 7 and 14 hold the value k and the cursor carries $e_{h+o+2k} - 1$ when $k \ge 1$ (the last mark of the word of the row's last denominator, which is positive) and e_{h+o} when $k = 0$.

Lemma I.76 (Selecting a row)**.** *Let*

$$\begin{aligned}
\mathsf{pbank} &= \mathsf{dim};\mathsf{cc}_{11\to 6};\mathsf{blk}^1;\mathsf{blk}^2;\mathsf{fword},\\
\mathsf{coff} &= \mathsf{clear}_{14};\mathsf{acc}_6^{\times 4};\mathsf{acc}_5^{\times 2}, \qquad \mathsf{twice} = \mathsf{clear}_{14};\mathsf{acc}_7^{\times 2},\\
\mathsf{pend} &= \mathsf{pbank};\mathsf{coff};\mathsf{wskip};\mathsf{twice};\mathsf{wskip},\\
\mathsf{gcur}^a &= \mathsf{cc}_{9\to 13};\mathsf{srows}^{1,a};\mathsf{fword};\mathsf{cc}_{11\to 7},\\
\mathsf{cont} &= \mathsf{branch}(\mathsf{skip},\ \mathsf{home}_{14};\mathsf{retr}_2;\mathsf{left}^{15}),\\
\mathsf{brow} &= \mathsf{cc}_{7\to 14};\mathsf{left}^{15};\mathsf{cont};\mathsf{home}_{14},
\end{aligned}$$

where $\mathsf{acc}_k^{\times n}$ *is* n *copies of* $\mathsf{acc}_{k\to 14}^{11}$ *followed by* skip*; and*

$$\begin{aligned}
\mathsf{sel}_A &= \mathsf{clear}_5;\mathsf{dim};\mathsf{gcur}^1;\mathsf{pend};\mathsf{brow},\\
\mathsf{sel}_B &= \mathsf{clear}_5;\mathsf{dim};\mathsf{cc}_{11\to 13};\mathsf{srows}^{1,1};\mathsf{gcur}^2;\mathsf{pend};\mathsf{brow},\\
\mathsf{csel}^\varepsilon &= \mathsf{clear}_5;\mathsf{pbank};\mathsf{cnt}^\varepsilon;\mathsf{clear}_{14};\mathsf{acc}_6^{\times 2};\mathsf{acc}_9^{\times 2\varepsilon};\\
&\qquad \mathsf{wskip};\mathsf{twice};\mathsf{wskip};\mathsf{brow} \qquad (\varepsilon = 0, 1),
\end{aligned}$$

with $\mathsf{cnt}^1 = \mathsf{clear}_7;\mathsf{inc}_7$ *and* $\mathsf{cnt}^0 = \mathsf{cc}_{6\to 7}$*. Let* τ *be within* R *rows with a bank view, and for* sel_A*,* sel_B *and* csel^1 *let track* 9 *carry* $j < d$*. Every routine runs from the root to the root, writes only tracks* 2*,* 5*,* 6*,* 7*,* 11*,* 13 *and* 14*, and ends within* R *rows with the bank view.*

(a) pbank *leaves the cursor after entry* h *(that of* q*) and the value* d *on track* 6*, does not change track* 5*, and takes at most* $c_p(R+1)^2$ *units,* $c_p = (w_A+1)\cdot 120000 + (w_B+1)\cdot 180000 + 40000$*.*

(b) sel_A *makes the pairs of the A-row of coordinate* j *ready and leaves* P_j^A *on track* 5*;* sel_B *does the same for the B-row, with* P_j^B *on track* 5*. Each takes at most* $(c_s + 1000)(R+1)^2$ *units,* $c_s = c_p + (w_A+1)\cdot 120000 + (w_B+1)\cdot 180000 + 12000(q+2) + 100000$*.*

(c) csel^0 *makes the pairs of the row of all constants ready, and* csel^1 *those of the row of* c_j*; each takes at most* $c_c(R+1)^2$ *units,* $c_c = c_p + 12000(q+2) + 20000$*, which is less than* c_s*.*

Proof. (a) dim puts the cursor after entry 1 and d on track 11, which $\mathsf{cc}_{11\to 6}$ copies to track 6. The two calls of blk pass the d rows of the linear and of the bilinear group (Lemma I.75(d)), and fword reads q. The costs are $20000(R+1)^2$, $300(R+1)$, $((w_A+1)120000 + 1000)(R+1)^2$, $((w_B+1)180000 + 1000)(R+1)^2$ and $10000(R+1)^2$.

(b) For sel_A: clear_5 blanks track 5; dim puts the cursor after entry 1; in gcur^1, $\mathsf{cc}_{9\to 13}$ puts j on track 13, $\mathsf{srows}^{1,1}$ passes the first j rows of the linear group and adds their counts to track 5, so that it carries P_j^A, and fword and $\mathsf{cc}_{11\to 7}$ read the count $k = k_j^A$ of row j onto track 7. Then pend resets the cursor to the entry of q; coff puts $4d + 2P_j^A = o$ on track 14 by six additions, each at most $500(R+1)^2 + 1$ units (Lemma I.15(b); all these numbers are entries of the bank or sums of them, at most R); wskip passes the o payload entries before the row, twice puts $2k$ on track 14, and wskip passes the $2k$ entries of the row: the cursor now carries e_{h+o+2k}. Finally brow copies k to track 14 and, if $k \geq 1$, steps the cursor back by one cell (cont scans $(0, 14)$, which is 1 exactly when $k \geq 1$). For sel_B the first $\mathsf{srows}^{1,1}$ passes all d rows of the linear group, adding $\sum_i k_i^A$ to track 5, and gcur^2 passes j rows of the bilinear group. The bounds of Lemma I.75 give at most $((w_A+1)120000 + (w_B+1)180000 + 50000)(R+1)^2$ for the

part before pend, at most $(c_p + 12000(o + 2k + 2) + 10000)(R + 1)^2$ for pend (with $o + 2k \le q$), and $1000(R + 1)^2$ for brow.

(c) pbank puts d on track 6 and the cursor at the entry of q; $\mathsf{cnt}^{\varepsilon}$ puts $k = 1$ or $k = d$ on track 7; the four or six additions put $o = 2d + 2\varepsilon j$ on track 14; and the rest proceeds as in (b). Besides $c_p(R + 1)^2$ for pbank and $12000(o + 2k + 2)(R + 1)^2$ for the two skips, the parts cost at most $5468(R + 1)^2$, and $o + 2k \le q$. □

I.8.5 Frame widths and unary arithmetic

The capacities s and s_0 count binary digits, and these are read off the saved request itself: the frame of an integer z has $\mathrm{bl}(|z|) + 2$ bits, so its length minus two is $\mathrm{bl}(|z|)$. A cursor on track 5 walks along ω and a flag on track 12 records whether the current cell still belongs to the same frame.

Lemma I.77 (Frame widths)**.** *Let*

$$\begin{aligned}
\mathsf{probe} &= \mathsf{branch}\big(\mathsf{left}^9; \mathsf{write}\,0; \mathsf{right}^3; \mathsf{left}^3,\\
&\qquad \mathsf{left}^{12}; \mathsf{branch}(\mathsf{right}^3; \mathsf{write}\,1,\ \mathsf{right}^3; \mathsf{write}\,0)\big),\\
\mathsf{wprobe} &= \mathsf{seek}_5; \mathsf{right}; \mathsf{right}; \mathsf{probe}, \qquad \mathsf{wstep} = \mathsf{home}_{12}; \mathsf{inc}_{13}; \mathsf{inc}_5; \mathsf{wprobe},\\
\mathsf{wspan} &= \mathsf{wprobe}; \mathsf{loop}(\mathsf{wstep}); \mathsf{home}_{12}, \qquad \mathsf{fw} = \mathsf{inc}_5; \mathsf{inc}_5; \mathsf{wspan},\\
\mathsf{rfw} &= \mathsf{fw}; \mathsf{fw}, \qquad \mathsf{skip1} = \mathsf{clear}_{13}; \mathsf{fw}, \qquad \mathsf{fskip} = \mathsf{down}_{14}(\mathsf{skip1}).
\end{aligned}$$

Let τ keep the saved request and be within R rows.

(a) From $\mathrm{cell}(x, 3)$, probe *runs in* 20 *units to* $\mathrm{cell}(x, 12)$ *and sets* $(x, 12)$ *to* 1 *if* $(x, 3) = 1$ *and* $(x, 15) = 0$*, and to* 0 *otherwise. If track* 5 *carries* x*,* wprobe *runs from the root in* $18x + 30$ *units to* $\mathrm{cell}(x, 12)$ *with the same effect.*

(b) Let track 5 *carry* x *and track* 13 *hold the value* v*. Let the rows* $x, \dots, x + n - 1$ *belong to* ω *and carry no frame-start mark, and let row* $x + n$ *carry a frame-start mark or lie after* ω*, with* $x + n \le R$ *and* $v + n \le R$*. Then* wspan *runs from the root to the root within* $(18x + 30) + n(300(R + 1) + 1) + 1 + 18(x + n) + 16$ *units, leaving the counter* $x + n$ *on track* 5 *and the value* $v + n$ *on track* 13*; only tracks* 5*,* 12 *and* 13 *change.*

(c) If the frame of an integer z *begins at row* x*, track* 5 *carries* x*, track* 13 *holds* v*,* $x + \mathrm{bl}(|z|) + 2 \le R$ *and* $v + \mathrm{bl}(|z|) \le R$*, then* fw *adds* $\mathrm{bl}(|z|)$ *to the value on track* 13 *and moves the cursor to* $x + \mathrm{bl}(|z|) + 2$*, within* $1000(R + 1)^2$ *units. For a coefficient* $q = u/e$ *whose two frames begin at row* x*,* rfw *adds* $\mathrm{cap}(q) = \mathrm{bl}(|u|) + \mathrm{bl}(e)$ *to track* 13 *and moves the cursor past both frames, within* $2000(R + 1)^2$ *units, and* $\mathsf{skip1}$ *moves the cursor past one frame within* $2000(R + 1)^2$ *units.*

(d) If track 14 *holds the value* c *and the frames of* c *payload integers begin at the cursor,* fskip *moves the cursor past them and leaves* 0 *on track* 14*, within* $(c + 1) \cdot 4000(R + 1)^2$ *units.*

Proof. (a) On a blank $(x, 3)$ the first branch reaches $(x, 12)$ in 10 units, writes 0, and moves three cells and back; on a mark it moves to $(x, 15)$ (13 units), branches on the frame-start mark

and writes the flag three cells to the right. With the tests, 20 units either way. seek_5 costs $18x + 8$ and the two moves 2.

(b) For $i \le n$ let I_i be the configuration at $(x+i, 12)$ on which track 5 carries $x+i$, track 13 holds $v+i$, and $(x+i, 12)$ holds the flag of row $x+i$. By (a) the flag is 1 for $i < n$ and 0 for $i = n$. A pass from I_i, $i < n$, returns to the root $(18(x+i)+16)$, advances tracks 13 and 5 $(36(v+i)+70$ and $36(x+i)+54)$ and probes the next row $(18(x+i+1)+30)$: $72(x+i)+36(v+i)+188 \le 300(R+1)$ units, ending in I_{i+1}. Lemma I.6 and the final home_{12} give the bound.

(c) The frame of z occupies rows $x, \dots, x+\mathrm{bl}(|z|)+1$, and only row x carries a frame-start mark. The two increments $(36x+54+36x+90$ units) put the cursor at $x+2$, and (b) with $n = \mathrm{bl}(|z|)$ counts the remaining rows of the frame. The total is at most $300R^2+427R+271 \le 1000(R+1)^2$. rfw applies this to the frame of u and then to that of e, which begins where the first ends. For $\mathsf{skip1}$ add clear_{13}.

(d) Lemma I.74(a) with $k = 14$, $n = c$ and $b_j = 2000(R+1)^2$; $\mathsf{skip1}$ does not write track 14. The bound is $c(2000(R+1)^2 + 36c + 70) + 35$. □

Division with rounding up works on unary values: the dividend is walked mark by mark, a remainder counter is advanced, and each time it reaches the divisor it is reset and the quotient grows by one mark.

Lemma I.78 (Ceilings of quotients). *Let* $\mathsf{rcol}_{k,l} = \mathsf{seek}_k; \mathsf{shift}_{k\to l}$ *and*

$$\begin{aligned}
\mathsf{dbody} &= \big[\mathsf{home}_{11}, \mathsf{inc}_2, \mathsf{inc}_5, \mathsf{rcol}_{5,12},\\
&\qquad \mathsf{branch}\big([\mathsf{home}_{12}, \mathsf{reset}_5, \mathsf{mark}_6],\ \mathsf{home}_{12}\big),\ \mathsf{rcol}_{2,11}\big],\\
\mathsf{udiv} &= \big[\mathsf{rcol}_{2,11}, \mathsf{loop}(\mathsf{dbody}), \mathsf{home}_{11}\big],\\
\mathsf{bump} &= \mathsf{left}^6; \mathsf{branch}(\mathsf{right}^6,\ \mathsf{right}^6; \mathsf{mark}_6), \qquad \mathsf{ceil} = \mathsf{udiv}; \mathsf{bump}.
\end{aligned}$$

Let τ have origin marks up to R, hold the value a on track 11 and the value b on track 12, with $1 \le b \le R$ and $a+1 \le R$, carry 0 on tracks 2, 5 and 6, and have track 7 blank. Then udiv *runs from the root to the root within $1000(a+b+1)^2$ units, leaving the value $\lfloor a/b \rfloor$ on track 7, the counter $\lfloor a/b \rfloor$ on track 6 and the counter $a \bmod b$ on track 5.* ceil *runs within $1200(a+b+1)^2$ units and leaves the value $\lceil a/b \rceil$ on track 7. Only tracks 2, 5, 6 and 7 change.*

Proof. $\mathsf{rcol}_{2,11}$ (15 units) reaches $(0, 11)$. For $j \le a$ let I_j be the configuration at $(j, 11)$ on which track 2 carries j, track 5 carries $\varrho = j \bmod b$, track 6 carries $\theta = \lfloor j/b \rfloor$ and track 7 holds the value θ. A pass from I_j, $j < a$, scans a mark of the dividend, returns to the root, advances tracks 2 and 5, and reads $(\varrho+1, 12)$, which is 1 exactly when $\varrho + 1 < b$. In that case it returns ($72j + 72\varrho + 220$ units in all). Otherwise $\varrho + 1 = b$: it resets track 5 to 0 and mark_6 writes 1 in $(\theta, 7)$ and advances track 6 ($72j + 108\varrho + 36\theta + 354$ units). Then it reads $(j+1, 11)$. Since $j + 1 = \theta b + \varrho + 1$, the pass ends in I_{j+1} (Lemmas I.11 and I.14; the origin marks reach b and $a+1$). At I_a the scanned cell is the blank $(a, 11)$. With $\varrho < b$ and $\theta \le a$ each pass costs at most $108a + 108b + 355$ units with its test, and with the final home_{11} and the list the total is at most $108a^2 + 108ab + 373a + 32 \le 1000(a+b+1)^2$. bump reads $(0, 5)$, which is 1 exactly when $a \bmod b \ne 0$, and then adds one mark to the quotient: 15 or $36\lfloor a/b \rfloor + 76$ units. So track 7 holds $\lfloor a/b \rfloor + [a \bmod b \ne 0] = \lceil a/b \rceil$. □

Lemma I.79 (Maximum of two values)**.** *Let A, B, C and F be distinct tracks with $C, F \geq 2$, and put*

$$\begin{aligned} \mathsf{em}_k(b) &= \mathsf{shift}_{k\to F}; \mathsf{write}\, b, \\ \mathsf{mprobe} &= \mathsf{shift}_{F\to A}; \mathsf{branch}\big(\mathsf{shift}_{A\to B}; \mathsf{branch}(\mathsf{em}_B(0), \mathsf{em}_B(1)),\ \mathsf{em}_A(1)\big), \\ \mathsf{max}^{F}_{A,B\to C} &= \mathsf{zero}_C; \mathsf{left}^{F+1}; \mathsf{mprobe}; \mathsf{loop}(\mathsf{shift}_{F\to C}; \mathsf{next}; \mathsf{shift}_{C\to F}; \mathsf{mprobe}); \\ &\qquad \mathsf{home}_F. \end{aligned}$$

If tracks A and B hold the values a and b and the tape has origin marks up to $R \geq \max(a,b)$, then $\mathsf{max}^{F}_{A,B\to C}$ runs from the root to the root within $400(a+b+1)$ units, after which track C carries $\max(a,b)$; only tracks C and F change, in rows $j \leq \max(a,b)$.

Proof. From (j,F), mprobe writes in (j,F) the bit $\tau(j,A) \vee \tau(j,B)$ and returns to (j,F), within 52 units: at most three shifts of at most 16 units, two tests and one write. Because A and B hold values, this bit is 1 exactly when $j < M = \max(a,b)$. zero_C $(2C+7)$ and left^{F+1} $(F+2)$ lead to $(0,F)$, where the first probe is made. Let I_j be the configuration at (j,F) with the flag of row j written and the counter j on track C. A pass from I_j, $j < M$, moves to the hole (j,C), advances it by next (20 units), returns to track F in row $j+1$ and probes it: at most 105 units with its test. At I_M the flag is 0. home_F from row M adds $18M + F + 4$. The total is at most $123M + 2C + 2F + 66 \leq 400(a+b+1)$. □

The fold routines use $\mathsf{max}^{12}_{7,13\to 11}$, $\mathsf{max}^{12}_{11,13\to 7}$ and $\mathsf{max}^{14}_{11,12\to 8}$; the last also serves the schedule tail of Section I.9.

I.8.6 One row at a time

The folds call, for one coordinate j at a time, a program that computes a number of the row of j and leaves it on track 11; track 9 holds the index j.

Definition I.80 (Row readers)**.** Let f map $\{0,\dots,d-1\}$ to $\mathbb{N}$ and let $K \in \mathbb{N}$. A program P is a *row reader* for f with constant K if, for every $j < d$ and every tape in the gather state (with any archive and any number R of rows) on which track 9 carries j, P runs from the root to the root within $K(R+1)^3$ units to a tape within R rows on which track 11 carries $f(j)$, $f(j) \leq R$, track 9 still carries j, and tracks 3, 4, 10 and 15 are unchanged.

A row reader keeps the gather state: the archive and the frame-start marks lie on tracks 3, 4 and 15, and the bank view on track 10. Every number it computes below is at most the sum of the bank entries, which is less than $|\operatorname{rec}(\mathbf{b})| \leq R+1$; so the hypotheses "value at most R" of the routines are met.

Lemma I.81 (Summing and maximizing over a row)**.** *Let*

$$\begin{aligned}
\mathsf{bword} &= \mathsf{clear}_{11};\mathsf{seek}_{2};\mathsf{left}^{8};\mathsf{tail},\\
\mathsf{pair} &= \mathsf{bword};\mathsf{cc}_{11\to12};\mathsf{retr}_{2};\mathsf{bword};\mathsf{cc}_{2\to8};\mathsf{clear}_{2,5,6,7};\mathsf{ceil},\\
\mathsf{pbody} &= \mathsf{home}_{14};\mathsf{pair};\mathsf{acc}^{2}_{7\to13};\mathsf{cc}_{8\to2};\mathsf{retr}_{14};\mathsf{left}^{15};\mathsf{cont},\\
\mathsf{prow} &= \mathsf{clear}_{13};\mathsf{left}^{15};\mathsf{loop}(\mathsf{pbody});\mathsf{home}_{14};\mathsf{cc}_{13\to11};\mathsf{cc}_{11\to13},\\
\mathsf{crow} &= \mathsf{prow};\mathsf{cc}_{13\to11}, \qquad \mathsf{pmax} = \mathsf{pair};\mathsf{max}^{12}_{7,13\to11};\mathsf{cc}_{11\to13};\mathsf{cc}_{8\to2},\\
\mathsf{gbody} &= \mathsf{home}_{14};\mathsf{pmax};\mathsf{retr}_{14};\mathsf{left}^{15};\mathsf{cont},\\
\mathsf{gam} &= \mathsf{clear}_{13};\mathsf{left}^{15};\mathsf{loop}(\mathsf{gbody});\mathsf{home}_{14}.
\end{aligned}$$

Let τ be within R rows with a bank view.

(a) Let $(x,10)=0$, $(x+i,10)=1$ for $1\le i\le a$, $(x+a+1,10)=0$ and $(x+a+1+i,10)=1$ for $1\le i\le b$, with $b\ge1$, and let the cursor carry $x+a+1+b\le R$: the words $u(a)\,u(b)$ follow the blank $(x,10)$, and the cursor is on the last mark of $u(b)$. Then pair *runs from the root to the root within $3000(R+1)^2$ units, leaving the value $\lceil a/b\rceil$ on track 7 and the value x on track 8; only tracks 2, 5, 6, 7, 8, 11 and 12 change.*

(b) Let the pairs of a row with coefficients $q_1,\dots,q_k$ be ready, with $k\le R$ and $\Sigma=\sum_l\lceil|q_l|\rceil\le R$. Then prow *and* crow *leave the value Σ on tracks 11 and 13, and* gam *leaves the value $\Gamma=\max_l\lceil|q_l|\rceil$ on track 13 ($\Gamma=0$ if $k=0$); each takes at most $22000(R+1)^3$ units and changes only tracks 2, 5, 6, 7, 8, 11, 12, 13 and 14.*

Proof. (a) The first bword blanks track 11, goes to the cursor and steps to track 10 ($61R+31+18(x+a+1+b)+5+9$ units), and Lemma I.64 with $s=x+a+1$ and $n=b$ leaves the value b on track 11 and the cursor at $x+a+1$, within $b(36R+113)+1+18R+14$ units. $\mathsf{cc}_{11\to12}$ saves b on track 12, retr_2 moves the cursor to $x+a$, and the second bword reads a in the same way, leaving the cursor at x, which $\mathsf{cc}_{2\to8}$ saves on track 8. $\mathsf{clear}_{2,5,6,7}$ ($196R+73$ units) prepares Lemma I.78, whose hypotheses hold because $b\ge1$ and $a+1\le R$; it leaves $\lceil a/b\rceil$ on track 7 within $1200(R+1)^2$ units. With the two copies and the step back the total is at most $72R^2+970R+498+1200(R+1)^2\le3000(R+1)^2$.

(b) Write $q_l=\pm a_l/b_l$, so that the magnitudes of the row are $a_1,b_1,\dots,a_k,b_k$ and $\lceil|q_l|\rceil=\lceil a_l/b_l\rceil$. Let x_l be the blank before $u(a_l)$; then x_{l+1} is the blank that ends $u(b_l)$, and $x_1=e_{h+o}$. clear_{13} and left^{15} lead to $(0,14)$. For $i\le k$ let I_i be the configuration at $(0,14)$ on which track 14 carries $k-i$, track 13 holds the value $\sum_{l>k-i}\lceil a_l/b_l\rceil$, and the cursor carries the last mark of $u(b_{k-i})$ if $i<k$ and x_1 if $i=k$. A pass from I_i, $i<k$, scans the mark $(0,14)$, returns to the root, runs pair on the pair $k-i$ by (a), adds $\lceil a_{k-i}/b_{k-i}\rceil$ to track 13 ($\mathsf{acc}^2_{7\to13}$, which uses track 2 as scratch, within $500(R+1)^2$ units), restores the cursor to x_{k-i} from track 8, counts track 14 down and returns to $(0,14)$. If pairs remain, cont steps the cursor back to $x_{k-i}-1$, the last mark of $u(b_{k-i-1})$. The pass ends in I_{i+1} within $20000(R+1)^2$ units. At I_k the counter is 0. With the clearing, the final return and the two copies the total is at most $k(20000(R+1)^2+1)+700(R+1)+120\le22000(R+1)^3$; crow adds a copy. For gam the pass runs pmax instead: after pair, Lemma I.79 with $A=7$, $B=13$, $C=11$ and $F=12$ puts $\max(\lceil a/b\rceil,\text{previous})$ on track 11 within $400(2R+1)$ units, and the copies return it to track 13 and restore the cursor; the same count applies. □

Lemma I.82 (The row readers). *Let c_s be the constant of Lemma I.76 and put*

$$\begin{aligned}
\mathsf{row}_A &= \mathsf{sel}_A;\mathsf{crow}, \qquad \mathsf{row}_B = \mathsf{sel}_B;\mathsf{crow}, \qquad \mathsf{gsum} = \mathsf{csel}^0;\mathsf{gam};\mathsf{cc}_{13\to 11},\\
\mathsf{wrow} &= \mathsf{clear}_{13};\mathsf{down}_{14}(\mathsf{rfw}),\\
\mathsf{swidth} &= \mathsf{cc}_{14\to 12};\mathsf{cc}_{12\to 14};\mathsf{load}_{0,5};\mathsf{fskip};\mathsf{cc}_{7\to 14};\mathsf{wrow},\\
\mathsf{wpart}^A &= \mathsf{sel}_A;\mathsf{pbank};\mathsf{coff};\mathsf{swidth}, \qquad \mathsf{wpart}^B = \mathsf{sel}_B;\mathsf{pbank};\mathsf{coff};\mathsf{swidth},\\
\mathsf{wpart}^c &= \mathsf{csel}^1;\mathsf{clear}_5;\mathsf{pbank};\mathsf{clear}_{14};\mathsf{acc}_6^{\times 2};\mathsf{acc}_9^{\times 2};\mathsf{swidth},\\
\mathsf{row}_W &= \mathsf{wpart}^A;\mathsf{cc}_{13\to 8};\mathsf{wpart}^B;\mathsf{acc}^{12}_{13\to 8};\mathsf{wpart}^c;\mathsf{acc}^{12}_{13\to 8};\\
&\qquad \mathsf{cc}_{8\to 13};\mathsf{cc}_{13\to 11},\\
\mathsf{row}_L &= \mathsf{sel}_A;\mathsf{cc}_{7\to 8};\mathsf{sel}_B;\mathsf{cc}_{7\to 13};\mathsf{acc}^{12}_{13\to 8};\mathsf{cc}_{8\to 13};\mathsf{cc}_{13\to 11}.
\end{aligned}$$

For a coordinate j let

$$\alpha_j = \sum_{(a,i)} \lceil |a| \rceil, \quad \beta_j = \sum_{(b,i,i')} \lceil |b| \rceil, \quad s_j = \mathrm{cap}(c_j) + \sum_{(a,i)} \mathrm{cap}(a) + \sum_{(b,i,i')} \mathrm{cap}(b), \quad L_j = k_j^A + k_j^B,$$

the sums running over the terms of coordinate j. Then row_A and row_B are row readers for $j \mapsto \alpha_j$ and $j \mapsto \beta_j$ with constant $c_s + 23000$, row_W is a row reader for $j \mapsto s_j$ and row_L one for $j \mapsto L_j$, with constants depending only on the problem. From a gather state with R rows, gsum leaves the value γ on track 11 within $(c_s + 22000)(R+1)^3$ units and keeps track 9 and the gather state.

Proof. For row_A: sel_A makes the pairs of the A-row of j ready within $(c_s + 1000)(R+1)^2$ units (Lemma I.76), and crow leaves α_j on track 11 within $22000(R+1)^3$ units (Lemma I.81). The tracks written are among 2, 5, 6, 7, 8, 11, 12, 13 and 14. row_B is the same. gsum selects the row of all constants within $c_c(R+1)^2$ units and takes the maximum of their ceilings within $22000(R+1)^3$, which is γ by Definition 15.24; with the final copy and $c_c + 300 \le c_s$ the bound follows.

For row_W consider first wpart^A. After sel_A, track 7 holds $k = k_j^A$ and track 5 carries P_j^A; pbank puts d on track 6 without changing tracks 5 and 7, and coff puts $o = 4d + 2P_j^A$ on track 14. In swidth the two copies make o a value on track 14; $\mathsf{load}_{0,5}$ puts on track 5 the first archive entry, which is the payload row p (Lemma I.68(c)); fskip passes the frames of $z_1, \dots, z_o$ (Lemma I.77(d)), so that the cursor stands at the frame of z_{o+1}, the numerator of the first coefficient of the row; $\mathsf{cc}_{7\to 14}$ puts k on track 14; and wrow adds $\mathrm{cap}(q)$ for each of the k coefficients (Lemma I.77(c) and Lemma I.74(a) with $b = 2000(R+1)^2$), leaving their sum on track 13. wpart^B is the same with the B-row, and wpart^c with the row of c_j, whose offset $2d + 2j$ is built from tracks 6 and 9. row_W adds the three sums on track 8 and copies the total s_j to track 11. For row_L, the two selections leave k_j^A and k_j^B on track 7, and their sum is formed on track 8. All parts are bounded by Lemmas I.66, I.68, I.76 and I.77 by constants depending only on the problem (the weights w_A, w_B, q and d) times $(R+1)^3$, since every loop runs at most R times. None of them writes tracks 3, 4, 9, 10 or 15, nor a header or an origin mark. □

The capacity s_0 of the initial point is a maximum over the coordinates of y_0, whose frames come first in the payload.

Lemma I.83 (The initial capacity)**.** *Let*

$$\mathsf{istep} = \mathsf{clear}_{13};\mathsf{rfw};\mathsf{max}^{12}_{11,13\to 7};\mathsf{cc}_{7\to 11}, \qquad \mathsf{iw} = \mathsf{clear}_{11};\mathsf{down}_{14}(\mathsf{istep}),$$
$$\mathsf{isum} = \mathsf{dim};\mathsf{cc}_{11\to 14};\mathsf{load}_{0,5};\mathsf{iw}.$$

From every gather state with R rows, isum *runs from the root to the root within $10^5(R+1)^3$ units to a tape that holds the value s_0 on track* 11 *and is still in the same gather state; it writes only tracks* 2, 5, 7, 11, 12, 13 *and* 14*.*

Proof. dim and $\mathsf{cc}_{11\to 14}$ put d on track 14, and $\mathsf{load}_{0,5}$ puts the payload row p on track 5: the cursor stands at the frame of the numerator of $y_{0,0}$. A pass of down_{14} measures $\mathrm{cap}(y_{0,l})$ on track 13 by Lemma I.77(c) and replaces the value on track 11 by the maximum of the two (Lemma I.79 with $A=11$, $B=13$, $C=7$, $F=12$, and a copy), within $5000(R+1)^2$ units; the cursor moves to the next coordinate. After d passes track 11 holds $\max_l \mathrm{cap}(y_{0,l}) = s_0$. By Lemma I.74(a) and the bounds of dim and $\mathsf{load}_{0,5}$, the total is at most $80000(R+1)^2 + d(5000(R+1)^2 + 36d + 70) + 400(R+1) \le 10^5(R+1)^3$, as $d \le R$. □

I.8.7 The six folds

A fold runs a row reader for every coordinate, pushing each row value onto the archive, and then replaces these d values by their maximum.

Lemma I.84 (Gathering, maximizing and collapsing)**.** *Let*

$$\mathsf{dimc}_k = \mathsf{dim};\mathsf{cc}_{11\to k}, \qquad \mathsf{gather}(P) = \mathsf{down}^{\circ}_{9}(P;\mathsf{push}),$$
$$\mathsf{amax} = \mathsf{clear}_{11};\mathsf{down}_9\big(\mathsf{rd};\mathsf{max}^{14}_{11,12\to 8};\mathsf{cc}_{8\to 11}\big),$$
$$\mathsf{collapse}_c = \mathsf{prefix}_c;\mathsf{amax};\mathsf{trunc}_c;\mathsf{push},$$
$$\mathsf{pass}(P,c) = \mathsf{dimc}_9;\mathsf{gather}(P);\mathsf{dimc}_9;\mathsf{collapse}_c.$$

(a) *With a bank view within R rows,* dimc_k *($k = 9, 14$) puts the value d on track k within $22000(R+1)^2$ units, changing only tracks* 2, 11 *and k.*

(b) *Let P be a row reader for f with constant K, and let τ be in the gather state with archive v and R rows, with d on track* 9 *and $d \le R$. Then* gather(P) *runs from the root to the root to a tape in the gather state with archive $v, f(d-1), \dots, f(0)$ and $R + \rho_f$ rows, $\rho_f = \sum_{j<d}(1+f(j))$, with* 0 *on track* 9*, within $(d+2)(K+1000200)(R+\rho_f+2)^3$ units.*

(c) *If track* 13 *carries x, the words $u(n_1)\cdots u(n_c)$ lie on track* 4 *from row x, $x + \sum_l (n_l+1) \le R$ and track* 9 *carries $c \le R$, then* amax *leaves the value $\max_l n_l$ on track* 11 *(and* 0 *if $c = 0$), the cursor on track* 13 *at $x + \sum_l (n_l+1)$ and* 0 *on track* 9*, within $16000(R+1)^3$ units; only tracks* 8, 9, 11, 12, 13 *and* 14 *change.*

(d) *If τ holds the archive $(v_1, \dots, v_c, w_1, \dots, w_d)$ within R rows and track* 9 *carries d, then* $\mathsf{collapse}_c$ *leaves the archive $(v_1, \dots, v_c, \max_l w_l)$ within $R + 1 + \max_l w_l$ rows,* 0 *on track* 9*, and tracks* 10 *and* 15 *unchanged, within $(c+5)\cdot 10^7(R+1)^3$ units.*

(e) *Let P be a row reader for f with constant K, and let τ be in the gather state with an archive v of c numbers and R rows. Then* pass(P,c) *runs from the root to the root to a tape in the*

gather state with archive v, $\max_j f(j)$ and $R+\rho_f+1+\max_j f(j)$ rows, with 0 on track 9, within

$$\big(44000+(d+2)(K+1000200)+(c+5)\cdot 10^7\big)(R+\rho_f+2)^3$$

units.

Proof. (a) Lemma I.75(b) and Lemma I.66(a).

(b) Lemma I.74(b) with $k=9$, $n=d$, and J_j the gather state with archive v, $f(d-1),\dots,f(j)$, $R_j=R+\sum_{i\ge j}(1+f(i))$ rows and the counter j on track 9. From a tape with J_j on which $(j-1,9)$ has been set to 0, the row reader leaves $f(j-1)\le R_j$ on track 11, keeps the counter $j-1$ on track 9 and the gather state, and push appends $f(j-1)$ (Lemma I.68(h)), keeping tracks 9, 10 and 15; the result has J_{j-1}. A pass costs at most $K(R_j+1)^3+10^6(R_j+f(j-1)+2)^2\le(K+10^6)(R+\rho_f+2)^3$, and the bound of Lemma I.74 is at most $d\big((K+10^6)(R+\rho_f+2)^3+36d+50\big)+25$.

(c) clear_{11} leaves the value 0. Apply Lemma I.74(a) with $k=9$, $n=c$, and J_j the tapes on which track 9 carries j, track 13 carries $x+\sum_{l\le c-j}(n_l+1)$ and track 11 holds the value $\max_{l\le c-j}n_l$. The body reads the next word onto track 12 (Lemma I.68(b)), forms the maximum on track 8 (Lemma I.79 with $A=11$, $B=12$, $C=8$, $F=14$) and copies it to track 11, within $12000(R+1)^2$ units, and does not write track 9. The total is at most $61R+31+c(12000(R+1)^2+36c+50)+25\le 16000(R+1)^3$.

(d) prefix_c puts the cursor at the first word $u(w_1)$, and amax leaves $W=\max_l w_l\le R$ on track 11 and 0 on track 9; trunc_c cuts the archive to $(v_1,\dots,v_c)$, and push appends W (Lemma I.68(h), (i)). The costs are at most $(c+3)\cdot 20000(R+1)^2$ twice, $16000(R+1)^3$ and $10^6(R+W+2)^2\le 4\cdot 10^6(R+1)^2$.

(e) dimc_9 puts d on track 9, $\mathsf{gather}(P)$ appends the d row values by (b), dimc_9 puts d on track 9 again (the bank view is unchanged), and $\mathsf{collapse}_c$ replaces the d values by their maximum $\max_j f(j)$ by (d). Add the four bounds; the gather state is kept because only tracks other than 3, 4, 10 and 15 are written, except by push, which extends the archive. □

The first and the last fold archive a single number. Put

$$\mathsf{Gam}=\mathsf{gsum};\mathsf{push},\qquad \mathsf{Ini}=\mathsf{isum};\mathsf{push}.$$

Proof of Theorem I.62(b). Let τ be in the gather state with archive (p) and r rows. clear_9 ($57r+27$ units) leaves the counter 0 on track 9. Gam computes γ (Lemma I.82) and appends it: archive (p,γ) within $r+1+\gamma$ rows, within $(c_s+22000)(r+1)^3+10^6(r+\gamma+2)^2$ units. The four passes append, by Lemma I.84(e) with the row readers of Lemma I.82, the maxima over the coordinates of α_j, β_j, s_j and L_j, which are α, β, s and L (Definition 15.24 and Section H.1); each pass starts with 0 on track 9 and ends with it, and the archive before the pass has 2, 3, 4 and 5 numbers. Ini computes s_0 (Lemma I.83) and appends it. The tape is then in the gather state with the archive $(p,\gamma,\alpha,\beta,s,L,s_0)$ and $r+\rho_S$ rows, where

$$\rho_S=(1+\gamma)+\sum_{g\in\{\alpha,\beta,s,L\}}\Big(\sum_{j<d}(1+g_j)+1+\max_j g_j\Big)+(1+s_0)$$

depends only on the problem. Each of the seven parts is bounded by a constant depending only on the problem times $(r+\rho_S+2)^3 \le (\rho_S+2)^3(r+1)^3$; so $t \le K_S(r+1)^3$ for such a constant K_S, and

$$t + (r + \rho_S + m) + 2 \le (K_S + \rho_S + 1)(r + m + 2)^3.$$

This is the bound with $K_2 = K_S + \rho_S + 1$. □

Proof of Theorem I.62(c). Let τ be a prepared request with r rows. By part (a), MetaBank ends after t_1 units within r' rows, with $t_1 + (r' + m) + 2 \le K_1(r + m + 2)^{24}$, on a tape that holds the archive (p), carries the bank, keeps the saved request, and is a workspace of r' rows with origin marks up to r'. This tape is in the gather state with archive (p) and r' rows: it is its own witness for the bank view, and track 15 carries the frame-start marks of the saved request. By part (b), Summ ends after t_2 units within $r'' = r' + \rho_S$ rows, with $t_2 + (r'' + m) + 2 \le K_2(r' + m + 2)^3$, in the gather state with the archive of the seven numbers; in particular it keeps the saved request and is a workspace of r'' rows with origin marks up to r''. Lemma I.73 with $x = r + m$, $y = r' + m$, $z = r'' + m$, $a = 24$ and $b = 3$ gives

$$t_1 + t_2 + (r'' + m) + 2 \le (K_1 + K_2K_1^3)(r + m + 2)^{72}.$$ □

The archive of the seven numbers, with the saved request, the workspace and the origin marks, is the input of the schedule tail of Section I.9, which reads M, T and n_0 from their saved frames and computes the schedule from these numbers. The exponent 72 of part (c), and the exponent 2 that Prepare adds in the composition of the whole stage (Lemma I.61), enter the exponent of the stage computed there.

I.9 The problem's constants: the schedule and the width

How does the machine find the width W_m of its answer word? Continue the example of Section I.8: the field $y' = -y^2$ with $y_0 = \frac{1}{2}$, whose archive ends as $(p, \gamma, \alpha, \beta, s, L, s_0) = (11, 0, 0, 1, 3, 1, 3)$, and take $M = 2$, $T = 1$ and $n_0 = 0$. The schedule of Definition 15.18 is

$$R = 0 + 0 + 1 \cdot 2 + 1 = 3, \quad \sigma = \mathrm{bl}(12) + 1 = 5, \quad S = 2^5 = 32, \quad G = \left\lfloor \frac{44^{32}}{2^{160}} \right\rfloor + 1 = 26650,$$

and $\kappa = \mathrm{bl}(26650 \cdot 257) + 2 = 25$. With $r = \mathrm{bl}(M) + \mathrm{bl}(R) + 1 = 5$, the coefficients of (H.1) are $q_P = 2rL + \sigma + r = 20$, $l_P = 3r + (s + 5r + 1)L + 4 = 48$ and $c_P = s_0 + 2s + 2r + (2s + 3r + 2)L + 7 = 49$. At the precision $m = 10$ the machine works at $N = \max(10, 0) + 25 = 35$ bits, the capacity is $\mathscr{B}(35) = (20 \cdot 35 + 48) \cdot 35 + 49 = 26229$ and the width is $W_{10} = 4 \cdot 26229 + 4 = 104920$. The machine computes every one of these numbers in unary, by a fixed list of fifty-one unary operations on the archive, and then evaluates the capacity by Horner's rule. On the way it writes the number 44^{32}, which has fifty-three decimal digits, as a run of marks. The number of rows this takes is enormous, but it depends only on the problem, so it enters the constant of the stage and not its exponent.

This section constructs the second half of the stage "Schedule" of Table 15.1 and composes the whole stage. Its programs are

$$\mathsf{Scalar} = \mathsf{Ctl}; \mathsf{Prog}; \mathsf{Seed}, \qquad \mathsf{Width} = \mathsf{corr}; \mathsf{max}^{14}_{11,12\to 8}; \mathsf{Code},$$
$$\mathsf{Schedule} = \big(\mathsf{Prepare}; (\mathsf{MetaBank}; (\mathsf{Summ}; \mathsf{Scalar}))\big); \mathsf{Width}.$$

Ctl reads M, T and n_0 from their saved frames and appends them to the archive (Section I.9.1). Prog is the fixed scalar program of Table I.2: each of its fifty-one instructions reads one or two entries of the archive, computes a sum, a product, a quotient, a binary length or a power in unary, and appends the result (Sections I.9.2 to I.9.4). Seed reads m and loads σ, S, κ, q_P, l_P, c_P, m and n_0 into the unary registers. Width forms $\max(m, n_0)$, then $N = \max(m, n_0) + \kappa$, $\mathscr{B}(N)$ and W_m (Section I.9.6). The routines Prepare, MetaBank, Summ, corr and $\mathsf{max}^{14}_{11,12\to 8}$ are those of Section I.8.

The registers and the contracts

As in Section I.8, "within R rows" includes that the tape is a workspace of R rows with origin marks up to R, and ω is the saved request. The archive entries are numbered from 0: an archive $(v_0, v_1, \ldots)$ holds v_k in its k-th word. Throughout, the problem has a coefficient field; σ, S, G and κ are its schedule (Definition 15.18), q_P, l_P and c_P the coefficients of its capacity $\mathscr{B}(N) = q_P N^2 + l_P N + c_P$ (H.1), $N = N(\max(m, n_0)) = \max(m, n_0) + \kappa$ and $W_m = 4\mathscr{B}(N) + 4$. Put

$$\rho(m) = \sigma + S + \kappa + m + n_0 + q_P + l_P + c_P + N + q_P N \\ + (q_P N + l_P) + (q_P N + l_P)N + \mathscr{B}(N) + W_m + 10,$$

the *tail room*: the sum of every number the last program holds, with ten to spare.

Definition I.85 (Seed and scheduled request)**.** Fix a problem with a coefficient field, n_0, i and m, and let τ be a tape and $r \in \mathbb{N}$.

(a) τ is a *seed with r rows* if it carries the saved request (Definition I.41), is a workspace of r rows with origin marks up to r, tracks 5, 6, 7, 8, 9, 10 and 13 carry the counters σ, S, κ, 0, q_P, l_P and c_P, tracks 11 and 12 hold the values m and n_0, and $\rho(m) \le r$.

(b) τ is a *scheduled request with r rows* if it carries the saved request, is a workspace of r rows with origin marks up to r, tracks 5, 6, 7, 8, 9 and 10 carry the counters

$$\sigma, \quad S, \quad \kappa, \quad N, \quad W_m, \quad \mathscr{B}(N),$$

and $\sigma + S + \kappa + N + W_m + \mathscr{B}(N) \le r$.

So a scheduled request keeps the whole request on tracks 3, 4 and 15 and adds, in unary, every number of the schedule that the later stages need. The last inequality says that each of these numbers is at most the number of rows, which is what lets the later stages count up to them with their cursors. The three results below are proved at the ends of Sections I.9.5, I.9.6 and I.9.7.

Proposition I.86 (The scalar tail)**.** *Fix a problem with a coefficient field, n_0 and a number p. There is a constant K_T, depending only on these, with the following property for every i, m, r and tape τ. If τ carries the saved request and holds the archive $(p, \gamma, \alpha, \beta, s, L, s_0)$ within r rows, where γ, α, β, s, L and s_0 are the bounds of Theorem I.62, then* Scalar *runs from the root to the root in some t units to a seed with r' rows, and*

$$t + r' + 2 \le K_T (r + m + 2)^{80 \cdot 6^{51}}.$$

Lemma I.87 (The width)**.** *From every seed with r rows,* Width *runs from the root to the root in some t units to a scheduled request with r rows, and*

$$t \le 14 \cdot 10^5 \big(\rho(m) + 1\big)^3 + 37r + 13.$$

Moreover $\rho(m) \le c_\rho X^2$ for a constant c_ρ depending only on the problem and n_0, where $X = m + n_0 + \kappa + 1$.

Theorem I.88 (The stage Schedule)**.** *Fix a problem with a coefficient field and n_0. There is a constant K_q, depending only on the problem and n_0, such that for every i, m, r and every decoded request τ with r rows (Definition I.56),* Schedule *runs from the root to the root in some t units to a scheduled request with r' rows, and*

$$t + r' + 1 \le K_q \, (X + r + 1)^{g_q}, \qquad g_q = 4\big(72 \cdot 80 \cdot 6^{51} + 3\big) = 23040 \cdot 6^{51} + 12.$$

The stage writes the headers and the new rows, the origin marks of track 1, the scratch and register tracks 2 and 5 to 14, and tracks 3 and 4 beyond the end of ω, where the archive lies. It does not change ω or track 15; the numeric record of the decoded request is used and then overwritten.

The exponent is a fixed number, the same for every problem:

$$g_q = 111736803796728983743307618367111577196298252.$$

It is the product of the exponents of the parts. The archive reads of Ctl have exponent 2 each, the fifty-one instructions of Prog exponent 6 each, and Seed exponent 10; two bounds of this kind compose by Lemma I.73 with the product of their exponents, which gives $2^3 \cdot 6^{51} \cdot 10 = 80 \cdot 6^{51}$ for Scalar. The front half contributes 72 (Theorem I.62(c)), Prepare adds 2, and Width, whose exponent is 3, turns s into $4(s + 1)$ through Lemma 15.36(a). The exponent 6 of one instruction is $2 \cdot 3$: each instruction first adds about $64(r + 1)^2$ rows, so that a product of two archived numbers, each at most r, has room, and then works at a cost at most cubic in the new number of rows.

I.9.1 Reading a control number from its frame

The numbers M, T, n_0 and m are the frames number 5, 4, 3 and 1 from the end of the saved request. The machine finds such a frame by walking back from the end of ω over the frame-start marks of track 15, and reads it as Section I.7 reads every frame: it copies the bits to the binary stream and converts them to unary. Write the saved request as in Definition I.41: its frames are $f_0, \dots, f_F$, and f_k begins at row s_k, with $s_{F+1} = |\omega|$.

Lemma I.89 (Walking back over frames)**.** *Let*

$$\mathsf{send} = \mathsf{left}^4; \mathsf{scanL}, \qquad \mathsf{mk} = \mathsf{branch}(\mathsf{right}; \mathsf{write}\,1,\ \mathsf{right}; \mathsf{write}\,0),$$
$$\mathsf{prev} = \mathsf{right}^4; \mathsf{mk}; \mathsf{loop}(\mathsf{right}^{15}; \mathsf{mk}); \mathsf{left},$$

and $\mathsf{pf}^0 = \mathsf{skip}$, $\mathsf{pf}^{k+1} = \mathsf{pf}^k; \mathsf{prev}; \mathsf{right}^{12}$.

(a) If ω lies on tracks 3 and 4 from row 0, send *runs from $(-1,\tau)$ to $(\mathrm{cell}(|\omega|,3),\tau)$ in $18|\omega|+6$ units.*

(b) mk *runs from $\mathrm{cell}(j,15)$ to $\mathrm{cell}(j,14)$ in 3 units and writes into $(j,14)$ the complement of $(j,15)$.*

(c) If $\tau(a,15)=1$ and $\tau(j,15)=0$ for $a<j\le a+n$, then prev *runs from $\mathrm{cell}(a+n+1,3)$ to $\mathrm{cell}(a,15)$ in $20n+10$ units, writing only the cells $(j,14)$, $a\le j\le a+n$.*

(d) If τ carries the saved request and $1\le k\le F$, then pf^k *runs from $\mathrm{cell}(s_{F+1},3)$ to $\mathrm{cell}(s_{F+1-k},3)$ in $20(s_{F+1}-s_{F+1-k})+3k+1$ units, writing only track 14.*

Proof. (a) left^4 (5 units) reaches $-5=\mathrm{cell}(0,3)$, and scanL walks down the presence track of ω to its blank $(|\omega|,3)$ in $18|\omega|+1$ units (Lemma I.10). (b) A test, a move from $\mathrm{cell}(j,15)$ to $\mathrm{cell}(j,15)+1=\mathrm{cell}(j,14)$ and a write. (c) right^4 (5 units) moves from $\mathrm{cell}(a+n+1,3)$ to $\mathrm{cell}(a+n+1,3)+4=\mathrm{cell}(a+n,15)$, and mk (3) writes the complement of the mark of row $a+n$ into $(a+n,14)$. For $j\le n$ let I_j be the configuration at $(a+n-j,14)$ in which the cells $(a+n-i,14)$, $i\le j$, hold the complements of the marks of their rows. The scanned cell of I_j is 1 exactly when $j<n$. A pass from I_j, $j<n$, moves by right^{15} from $(a+n-j,14)$ to $(a+n-j-1,15)$ (16 units) and runs mk: 20 units with its test, ending in I_{j+1}. Lemma I.6 gives $20n+1$ units, and left returns from $(a,14)$ to $(a,15)$: in all $5+3+20n+1+1$. (d) Induction on k. Put $e=s_{F+1-k}$ and $e'=s_{F+2-k}$. By the induction hypothesis pf^{k-1} reaches $\mathrm{cell}(e',3)$; the marks of track 15 are those of the frame starts, so $(e,15)=1$ and the rows strictly between e and e' carry no mark. Part (c) with $a=e$ and $n=e'-e-1$, and right^{12} (13 units) from $\mathrm{cell}(e,15)$ to $\mathrm{cell}(e,3)$, add $20(e'-e)+3$ units. □

Each control number is read by the program

$$\mathsf{cur}_k=\mathsf{send};\mathsf{pf}^k;\mathsf{tc},\qquad \mathsf{getc}_k=\mathsf{cur}_k;\mathsf{clear}_{8,9};\mathsf{cc}_{2\to5};\mathsf{fetch};\mathsf{reset}_8;\mathsf{toUnary}^+,$$
$$\mathsf{ctl}_k=\mathsf{getc}_k;\mathsf{cc}_{9\to11};\mathsf{push},\qquad \mathsf{Ctl}=\mathsf{ctl}_5;\mathsf{ctl}_4;\mathsf{ctl}_3;\mathsf{skip},$$

where tc, cc and push are the routines of Lemmas I.66 and I.68, and fetch and $\mathsf{toUnary}^+$ those of Lemmas I.45 and I.49. The proof of Lemma I.68(g) shows that tc runs from $\mathrm{cell}(h,3)$, on a tape with origin marks up to h, to the root in $21h+7$ units, makes track 2 carry the counter h, and changes only track 2. For a number v write $\mathrm{bits}(v)$ for the word of its $\mathrm{bl}(v)+1$ lowest binary digits, so that the frames of M, T, n_0 and m are $\mathrm{bits}(M)$, $\mathrm{bits}(T)$, $\mathrm{bits}(n_0)$ and $\mathrm{bits}(m)$.

Lemma I.90 (Reading and archiving a control number)**.** *Let τ carry the saved request and be a workspace of R rows with origin marks up to R. For $1\le k\le 5$ let c_k be the control number whose frame is the k-th from the end: $c_5=M$, $c_4=T$, $c_3=n_0$, $c_2=i$ and $c_1=m$.*

(a) cur_k *runs from the root to the root within $(100+3k)(R+1)$ units, makes track 2 carry the first row $e=s_{F+1-k}$ of that frame and changes only tracks 2 and 14.*

Let moreover $k\in\{1,3,4,5\}$, and let τ hold an archive $v=(v_0,\dots,v_{K-1})$ within R rows.

(b) getc_k *runs from the root to the root in some t units to a tape that holds the value c_k on track 9, carries the saved request and holds the archive v within $R + c_k$ rows, and*

$$t + (R + c_k) + 1 \le 55000\,(R + c_k + 1)^2.$$

(c) ctl_k *runs from the root to the root in some t units to a tape that carries the saved request and holds the archive (v, c_k) within $r' = R + 2c_k + 1$ rows, and*

$$t + r' + 2 \le 10^8 (c_k + 1)^2 (R + 2)^2.$$

(d) Ctl *runs from the root to the root in some t units to a tape that carries the saved request and holds the archive (v, M, T, n_0) within r' rows, and $t + r' + 2 \le K_C (R + 2)^8$, where K_C depends only on M, T and n_0.*

Proof. (a) The presence marks of ω lie in rows $j \le R$, so $|\omega| \le R + 1$. Lemma I.89(a) and (d) take $18|\omega| + 6 + 20(|\omega| - e) + 3k + 1$ units to reach cell$(e, 3)$, writing only track 14, and tc takes $21e + 7$; since $e \le |\omega| \le R + 1$ the sum is at most $39(R + 1) + 3k + 14 \le (100 + 3k)(R + 1)$.

(b) The archive gives $|\omega| + 1 \le R$. After (a), $\mathsf{clear}_{8,9}$ ($112R + 51$ units, Lemma I.16) leaves tracks 8 and 9 blank, and $\mathsf{cc}_{2\to5}$ (at most $300(R + 1)$) puts the value e on track 5. By Lemma I.44 the tape lays out $g = \mathrm{bits}(c_k)$, followed by the remaining frames of ω, from row e, and $n = |g|$ satisfies $e + n \le |\omega| \le R$. Lemma I.45 with $a = e$ and $o = 0$ copies g to the binary stream within $1000(R+1)^2$ units, leaving track 8 carrying n; reset_8 ($36n + 48$ units, Lemma I.14) brings it back to 0, and track 9 still holds the value 0. Lemma I.49 with $\ell = n$, $r = 0$ and the value c_k of g then writes the value c_k on track 9 and adds c_k rows, within $1000(n + R + c_k + 1)^2 \le 4000(R + c_k + 1)^2$ units. No routine writes tracks 3, 4 or 15 in the old rows, and the new rows carry 0 there, so the saved request and the archive are kept; the root and the cells $x \ge 0$ are not written. With $x = R + c_k + 1$ the total plus $R + c_k + 1$ is at most $5000x^2 + 700x \le 55000x^2$.

(c) After (b), $\mathsf{cc}_{9\to11}$ (at most $300(R + c_k + 1)$) puts c_k on track 11, and Lemma I.68(h), with $R + c_k$ rows, $n = c_k$ and the counter c_k on track 9, appends c_k to the archive within $10^6(R + 2c_k + 2)^2$ units and $R + 2c_k + 1$ rows. With $x = R + 2c_k + 2 \le (c_k + 1)(R + 2)$ the total plus $r' + 2$ is at most $55000x^2 + 300x + 10^6x^2 + x \le 10^8x^2$.

(d) The program skip takes 1 unit and keeps the rows, so $1 + R + 2 \le 2(R + 2)^1$. Lemma I.73 combines this with (c) for $k = 3$ (exponents 2 and 1), then with (c) for $k = 4$ (exponents 2 and 2), then with (c) for $k = 5$ (exponents 2 and 4). The exponent is $2 \cdot 2 \cdot 2 = 8$, and the constant is built from $10^8(n_0 + 1)^2$, $10^8(T + 1)^2$, $10^8(M + 1)^2$ and 2 alone. □

I.9.2 Rows for products

A unary number needs one row per unit, and a product of two numbers that each fit the rows need not. Before each instruction of the scalar program, the machine therefore makes the number of rows roughly quadratic: it counts the rows on track 12 and adds 64 times that many rows, once for every row. The count of track 12 is copied from the headers of track 0, and track $c \in \{13, 14\}$ is the outer cursor. Put

$$Q(R) = R + 1 + 64(R + 1)^2, \qquad \text{so that} \qquad R \le Q(R) \quad \text{and} \quad Q(R) + 1 \le 66(R + 2)^2.$$

Lemma I.91 (Quadratic growth). *Let $c \in \{13, 14\}$, let* rdc *be the routine of Lemma I.67, and put*

$$\mathsf{hc}_c = \mathsf{clear}_{12,c}; \mathsf{zero}_{12}; \mathsf{left}^1; \mathsf{loop}(\mathsf{shift}_{0\to 12}; \mathsf{next}; \mathsf{shift}_{12\to 0}); \mathsf{left}; \mathsf{home}_1,$$
$$\mathsf{more} = \mathsf{rdc}; \mathsf{loop}(\mathsf{home}_{12}; \mathsf{grow}; \mathsf{inc}_2; \mathsf{rdc}); \mathsf{home}_{12}, \qquad \mathsf{one} = \mathsf{zero}_2; \mathsf{more},$$
$$\mathsf{roc}_c = \mathsf{seek}_c; \mathsf{shift}_{c\to 12}, \qquad \mathsf{res}_c = \mathsf{roc}_c; \mathsf{loop}(\mathsf{home}_{12}; \mathsf{one}^{64}; \mathsf{inc}_c; \mathsf{roc}_c); \mathsf{home}_{12},$$
$$\mathsf{quad}_c = \mathsf{grow}; \mathsf{hc}_c; \mathsf{res}_c; \mathsf{clear}_{12,c}, \qquad \mathsf{room} = \mathsf{clear}_{5,6,7,8,9,10,11}; \mathsf{quad}_{13},$$

where one^{64} *is* 64 *copies of* one *followed by* skip. *Let τ be a workspace of R rows with origin marks up to R. Each routine runs from the root to the root, and none writes tracks* 3, 4 *or* 15 *in the rows $j \le R$.*

(a) hc_c *makes track* 12 *hold the value R and track c carry* 0, *within* $300(R+1)$ *units; only tracks* 12 *and c change.*

(b) If track 12 *holds a value $n \le R$, then* one *leaves a workspace of $R+n$ rows with origin marks up to $R+n$ and track* 12 *still holding n, within* $2000(R+n+2)^2$ *units. Besides the headers of the rows $R, \dots, R+n-1$ and the new rows, only track* 2 *is written; so every counter at most R on a track other than* 2 *is kept.*

(c) If track 12 *holds $n \le R$ and track c carries* 0, *then* res_c *leaves a workspace of $R + 64n^2$ rows with origin marks up to $R + 64n^2$, track* 12 *still holding n and track c carrying n, within* $500000(n+1)(R+64n^2+65n+2)^2$ *units; every counter at most R on a track other than* 2 *and c is kept.*

(d) quad_c *leaves a workspace of $Q(R)$ rows with origin marks up to $Q(R)$ and tracks* 12 *and c blank, within* $3 \cdot 10^9 (R+2)^5$ *units; every counter at most R on a track other than* 2, 12 *and c is kept.*

(e) If τ holds an archive within R rows, then room *leaves the same archive within $Q(R)$ rows, within* $4 \cdot 10^9 (R+2)^5$ *units.*

Proof. (a) $\mathsf{clear}_{12,c}$ costs at most $130R + 69$ units (Lemma I.16), zero_{12} costs 31 and left^1 (2) reaches the header $(0, 0)$. The loop is the copying loop of Lemma I.15(a) with the source track 0, whose headers carry the counter R: a pass from $(j, 0)$, $j < R$, advances the hole of track 12 and moves to $(j+1, 0)$ in 47 units with its test, and the loop stops at the sentinel, in $47R + 1$ units. left (1) steps to $(R, 1)$, and home_1 $(18R + 5)$ returns along the origin marks. In all at most $195R + 109 \le 300(R+1)$. Track 12 was blank, so it now holds the value R.

(b) zero_2 (11 units) makes track 2 carry 0, and more is alloc of Lemma I.67 without its first grow. The proof of that lemma, with R in place of $R+1$, shows that rdc (16 units) reaches $(0, 12)$, that the pass from row $j < n$ adds one row and advances track 2 in $72R + 144j + 198$ units with its test, and that the loop stops at the blank $(n, 12)$; the final home_{12} costs $18n + 16$. The total is $72Rn + 72n^2 + 144n + 44 \le 2000(R+n+2)^2$. A new row has 0 on track 12, and it lies beyond the hole of every counter at most R.

(c) roc_c ($c + |c-12| + 4 \le 20$ units) reaches $(0, 12)$. For $j \le n$ let I_j be the configuration at $(j, 12)$ whose tape is a workspace of $R_j = R + 64jn$ rows with origin marks up to R_j, holds n on track 12 and carries j on track c. A pass from I_j, $j < n$, scans a mark, returns to the root $(18j + 16)$, runs one sixty-four times by (b), each time adding n rows within $2000(R_{j+1} + n + 2)^2$ units,

advances track c ($36j + 2c + 44$, Lemma I.14) and reads $(j + 1, 12)$ ($18j + c + |c - 12| + 22$): at most $200000(R_j + 65n + 2)^2$ units, ending in I_{j+1}. At I_n the scanned cell is the blank $(n, 12)$. Lemma I.6 and the final home_{12} ($18n + 16$) give the bound, since $R_j \le R + 64n^2$.

(d) grow ($72R + 99$ units, Lemma I.17) gives $R + 1$ rows; (a) puts the count $R + 1$ on track 12 within $300(R + 2)$ units; (c) with $n = R + 1$ gives $R + 1 + 64(R + 1)^2 = Q(R)$ rows within $500000(R + 2)\big(64(R + 1)^2 + 66(R + 1) + 2\big)^2 \le 500000 \cdot 4096(R + 2)^5$ units; and $\mathsf{clear}_{12,c}$ on $Q(R)$ rows costs at most $131Q(R) + 69 \le 8715(R + 2)^2$. The sum is at most $3 \cdot 10^9(R + 2)^5$. A counter at most R has its hole in an old row, which none of these parts writes on its track.

(e) $\mathsf{clear}_{5,\dots,11}$ costs $385R + 169$ units; then (d) with $c = 13$. The archive lies on tracks 3 and 4, whose old rows are not written, and the new rows carry 0 there. □

I.9.3 Unary products, binary lengths and powers

The scalar program and the last program of the stage multiply unary numbers, and the scalar program also takes binary lengths and powers. All three are loops of the counter routines of Section I.4 and the division udiv of Lemma I.78: a product adds one factor once for each mark of the other, a binary length halves until nothing is left, and a power multiplies by the base once for each mark of the exponent, after reserving the rows for the next power.

Lemma I.92 (Unary products)**.** *For distinct tracks $A, B, C, s, c \in \{2, \dots, 15\}$ put*

$$\mathsf{umul}^{s,c}_{A,B\to C} = \mathsf{zero}_C; \mathsf{zero}_c; \mathsf{seek}_c; \mathsf{shift}_{c\to B}; \mathsf{loop}(\Pi); \mathsf{home}_B,$$
$$\Pi = \mathsf{shift}_{B\to c}; \mathsf{next}; \mathsf{home}_c; \mathsf{acc}^{s}_{A\to C}; \mathsf{seek}_c; \mathsf{shift}_{c\to B}.$$

If track A carries a, track B carries b, and τ has origin marks up to R with $a, b, ab \le R$, then $\mathsf{umul}^{s,c}_{A,B\to C}$ runs from the root to the root within $2000(a + b + ab + 1)^3$ units; afterwards track C carries ab and track c carries b. Only tracks C, s and c change, and only in rows $j \le R$.

Proof. zero_C, zero_c, seek_c and $\mathsf{shift}_{c\to B}$ take at most $2C+3c+|c-B|+18$ units and reach $(0, B)$ with the counters 0 on tracks C and c. For $j \le b$ let I_j be the configuration at (j, B) in which track c carries j and track C carries ja. A pass from I_j, $j < b$, scans a mark of B, moves to the hole (j, c) and advances it ($|B-c|+21$ units), returns to the root ($18(j+1)+c+4$), adds a to track C (at most $500((j+1)a+1)^2$ units by Lemma I.15(b), since $(j+1)a \le R$), and goes back to the hole of track c and over to $(j+1, B)$ ($18(j+1)+c+|c-B|+4$). It ends in I_{j+1} within $500(a+b+ab+1)^2+36b+111$ units with its test. At I_b the scanned cell is the hole of track B. Lemma I.6 and home_B ($18b+B+4$) bound the total by $500b(a+b+ab+1)^2 + 36b^2 + 129b + 126 \le 2000(a+b+ab+1)^3$. The addition writes only tracks C and s, and the advances only track c, all in rows at most $\max(ab, b) \le R$. □

Lemma I.93 (Binary length)**.** *Let*

$$\mathsf{ublen} = \mathsf{left}^{12}; \mathsf{loop}\big(\mathsf{home}_{11}; \mathsf{udiv}; \mathsf{clear}_{11}; \mathsf{copy}_{7\to 11}; \mathsf{clear}_{2,5,6,7}; \mathsf{inc}_8; \mathsf{left}^{12}\big); \mathsf{home}_{11}.$$

Let τ be a workspace of R rows with origin marks up to R that holds the value n on track 11 and the value 2 on track 12, carries 0 on tracks 2, 5 and 6, and has tracks 7 and 8 blank, with $n + 2 \le R$. Then ublen runs from the root to the root within $(2n + 1) \cdot 10^4(R + 1)^2 + 28$ units to a workspace of R rows with origin marks up to R that holds the value $\mathrm{bl}(n)$ on track 8, the value 0 on track 11 and the value 2 on track 12. Tracks 3, 4 and 15 are not written.

Proof. left^{12} (13 units) reaches $(0, 11)$. For $k \le \mathrm{bl}(n)$ let J_k be the configuration at $(0, 11)$ whose tape holds $\lfloor n/2^k \rfloor$ on track 11, k on track 8 and 2 on track 12, carries 0 on tracks 2, 5 and 6, and has track 7 blank. The scanned cell is 1 exactly when $\lfloor n/2^k \rfloor \ge 1$, that is when $k < \mathrm{bl}(n)$. A pass from J_k returns to the root (15 units); udiv leaves the value $\lfloor \lfloor n/2^k \rfloor / 2 \rfloor = \lfloor n/2^{k+1} \rfloor$ on track 7 within $1000(n+3)^2$ units (Lemma I.78, with $b = 2$); clear_{11} and $\mathsf{copy}_{7\to 11}$ move it to the blanked track 11, so that track 11 holds it as a value; $\mathsf{clear}_{2,5,6,7}$ blanks the scratch tracks; inc_8 makes track 8 hold $k+1$; and left^{12} returns to $(0, 11)$. By Lemmas I.16, I.15 and I.14 the pass costs at most $9000(R+1)^2$ units and ends in J_{k+1}. Lemma I.6 with $\mathrm{bl}(n) \le n$ passes and home_{11} (15) give the bound. Every part writes only tracks 2, 5, 6, 7, 8 and 11, in rows $j \le R$. □

Lemma I.94 (Powers with their rows)**.** *Let* one *be the routine of Lemma I.91 and put*

$$\begin{aligned}
\mathsf{rde} &= \mathsf{seek}_2; \mathsf{shift}_{2\to 6}, \qquad \mathsf{prr} = \mathsf{seek}_{14}; \mathsf{shift}_{14\to 11},\\
\mathsf{prs} &= \mathsf{prr}; \mathsf{loop}(\mathsf{home}_{11}; \mathsf{one}; \mathsf{inc}_{14}; \mathsf{prr}); \mathsf{home}_{11},\\
\mathsf{rsv} &= \mathsf{cc}_{2\to 8}; \mathsf{cc}_{5\to 12}; \mathsf{cc}_{7\to 11}; \mathsf{clear}_{13,14}; \mathsf{prs}; \mathsf{cc}_{12\to 5}; \mathsf{cc}_{8\to 2},\\
\mathsf{pbody} &= \mathsf{home}_6; \mathsf{umul}^{12,14}_{5,7\to 11}; \mathsf{clear}_7; \mathsf{copy}_{11\to 7}; \mathsf{inc}_2; \mathsf{rde},\\
\mathsf{upow} &= \mathsf{rde}; \mathsf{loop}(\mathsf{home}_6; \mathsf{rsv}; \mathsf{rde}; \mathsf{pbody}); \mathsf{home}_6.
\end{aligned}$$

Let τ be a workspace of R rows with origin marks up to R that holds the values $a \ge 1$, n and 1 on tracks 5, 6 and 7 and carries 0 on track 2, with $a, n \le R$. Then upow *runs from the root to the root within $4 \cdot 10^6 (n+1)(R + na^n + 1)^3$ units to a workspace of R_n rows with origin marks up to R_n that holds the value a^n on track 7, where*

$$R_0 = R, \qquad R_{j+1} = R_j + a^{j+1}, \qquad \text{so that} \quad R_n \le R + na^n \quad \text{and} \quad a^n \le R_n.$$

No cell of tracks 3, 4 or 15 changes.

Proof. For $j \le n$ let P_j be the configuration at $(j, 6)$ whose tape is a workspace of R_j rows with origin marks up to R_j, holds a, n and a^j on tracks 5, 6 and 7, and carries j on track 2. Every one of these numbers is at most R_j: a, n and $j \le n$ are at most $R \le R_j$, $a^0 = 1 \le a \le R$, and for $j \ge 1$ the power a^j is a summand of R_j. rde ($18j + 10$ units from the root) reaches $(j, 6)$, so the loop starts in P_0; its test is 1 exactly when $j < n$.

A pass from P_j, $j < n$, returns to the root ($18j + 10$) and runs rsv. Its first four parts save j on track 8, put the base a on track 12 and the count a^j on track 11, and blank tracks 13 and 14, within $1000(R_j + 1)$ units (Lemmas I.66 and I.16). prs runs one once for each of the a^j marks of track 11, with track 14 as its cursor; by Lemma I.91(b) each run adds a rows, so prs adds $a \cdot a^j = a^{j+1}$ rows, within $30000(a^j+1)(R_{j+1}+a+2)^2$ units, as in the proof of Lemma I.91(c). The new rows carry 1 on tracks 2, 5, 8, 11 and 14 (Lemma I.17), which keeps every counter whose hole lies in an old row; the last two copies restore the value a on track 5 and the counter j on track 2, which the runs of one used as their own counter. So rsv costs at most $10^6(R_{j+1}+1)^3$ units and leaves R_{j+1} rows. Then rde returns to $(j, 6)$, and pbody returns to the root, forms $a \cdot a^j = a^{j+1} \le R_{j+1}$ on track 11 (Lemma I.92, within $2000(a + a^j + a^{j+1} + 1)^3 \le 54000(R_{j+1}+1)^3$ units), moves it to the blanked track 7, advances track 2 to $j+1$ and reads $(j+1, 6)$. The pass costs at most $2 \cdot 10^6 (R_{j+1}+1)^3$ units with its test and ends in P_{j+1}. At P_n the scanned cell is the blank $(n, 6)$. Lemma I.6, with every pass bounded by $2 \cdot 10^6 (R + na^n + 1)^3$, and home_6

j	instruction	v_j	j	instruction	v_j

Table I.2. The scalar program. Instruction j computes v_j from earlier entries of the archive and appends it. The archive starts with $v_0=p$, $(v_1,\dots,v_6)=(\gamma,\alpha,\beta,s,L,s_0)$ and $(v_7,v_8,v_9)=(M,T,n_0)$; here $r=\mathrm{bl}(M)+\mathrm{bl}(R)+1$.

give the bound. Finally $R_n=R+\sum_{1\le j\le n}a^j\le R+na^n$. The routines write only the headers, tracks 2, 5, 7, 8 and 11 to 14, and the new rows, which carry 0 on tracks 3, 4 and 15. $\square$

I.9.4 The scalar program

After Ctl the archive holds ten numbers, $v_0=p$, $(v_1,\dots,v_6)=(\gamma,\alpha,\beta,s,L,s_0)$ and $(v_7,v_8,v_9)=(M,T,n_0)$. The scalar program appends fifty-one more, $v_{10},\dots,v_{60}$, each computed from earlier entries by one of six operations: a constant at most 4, a sum, a product, a floor quotient, a binary length or a power. Table I.2 lists them. The instructions refer to entries by their fixed positions, never by their values, so the program is the same for every problem.

Lemma I.95 (What the scalar program computes). *Let $v_0, \dots, v_9$ be as above and, for $10 \le j \le 60$, let v_j be the result of instruction j of Table I.2 on $v_0, \dots, v_{j-1}$. Every instruction reads only earlier entries, every constant is at most 4, the divisor v_{28} is positive and the bases v_{11} and v_{25} of the powers are at least 1. Each v_j is the number in the third column; in particular*

$$(v_{19}, v_{22}, v_{24}, v_{30}, v_{37}) = (R, \sigma, S, G, \kappa), \qquad (v_{45}, v_{52}, v_{60}) = (q_P, l_P, c_P),$$

the schedule of Definition 15.18 and the coefficients of the capacity (H.1).

Proof. Induction along the table: each row applies its operation to rows already identified. For instance $v_{19} = (\gamma + \alpha + \beta M) + 1 = R$, $v_{22} = \mathrm{bl}(4R) + 1 = \sigma$, $v_{24} = T2^{\sigma} = S$, $v_{30} = \lfloor (2^{\sigma}+4R)^{S}/2^{\sigma S} \rfloor + 1 = G$ and $v_{37} = \mathrm{bl}(G(1+2S(M+2)))+2 = \kappa$; with $r = v_{41} = \mathrm{bl}(M)+\mathrm{bl}(R)+1$ as in Section H.1, $v_{45} = 2rL + \sigma + r = q_P$, $v_{52} = 3r + (s + 5r + 1)L + 4 = l_P$ and $v_{60} = s_0 + 2s + 2r + (2s + 3r + 2)L + 7 = c_P$. The divisor is $2^{\sigma S} \ge 1$, and the bases are 2 and $2^{\sigma} + 4R \ge 1$. □

Every instruction is a program that grows the rows, loads its operands from the archive, computes, and appends the result. The loading and appending are common to all six kinds:

$$\mathsf{store}_k = \mathsf{cc}_{k \to 11}; \mathsf{start}; \mathsf{end}; \mathsf{append} \qquad (5 \le k \le 10),$$
$$\mathsf{pair}_{i,j}^{A,B} = \mathsf{room}; \mathsf{load}_{i,A}; \mathsf{load}_{j,B},$$

with the archive routines of Lemma I.68 and room of Lemma I.91.

Lemma I.96 (Loading and storing). *Let τ hold an archive $v = (v_0, \dots, v_{K-1})$ within R rows.*

(a) If track k carries $x \le R$, then store_k runs from the root to the root within $10^6(R+1)^2$ units to a tape that holds the archive (v, x) within $R + 1 + x$ rows; track 15 does not change.

(b) If $i, j < K$ and $A \ne B$ lie in $\{5, \dots, 11\}$, then $\mathsf{pair}_{i,j}^{A,B}$ runs from the root to the root within $4 \cdot 10^9(R+2)^5 + (i + j + 6) \cdot 20000\,(Q(R)+1)^2$ units to a tape that holds the same archive within $Q(R)$ rows and the values v_i and v_j on tracks A and B; track 15 does not change.

Proof. (a) $\mathsf{cc}_{k \to 11}$ (at most $300(R+1)$ units) puts the value x on track 11. By Lemma I.68(a) and (g), $\mathsf{start}; \mathsf{end}$ puts on track 13 the end $e = |\omega| + 1 + \sum_j (v_j + 1) \le R$ of the archive within $3000(R+1)$ units, and by (f) append writes the word $u(x)$ from row e and its terminator within $100000(R + e + x + 3)^2 \le 900000(R+1)^2$ units, ending within $R + 1 + x$ rows, with the rows before e of tracks 3 and 4 and all of track 15 unchanged. The sum is at most $10^6(R+1)^2$. (b) Lemma I.91(e), then Lemma I.68(c) twice with $Q(R)$ rows; the second load changes only tracks 12, 13 and B, so track A keeps v_i. □

The six instruction programs are

$$\begin{aligned}
\mathsf{op}[c] &= \mathsf{room};\mathsf{clear}_5;\mathsf{inc}_5^{c};\mathsf{store}_5,\\
\mathsf{op}[v_i+v_j] &= \mathsf{pair}_{i,j}^{5,7};\mathsf{acc}_{5\to7}^{2};\mathsf{store}_7,\\
\mathsf{op}[v_i\cdot v_j] &= \mathsf{room};\mathsf{load}_{i,5};\mathsf{load}_{j,7};\mathsf{umul}_{5,7\to11}^{12,14};\mathsf{start};\mathsf{end};\mathsf{append},\\
\mathsf{op}[\lfloor v_i/v_j\rfloor] &= \mathsf{pair}_{i,j}^{11,10};\mathsf{clear}_{2,5,6,7};\mathsf{cc}_{10\to12};\mathsf{udiv};\mathsf{store}_7,\\
\mathsf{op}[\mathrm{bl}(v_i)] &= \mathsf{room};\mathsf{load}_{i,11};\mathsf{clear}_{2,5,6,7,8};\mathsf{clear}_{12};\mathsf{inc}_{12}^{2};\mathsf{ublen};\mathsf{store}_8,\\
\mathsf{op}[v_i^{\,v_j}] &= \mathsf{pair}_{i,j}^{5,6};\mathsf{clear}_{2,7,9,10};\mathsf{clear}_7;\mathsf{inc}_7^{1};\mathsf{upow};\mathsf{store}_7.
\end{aligned}$$

Lemma I.97 (One instruction)**.** *Let τ hold an archive $v=(v_0,\dots,v_{K-1})$ within r rows, and let ι be one of the six instructions with operand positions $i,j<K$, a constant $c\le 4$, a positive divisor and a base at least* 1*. Let $\iota(v)$ be its result. Then* $\mathsf{op}[\iota]$ *runs from the root to the root in some t units to a tape that holds the archive $(v,\iota(v))$ within r' rows, with track* 15 *unchanged, and*

$$t\le C_\iota(r+2)^6,\qquad r'\le D_\iota(r+2)^6,\qquad t+r'+2\le(C_\iota+D_\iota+2)(r+2)^6,$$

where (C_ι,D_ι) is $(10^{12},132)$ for a constant, $((i+j+11)10^{12},132)$ for a sum or a quotient, $((i+j+10)10^{12},132)$ for a product, $((i+10)10^{12},132)$ for a binary length, and, for a power with $a=v_i$ and $n=v_j$,

$$C_\iota=(i+j+10)10^{12}+\big(4\cdot10^6(n+1)+1010000\big)\cdot287496\,(na^n+1)^3,$$
$$D_\iota=66\big((n+1)a^n+1\big).$$

Proof. Put $Q=Q(r)$; then $(Q+1)^2\le4356(r+2)^6$ and $(Q+1)^3\le287496(r+2)^6$, and $(r+2)^5\le(r+2)^6$. Every entry of the archive is at most r, so a sum of two entries is at most $2r\le Q$, a product at most $r^2\le Q$, and a quotient or a binary length at most r. In the first five kinds the result x is therefore at most Q, and $r'=Q+1+x\le2Q+1\le132(r+2)^6$.

Constant. room costs at most $4\cdot10^9(r+2)^5$ (Lemma I.91(e)); clear_5 and inc_5^{c} ($49Q+19$ and $18c^2+36c+1$ units) leave the value c on track 5; store_5 costs at most $10^6(Q+1)^2$. The total is at most $4\cdot10^9(r+2)^5+2\cdot10^6(Q+1)^2\le10^{12}(r+2)^6$.

Sum. By Lemma I.96(b) tracks 5 and 7 hold $a=v_i$ and $b=v_j$; $\mathsf{acc}_{5\to7}^{2}$ makes track 7 carry $a+b$ within $500(Q+1)^2$ units (Lemma I.15(b)), and store_7 appends it within $10^6(Q+1)^2$. The total is at most $4\cdot10^9(r+2)^5+(i+j+6)\cdot20000(Q+1)^2+1010000(Q+1)^2\le(i+j+11)10^{12}(r+2)^6$.

Product. After the two loads, $\mathsf{umul}_{5,7\to11}^{12,14}$ leaves the counter ab on track 11 within $2000(a+b+ab+1)^3\le54000(Q+1)^3$ units (Lemma I.92), and $\mathsf{start};\mathsf{end};\mathsf{append}$ appends it within $3000(Q+1)+100000(3Q+3)^2$ units, as in Lemma I.96(a). The total is at most $4\cdot10^9(r+2)^5+(i+j+6)20000(Q+1)^2+54000(Q+1)^3+3000(Q+1)+900000(Q+1)^2\le(i+j+10)10^{12}(r+2)^6$.

Quotient. Tracks 11 and 10 hold $a=v_i$ and $b=v_j\ge1$. The clearing and $\mathsf{cc}_{10\to12}$ prepare Lemma I.78 (the value b on track 12, tracks 2, 5, 6 and 7 blank, $a+1\le Q$), and udiv leaves the value $\lfloor a/b\rfloor$ on track 7; the three parts cost at most $10^4(Q+1)^2$ units. With store_7 the total is at most the bound of a sum.

Binary length. After the load, track 11 holds $n = v_i$; the clearing and inc_{12}^{2} give the hypotheses of Lemma I.93 with Q rows and $n + 2 \le Q$, and ublen leaves the value $\mathrm{bl}(n)$ on track 8. These parts cost at most $40000(Q+1)^3$ units, the load and room at most $4 \cdot 10^9 (r+2)^5 + (i+3)20000(Q+1)^2$, and store_8 at most $10^6(Q+1)^2$; the total is at most $(i+10)10^{12}(r+2)^6$.

Power. Tracks 5 and 6 hold $a \ge 1$ and n; the clearing and inc_{7}^{1} (at most $10^4(Q+1)^2$ units) give the hypotheses of Lemma I.94 with $R = Q$, so upow leaves the value a^n on track 7 within $4 \cdot 10^6 (n+1)(Q + na^n + 1)^3$ units and $Q_n \le Q + na^n$ rows, with $a^n \le Q_n$; store_7 costs at most $10^6(Q_n+1)^2 \le 10^6(Q+na^n+1)^3$ and leaves $r' = Q_n + 1 + a^n$ rows. Since $Q + na^n + 1 \le (na^n+1)(Q+1) \le 66(na^n+1)(r+2)^2$, the time is at most $C_\iota (r+2)^6$; and $r' \le Q + (n+1)a^n + 1 \le ((n+1)a^n+1)(Q+1) \le D_\iota (r+2)^6$.

In every kind the routines write only scratch tracks, tracks 3 and 4 from the end of the archive on, and new rows; so the archive grows by exactly $\iota(v)$ and track 15 is kept. □

Lemma I.98 (The scalar program). *Let* $\mathsf{Prog} = \mathsf{op}[\iota_{10}]; \mathsf{op}[\iota_{11}]; \cdots; \mathsf{op}[\iota_{60}]; \mathsf{skip}$, *where* ι_j *is instruction* j *of Table I.2. Fix* $v_0, \dots, v_9$. *There is a constant* K_P, *depending only on* $v_0, \dots, v_9$, *such that from every tape that carries the saved request and holds the archive* $(v_0, \dots, v_9)$ *within* r *rows,* Prog *runs from the root to the root in some* t *units to a tape that carries the saved request and holds the archive* $(v_0, \dots, v_{60})$ *of Lemma I.95 within* r' *rows, and*

$$t + r' + 2 \le K_P (r+2)^{6^{51}}.$$

Proof. For $10 \le j \le 61$ let $\mathsf{Prog}_j = \mathsf{op}[\iota_j]; \cdots; \mathsf{op}[\iota_{60}]; \mathsf{skip}$, so that $\mathsf{Prog}_{61} = \mathsf{skip}$ and $\mathsf{Prog}_{10} = \mathsf{Prog}$. We show by downward induction on j that there is a constant K_j, depending only on $v_0, \dots, v_{j-1}$, such that from every tape holding $(v_0, \dots, v_{j-1})$ within r rows, Prog_j reaches a tape holding $(v_0, \dots, v_{60})$ within r' rows with $t + r' + 2 \le K_j (r+2)^{6^{61-j}}$. For $j = 61$, skip takes 1 unit and $1 + r + 2 \le 2(r+2)$. For $j \le 60$, Lemma I.95 says that ι_j is admissible on $(v_0, \dots, v_{j-1})$ with result v_j, and Lemma I.97 gives $t + r'' + 2 \le K_{\iota_j}(r+2)^6$ for $\mathsf{op}[\iota_j]$, where $K_{\iota_j} = C_{\iota_j} + D_{\iota_j} + 2$ depends only on j and the entries ι_j reads. Lemma I.73 with the exponents 6 and 6^{60-j} gives the claim for j with $K_j = K_{\iota_j} + K_{j+1} K_{\iota_j}^{6^{60-j}}$ and the exponent $6 \cdot 6^{60-j} = 6^{61-j}$. The saved request is kept because track 15 and the rows of ω are never written. For $j = 10$ the exponent is 6^{51}. □

So the exponent 6^{51} is 6, the exponent of one instruction, raised to the number 51 of instructions. The constant K_P is astronomically large, since the power instructions write $(2^\sigma + 4R)^S$ and $2^{\sigma S}$ in unary, but it is fixed once the problem is fixed.

I.9.5 The seed

The last part of Scalar reads m, copies the eight numbers that the tail needs from the archive into the registers, and adds enough rows for every number the tail will form. The archive

reads use tracks 12 and 13 as scratch, so the order of the moves matters: m is parked on track 8, n_0 on track 14, and c_P is moved to track 13 only after the last read. Put

$$\begin{aligned}\mathsf{mv} &= \mathsf{cc}_{9\to8};\mathsf{load}_{22,5};\mathsf{load}_{24,6};\mathsf{load}_{37,7};\mathsf{load}_{45,9};\mathsf{load}_{52,10};\mathsf{load}_{9,11};\mathsf{cc}_{11\to14};\\ &\qquad \mathsf{load}_{60,11};\mathsf{cc}_{11\to13};\mathsf{cc}_{8\to11};\mathsf{cc}_{14\to12};\mathsf{clear}_{8};\mathsf{skip},\\ \mathsf{troom} &= \mathsf{cc}_{12\to8};\mathsf{quad}_{14};\mathsf{quad}_{14};\mathsf{cc}_{8\to12};\mathsf{cc}_{11\to14};\mathsf{cc}_{14\to11};\mathsf{clear}_{8,14},\\ \mathsf{Seed} &= \mathsf{getc}_{1};\mathsf{mv};\mathsf{troom}.\end{aligned}$$

Lemma I.99 (The seed)**.** *Let τ carry the saved request and hold the archive $(v_0,\dots,v_{60})$ of Lemma I.95 within R rows. Then* Seed *runs from the root to the root in some t units to a seed with $r' = Q(Q(R+m))$ rows (Definition I.85(a)), and*

$$t + r' + 1 \le 2\cdot 10^{22}\,(R+m+2)^{10}.$$

Proof. Put $R' = R + m$. By Lemma I.90(b) with $k = 1$, getc_1 leaves the value m on track 9 and the archive within R' rows, within $55000(R'+1)^2$ units.

Each of the thirteen moves of mv is a clean copy (Lemma I.66(a)) or an archive read (Lemma I.68(c), with an index at most 60), and costs at most $64\cdot 20000(R'+1)^2$ units; with the final skip, mv costs at most $17920000(R'+1)^2$. A read changes only tracks 12, 13 and its target. Following the moves, with Lemma I.95 for the entries: track 8 receives m; tracks 5, 6, 7, 9 and 10 receive $v_{22} = \sigma$, $v_{24} = S$, $v_{37} = \kappa$, $v_{45} = q_P$ and $v_{52} = l_P$; track 11 receives $v_9 = n_0$, which is copied to track 14; track 11 then receives $v_{60} = c_P$, which is copied to track 13; finally m returns to track 11, n_0 to track 12, and track 8 is blanked. So tracks 5, 6, 7, 9, 10, 11, 12 and 13 hold the values σ, S, κ, q_P, l_P, m, n_0 and c_P, and track 8 holds 0. Each is at most R', since the entries of the archive are at most R.

In troom, $\mathsf{cc}_{12\to8}$ saves n_0 on track 8. Lemma I.91(d) with $c = 14$, applied twice, grows the workspace to $Q(Q(R'))$ rows and keeps the counters on tracks 5 to 11 and 13; it blanks tracks 12 and 14. The new rows carry 1 on track 11, so the value m there has become a counter; $\mathsf{cc}_{8\to12}$, $\mathsf{cc}_{11\to14}$ and $\mathsf{cc}_{14\to11}$ make tracks 12 and 11 hold the values n_0 and m again, and $\mathsf{clear}_{8,14}$ blanks tracks 8 and 14. The two growths cost at most $3\cdot 10^9\big((R'+2)^5 + (Q(R')+2)^5\big)$ units and the copies and clearings at most $50000(Q(Q(R')) + R' + 2)$. Since $Q(R') + 2 \le 67(R'+2)^2$ and $Q(Q(R')) \le 66\cdot 67^2(R'+2)^4$, troom and the row count $Q(Q(R'))+1$ together are at most $10^{22}(R'+2)^{10}$.

The tape is now a seed with $r' = Q(Q(R'))$ rows, except for the inequality $\rho(m) \le r'$. Put $x = R' + 1$, an upper bound for each of σ, S, κ, m, n_0, q_P, l_P and c_P. Then $N \le 2x$, $q_P N \le 2x^2$, $q_P N + l_P \le 3x^2$, $(q_P N + l_P)N \le 6x^3$, $\mathscr{B}(N) \le 7x^3$ and $W_m \le 28x^3 + 4$, so $\rho(m) \le 70x^3 \le 128x^3$. And $Q(y) \ge 64(y+1)^2$ for every y, so $Q(Q(R')) \ge 64(64(R'+1)^2)^2 \ge 128(R'+1)^3$. Hence $\rho(m) \le r'$. No part writes tracks 3, 4 or 15 in the old rows, and the new rows carry 0 there, so the saved request is kept. Adding the three bounds gives $t + r' + 1 \le 2\cdot 10^{22}(R'+2)^{10}$. □

Proof of Proposition I.86. Let τ carry the saved request and hold the archive $(p,\gamma,\alpha,\beta,s,L,s_0)$ within r rows.

(i) By Lemma I.90(d), Ctl runs in t_1 units to a tape holding the archive $(v_0,\dots,v_9)$, that is

$$(p,\gamma,\alpha,\beta,s,L,s_0,M,T,n_0),$$

within r_1 rows, with $t_1 + r_1 + 2 \le K_C(r+2)^8$.

(ii) By Lemma I.98, Prog runs in t_2 units to a tape holding $(v_0, \dots, v_{60})$ within r_2 rows, with $t_2 + r_2 + 2 \le K_P(r_1+2)^{6^{51}}$.

(iii) By Lemma I.99, Seed runs in t_3 units to a seed with r' rows, with $t_3 + r' + 2 \le F(r_2 + m + 2)^{10}$ and $F = 2 \cdot 10^{22} + 1$.

Lemma I.73 with the exponents 8 and 6^{51} combines (i) and (ii): $t_1 + t_2 + r_2 + 2 \le B(r+2)^A$ with $A = 8 \cdot 6^{51}$ and $B = K_C + K_P K_C^{6^{51}}$. Since $m \le (r+m+2)^A$ and $r + 2 \le r + m + 2$,

$$t_1 + t_2 + (r_2 + m) + 2 \le (B+1)\,(r+m+2)^A.$$

Lemma I.73 with $x = r + m$, $y = r_2 + m$, $z = r'$ and the exponents A and 10 combines this with (iii):

$$t_1 + t_2 + t_3 + r' + 2 \le \big((B+1) + F(B+1)^{10}\big)(r+m+2)^{80 \cdot 6^{51}}.$$

So $K_T = (B+1) + F(B+1)^{10}$, which depends only on p, the problem and n_0. The three programs run from the root to the root. □

I.9.6 The order, the capacity and the width

From a seed, the last program forms $\max(m, n_0)$ on track 8 with $\mathsf{max}^{14}_{11,12\to 8}$ (Lemma I.79) and then runs a straight-line code of eleven register instructions. Every instruction is a foundation routine or the product of Lemma I.92 acting on counters of the tracks 5 to 13, with tracks 2 and 14 as scratch:

$$\begin{aligned}\mathsf{Code} = {} & \mathsf{acc}^2_{7\to 8}; \mathsf{umul}^{2,14}_{9,8\to 11}; \mathsf{acc}^2_{10\to 11}; \mathsf{umul}^{2,14}_{11,8\to 12}; \mathsf{acc}^2_{13\to 12}; \mathsf{copy}_{12\to 10};\\ & \mathsf{copy}_{12\to 9}; \mathsf{acc}^2_{12\to 9}; \mathsf{acc}^2_{12\to 9}; \mathsf{acc}^2_{12\to 9}; \mathsf{inc}^4_9; \mathsf{skip}.\end{aligned}$$

With $n = \max(m, n_0)$ on track 8 it computes $N = n + \kappa$ on track 8, then $q_P N$, $q_P N + l_P$ on track 11, $(q_P N + l_P)N$ and $\mathscr{B}(N) = (q_P N + l_P)N + c_P$ on track 12 (Horner's rule), copies $\mathscr{B}(N)$ to tracks 10 and 9, and adds it three more times and 4 to track 9, which then carries $4\mathscr{B}(N) + 4 = W_m$.

Lemma I.100 (Register instructions). *Let τ have origin marks up to r, let $\rho \le r$, and let k, k' and l be distinct tracks among $5, \dots, 13$. Each of the following runs from the root to the root within $10^5(\rho+1)^3$ units and changes only the tracks named, in rows $j \le \rho$.*

(a) If track k carries $x \le \rho$, $\mathsf{copy}_{k\to l}$ makes track l carry x; only track l changes.

(b) If tracks k and l carry b and a with $a + b \le \rho$, $\mathsf{acc}^2_{k\to l}$ makes track l carry $a + b$; only tracks l and 2 change.

(c) If tracks k and k' carry a and b with $a, b, ab \le \rho$, $\mathsf{umul}^{2,14}_{k,k'\to l}$ makes track l carry ab; only tracks l, 2 and 14 change.

(d) If track l carries a, $c \le 4$ and $a + c \le \rho$, inc^c_l makes track l carry $a + c$; only track l changes.

Proof. (a) and (b) are Lemma I.15, within $100(x+1)$ and $500(a+b+1)^2$ units. (c) is Lemma I.92, within $2000(a+b+ab+1)^3 \le 54000(\rho+1)^3$ units. (d) is Lemma I.14(b), within $18c^2 + (36a+2l+26)c + 1 \le 144\rho + 497$ units. The cells written are those of the counters involved, in rows at most the largest number formed, which is at most ρ. □

Proof of Lemma I.87. Let τ be a seed with r rows, write $\rho = \rho(m) \le r$ and $n = \max(m, n_0)$. By Lemma I.63, corr costs at most $37r + 13$ units and writes the origin marks up to r again, changing only track 1. Tracks 11 and 12 hold m and n_0, and $n \le \rho$, so by Lemma I.79 $\mathsf{max}^{14}_{11,12\to 8}$ makes track 8 carry n within $400(m+n_0+1) \le 10^5(\rho+1)^3$ units, changing only tracks 8 and 14 in rows $j \le n$. Then tracks 5 to 13 carry

$$\sigma,\ S,\ \kappa,\ n,\ q_P,\ l_P,\ m,\ n_0,\ c_P.$$

The eleven instructions of Code change them, in order, as follows: track 8 becomes $n+\kappa = N$; track 11 becomes $q_P N$ and then $q_P N + l_P$; track 12 becomes $(q_P N + l_P)N$ and then $(q_P N + l_P)N + c_P = \mathscr{B}(N)$; tracks 10 and 9 become $\mathscr{B}(N)$; track 9 becomes $2\mathscr{B}(N)$, $3\mathscr{B}(N)$, $4\mathscr{B}(N)$ and $4\mathscr{B}(N) + 4 = W_m$. Every number formed, and every sum and product formed on the way, is one of the summands of ρ or at most W_m, so it is at most ρ, and Lemma I.100 applies to each instruction. Each instruction changes only its destination and the scratch tracks 2 and 14, so the other registers keep their counters. The code costs at most $11 \cdot 10^5(\rho+1)^3 + 1$ units. In all,

$$t \le 37r + 13 + 10^5(\rho+1)^3 + 11 \cdot 10^5(\rho+1)^3 + 1 \le 14 \cdot 10^5(\rho+1)^3 + 37r + 13.$$

Tracks 5 to 10 now carry σ, S, κ, N, W_m and $\mathscr{B}(N)$, and $\sigma + S + \kappa + N + W_m + \mathscr{B}(N) \le \rho \le r$. Tracks 3, 4 and 15 are not written, so the saved request is kept; every write is to a track $k \ge 1$ in a row $j \le r$, so the tape is still a workspace of r rows, and track 1 is not written after corr. This is a scheduled request with r rows.

For the bound on ρ: $N \ge \kappa \ge 2$, so $q_P N$, $q_P N + l_P$ and $(q_P N + l_P)N$ are at most $\mathscr{B}(N)$, and

$$\rho(m) \le (F+10) + m + N + 4\mathscr{B}(N) + W_m, \qquad F = \sigma + S + \kappa + n_0 + q_P + l_P + c_P.$$

Now $m \le X$ and $N \le X$, so N^2, N, 1 are at most X^2 and $\mathscr{B}(N) \le (q_P + l_P + c_P)X^2$; and $W_m \le (4(q_P + l_P + c_P) + 4)X^2$ by Proposition I.32(e). With $X \ge 1$ this gives $\rho(m) \le c_\rho X^2$ for $c_\rho = F + 16 + 8(q_P + l_P + c_P)$, which depends only on the problem and n_0. □

I.9.7 The whole stage

The stage is assembled from four bounds: Prepare in the rows, the front half and the scalar tail in the rows plus the precision, and Width in the tail room. Only the exponents are tracked; every constant that appears depends on the problem and n_0 alone.

Proof of Theorem I.88. Let τ be a decoded request with r rows, and put $Y = X + r + 1$, so that $Y \ge 1$, $m + 1 \le X$ and $r + 2 \le Y$.

(i) By Lemma I.61, Prepare runs in $t_0 \le 4000(r+2)^2 \le 4000Y^2$ units to a prepared request with $r+1$ rows.

(ii) By Theorem I.62(c), MetaBank; Summ then runs in t_1 units to a tape that carries the saved request and holds the archive $(p, \gamma, \alpha, \beta, s, L, s_0)$ within r_1 rows, with $t_1 + (r_1 + m) + 2 \le E((r+1) + m + 2)^{72}$ and $E = K_1 + K_2 K_1^3$.

(iii) By Proposition I.86, for the payload row p, which depends only on the problem, Scalar then runs in t_2 units to a seed with r_2 rows, with $t_2 + r_2 + 2 \le K_T(r_1 + m + 2)^b$ and $b = 80 \cdot 6^{51}$.

(iv) By Lemma I.87, Width then runs in $t_3 \le 14 \cdot 10^5(\rho(m) + 1)^3 + 37 r_2 + 13$ units to a scheduled request with $r' = r_2$ rows, and $\rho(m) \le r_2$.

Lemma I.73 with $x = r + 1 + m$, $y = r_1 + m$, $z = r_2$, $a = 72$ and the exponent b combines (ii) and (iii):

$$t_1 + t_2 + r_2 + 2 \le K_P(r + m + 3)^{g_P}, \qquad K_P = E + K_T E^b, \quad g_P = 72 \cdot 80 \cdot 6^{51}.$$

Since $r + m + 3 \le X + r + 2 \le 2Y$, this gives $t_1 + t_2 + r_2 + 1 \le K_P 2^{g_P} Y^{g_P}$, and with (i)

$$t_0 + t_1 + t_2 + r_2 + 1 \le K_S Y^{g_P + 2} \le K_S Y^{g_P + 3}, \qquad K_S = K_P 2^{g_P} + 16000.$$

For the last part, $\rho(m) + 1 \le Y + r_2 + 1$ and $38 r_2 + 14 \le 100(Y + r_2 + 1)^3$, so

$$t_3 + r_2 + 1 \le 1400100\,(Y + r_2 + 1)^3.$$

Lemma 15.36(a) with $N = Y$, $s = t_0 + t_1 + t_2$, $r = r' = r_2$, $A = K_S$, $e = g_P + 3$, $K = 1400100$ and $g = 3$ gives

$$(t_0 + t_1 + t_2 + t_3) + r' + 1 \le \left(K_S + 1400100(K_S + 1)^3\right) Y^{4(g_P + 3)}.$$

This is the claim with $K_q = K_S + 1400100(K_S + 1)^3$ and $g_q = 4(72 \cdot 80 \cdot 6^{51} + 3)$. The four programs run from the root to the root, so their sequence does. □

The exponent g_q enters the exponent λ of Theorem 15.33 as the exponent of the stage that follows the decoding (Section I.16). It is large because the composition rule multiplies exponents and the schedule is a long fixed sequence of polynomial steps; it is fixed, because the program Schedule and every count in this section are the same for every problem.

I.10 The first vector

How does the machine turn the initial point $y_0 = (\frac{1}{3}, -2)$ into its first stored vector? For illustration let $N = 3$. Lemma 15.35 asks for $Z_0 = \mathrm{near}(2^3 y_0)$, coordinate by coordinate, and $\mathrm{near}(u/v) = \lfloor (2u + v)/(2v) \rfloor$ for $v > 0$. For the first coordinate the request supplies the numerator 1 and the denominator 3. The machine forms the dividend $2 \cdot 1 \cdot 2^3 + 3 = 19$ and the divisor $2 \cdot 3 = 6$ and divides once: $\lfloor 19/6 \rfloor = 3 = \mathrm{near}(8/3)$. For the second coordinate, $-2 = -2/1$, the dividend is $2 \cdot (-2) \cdot 2^3 + 1 = -31$ and the divisor 2. The machine divides the magnitude, $31 = 2 \cdot 15 + 1$, and because the dividend is negative and the remainder is not zero it corrects the quotient to $-16 = \lfloor -31/2 \rfloor = \mathrm{near}(-16)$. It then writes the signed words $\mathrm{sw}_W(3)\,\mathrm{sw}_W(-16)$ on the binary stream, $2(W + 2)$ bits. Everything else in this section

is the bookkeeping around these divisions: the machine stores its controls, reserves the rows that every later stage will use, finds the frames of y_0 in the saved request, and after the last coordinate puts back the controls that the steps read.

This section constructs that stage, proves its contract and proves its step bound, with exponent 190674. The stored vector it leaves is the state between Taylor steps, defined first; the step loop that starts from it, the selection of the answer coordinate and the exponent of the whole trajectory are in Section I.13.

I.10.1 The stored vector and the stage

Throughout this section and Section I.13 a problem with a coefficient field of dimension d is fixed, with rational initial point y_0, radius $M \geq 1$, natural end time T, a level n_0 at which the region certificate holds, and the constants σ, S and κ of Definition 15.18. Write $y_{0,j} = u_j/e_j$ with the integer u_j and the positive integer e_j that the request carries. For a request with coordinate $i < d$ and precision m put $n = \max(m, n_0)$, $N = N(n)$, $W = W_m$ and $X = m + n_0 + \kappa + 1$, and let $Z_0, \dots, Z_S$ be the integer vectors of Lemma 15.35 at the level n, so that $Z_0 = \mathrm{near}(2^N y_0)$. Let c_{req} be the constant of Theorem I.42(c) and put

$$\rho_{\mathrm{traj}} = S + 100(d+1)(N+1)(W+2)^2 + (c_{\mathrm{req}} + 2)X + 1.$$

Definition I.101 (The stored vector)**.** Let $Z = (Z_0, \dots, Z_{d-1})$ be a list of d integers and $r \in \mathbb{N}$. A tape τ *holds the stored vector Z on r rows* if

(a) τ carries the saved request (Definition I.41);

(b) tracks 5, 8, 9 and 10 carry the counters m, N, W and σ;

(c) the binary stream holds the word $\mathrm{sw}_W(Z) = \mathrm{sw}_W(Z_0) \cdots \mathrm{sw}_W(Z_{d-1})$ of $d(W+2)$ bits;

(d) τ is a workspace of r rows with origin marks up to r;

(e) $r \geq \rho_{\mathrm{traj}}$ (the *reserve*).

In (c), $\mathrm{sw}_W(z)$ is the bit $[z < 0]$ followed by the $W+1$ lowest binary digits of $|z|$, as in Definition I.3(c); for every entry that fits W this is its signed word, and every vector the machine stores fits W (Proposition I.32(a)). The definition says nothing about tracks 2, 11 to 14, or about the cells of tracks 3 and 4 after the end of the saved request: the step loop keeps its counter on track 2 and the step count S on track 14, the coefficient stage uses the output buffer, and this stage leaves its archive of controls after the saved request. The reserve exceeds S, $d(W+2)$ and $100(d+1)(N+1)(W+2)^2$; the later stages use it for the step counter, the stored vector and the coefficient table.

The stage is

$$\mathsf{Init} = \mathsf{Arch};\mathsf{Res};\mathsf{Pos};\mathsf{Pack};\mathsf{Rest}, \qquad \mathsf{Pack} = \mathsf{Res};\mathsf{Pos};\mathsf{Begin};\mathsf{Coords},$$
$$\mathsf{Coords} = \mathsf{left}^{15};\mathsf{loop}(\mathsf{home}_{14};\mathsf{Coord};\mathsf{left}^{15});\mathsf{home}_{14},$$
$$\mathsf{Coord} = [\mathsf{Prep},\ \mathsf{Load},\ \mathsf{Copy},\ \mathsf{Scale},\ \mathsf{Add},\ \mathsf{Div},\ \mathsf{Emit},\ \mathsf{pred}_{14}],$$

with pred_{14} of Lemma I.127. Its parts do the following.

(1) Arch appends the five numbers S, σ, N, W and m to the saved request as an archive (Definition I.60), reading m from the last frame of the request (Lemma I.103).

(2) Res adds rows; afterwards there are at least $512(r+1)^4 \geq \rho_{\mathrm{traj}}$ of them (Lemma I.104).

(3) Pos finds the first payload frame and loads N and W from the archive (Lemma I.105). The reservation and the positioning run twice, once in Init and once at the start of Pack; the second pair acts on more rows and leaves the tape in the same form.

(4) Begin empties the binary stream, and Coords runs Coord once for each of the d marks of a counter on track 14. Each run reads the frames of u_j and e_j, computes $\mathrm{near}(2^N u_j/e_j)$ with one division, appends its signed word to the binary stream and removes one mark (Lemmas I.115 and I.116).

(5) Rest loads S, σ, N, W and m back from the archive onto the tracks the loop reads, puts S on track 14 and sets the step counter on track 2 to 0 (Lemma I.106).

Theorem I.102 (The first vector)**.** *There is a constant K_{i}, depending only on the problem and n_0, with the following property. Let $r \in \mathbb{N}$, $i < d$ and m, and let τ be a scheduled request with r rows (Definition I.85). Then* Init *runs from $(-1,\tau)$ to $(-1,\tau')$ in some number t of units, where for some r'*

(a) τ' holds the stored vector $Z_0 = \mathrm{near}(2^N y_0)$ on r' rows;

(b) track 2 of τ' carries the counter 0, and track 14 carries a retained word of length S from row 0;

(c) $t + r' + 1 \leq K_{\mathrm{i}}(X + r + 1)^{190674}$.

The exponent is built from the exponents of the parts by Lemma 15.36(a):

$$190674 = 66\big(8\big(90(2+2)+1\big)+1\big).$$

One coordinate costs at most $250000(r+1)^2$ units (exponent 2), so the loop over the d coordinates has exponent 3; the reservation contributes the exponent 10 and the positioning 8, which makes 90 for the first three parts of Pack and $90 \cdot 4 = 360$ for Pack; positioning in front of it gives $8 \cdot 361 = 2888$; the archive, of exponent 2, followed by the reservation gives $2 \cdot 11 = 22$, then $22 \cdot 2889$; and the restoration, of exponent 2, gives the factor 3. The constants are recorded in the proof, which closes the section.

I.10.2 Routines from the schedule

Two kinds of routine of this stage were already needed by the schedule. The precision m is the last frame of the request and the coordinate i the one before it; the machine finds such a frame by walking back from the end of the saved request over the frame-start marks of track 15, and reads it as Section I.7 reads every frame. With the routines send and pf^k of Lemma I.89,

$$\mathsf{cur}_k = \mathsf{send};\mathsf{pf}^k;\mathsf{tc}, \qquad \mathsf{getc}_k = \mathsf{cur}_k;\mathsf{clear}_{8,9};\mathsf{cc}_{2\to 5};\mathsf{fetch};\mathsf{reset}_8;\mathsf{toUnary}^+$$

Part	Bound	Reference
Arch	$t + r' + 1 \le 10^{10}(X + r + 1)^2$	Lemma I.103
Res	$t + r' + 1 \le 10^{22}(r + 2)^{10}$	Lemma I.104
Pos	$t + r' + 1 \le C_{\mathrm{pos}}(X + r + 1)^8$	Lemma I.105
Begin	48	Lemma I.116
Coord	$250000(r + 1)^2$, rows fixed	Lemma I.115
Coords	$t + r + 1 \le (250080(d + 1) + 2)(r + 1)^3$	Lemma I.116
Pack	$t + r' + 1 \le K_{\mathrm{pk}}(X + r + 1)^{360}$	Lemma I.117
Pos; Pack	$t + r' + 1 \le K_{\mathrm{pp}}(X + r + 1)^{2888}$	Lemma I.117
Rest	$t + r + 1 \le 2 \cdot 10^6(r + 1)^2$, rows fixed	Lemma I.106
Init	$t + r' + 1 \le K_{\mathrm{i}}(X + r + 1)^{190674}$	Theorem I.102

Table I.3. The bounds of the first-vector stage; r is the number of rows at the start of the part and r' at its end.

are the programs of Lemma I.90: cur_k puts on track 2 the first row of the k-th frame from the end, and getc_k reads that frame into unary on track 9. That lemma states getc_k for $k \in \{1, 3, 4, 5\}$ and cur_k for every $k \le 5$. The selection of Section I.13 uses cur_2: by part (a) of that lemma with $k = 2$, if τ carries the saved request and is a workspace of R rows with origin marks up to R, then cur_2 runs from the root to the root within $106(R + 1)$ units, makes track 2 carry the first row s_{F-1} of the frame of i, and changes only tracks 2 and 14, in rows $j \le R$. The reserve is made by the program $\mathsf{room} = \mathsf{clear}_{5,\dots,11}; \mathsf{quad}_{13}$ of Lemma I.91, which takes a tape that holds an archive within R rows to one that holds the same archive within $Q(R) = R + 1 + 64(R + 1)^2$ rows, within $4 \cdot 10^9(R + 2)^5$ units, writing tracks 3, 4 and 15 only in the new rows, where it leaves 0.

I.10.3 The controls, the reserve and the frames of y_0

The archive of Definition I.60(b) is built on the saved word $\omega = w_u$: a tape *holds the archive* $(v_1, \dots, v_k)$ *within R rows* if w_u lies on tracks 3 and 4 from row 0, the unary words $1^{v_1}0 \cdots 1^{v_k}0$ follow it from row $|w_u| + 1$, and $|w_u| + 1 + \sum_j (v_j + 1) \le R$. A program that writes no cell of tracks 3, 4 and 15 keeps the saved request and every archive. For a track k put $\mathsf{psh}_k = \mathsf{cc}_{k \to 11}; \mathsf{push}$, with push of Lemma I.68, and

$$\mathsf{Arch} = \mathsf{cc}_{5\to 10}; \mathsf{init}; \mathsf{psh}_6; \mathsf{psh}_{10}; \mathsf{psh}_8; \mathsf{psh}_9; \mathsf{grow}; \mathsf{getc}_1; \mathsf{psh}_9.$$

Lemma I.103 (The archive of the controls)**.** *Let τ be a scheduled request with r rows. Then* Arch *runs from $(-1, \tau)$ to $(-1, \tau_{\mathrm{a}})$ in some t units, where τ_{a} carries the saved request, holds the archive (S, σ, N, W, m) within r_{a} rows, is a workspace of r_{a} rows with origin marks up to r_{a}, $r \le r_{\mathrm{a}}$, and*

$$t + r_{\mathrm{a}} + 1 \le 10^{10}(X + r + 1)^2.$$

Proof. By Definition I.85, τ carries the saved request, is a workspace of r rows with origin marks up to r, and carries the counters σ, S, κ, N, W and $\mathscr{B}(N)$ on tracks 5 to 10, whose sum is at most r. Put $Y = X + r + 1$. The parts run from the root to the root, and each writes no cell of tracks 3, 4 and 15 except in the rows of the archive it extends.

(1) $\mathsf{cc}_{5\to 10}$ (at most $300(r+1)$ units, Lemma I.66) makes track 10 hold σ.

(2) init (Lemma I.68(e)) leaves the empty archive within $R_0 = r+2$ rows, keeps the counters S, N, W and σ on tracks 6, 8, 9 and 10, and takes at most $3000(r+3)$ units.

(3) Each psh_k copies the counter n of track k onto track 11 (at most $300(R+1)$ units) and appends it (Lemma I.68(h)): from an archive within R rows to the extended archive within $R{+}1{+}n$ rows, within $10^6(R{+}n{+}2)^2$ units. Its parts start and end write only tracks 2 and 13, and append keeps every counter at most R on tracks 8 to 11 (parts (a), (g) and (f) of that lemma); so the counters still to be archived survive. After psh_6, psh_{10}, psh_8 and psh_9 the tape holds (S,σ,N,W) within $R_4 = R_0+(S+1)+(\sigma+1)+(N+1)+(W+1)$ rows.

(4) grow ($72R_4+99$ units) adds a row, which keeps the archive, and getc_1 reads the last frame, that of m (Lemma I.90(b) with $k=1$): track 9 holds m, the tape carries the saved request and holds the archive within $R_5 = R_4+1+m$ rows, and the two parts take at most $72R_4+99+55000(R_4+m+2)^2$ units.

(5) The last psh_9 appends m: the archive (S,σ,N,W,m) within $r_{\mathrm{a}} = R_5+1+m$ rows.

Since $S+\sigma+N+W \le r$ and $r+m+1 \le Y-1$, every row count R above satisfies $R+m+2 \le r_{\mathrm{a}}+2 \le 2r+2m+10 \le 8Y$. So the five pushes cost at most $5(2400Y+64\cdot 10^6Y^2)$, the read $56000\cdot 64Y^2$, and the copies and init at most $9300Y$; with $r_{\mathrm{a}}+1 \le 8Y$ the total is below $10^{10}Y^2$. □

Lemma I.104 (The reserve). *Let* $\mathsf{Res} = \mathsf{room};\mathsf{room}$. *Let τ carry the saved request, hold the archive (S,σ,N,W,m) within R rows and be a workspace of R rows with origin marks up to R. Then* Res *runs from $(-1,\tau)$ to $(-1,\tau')$ in some t units, where τ' has the same properties for $R' = Q(Q(R))$ rows,*

$$\rho_{\mathrm{traj}} \le 512(R+1)^4 \le R', \qquad t+R'+1 \le 10^{22}(R+2)^{10}.$$

Proof. By Lemma I.91(e) twice, Res ends on a workspace of $Q(Q(R))$ rows with origin marks up to it and keeps the saved request and the archive: tracks 3, 4 and 15 are written only in new rows, where they get 0. Since $Q(R)+2 \le 66(R+2)^2$,

$$t \le 4\cdot 10^9(R+2)^5 + 4\cdot 10^9\,66^5(R+2)^{10}, \qquad R'+1 \le 66(Q(R)+2)^2 \le 66^3(R+2)^4,$$

and the sum is below $10^{22}(R+2)^{10}$. For the reserve, let $r_1 = R+1$. The entries of the archive are at most R and $|w_u|+1 \le R$. The payload holds the $2d$ nonempty frames of the u_j and e_j, so $d \le |w_u|$. The request without its last two frames has at most $3|w_u|$ cells, because the frame of a word b has $2|b|+1 \le 3|b|$ cells; so $c_{\mathrm{req}} \le 5|w_u|+7$ and $c_{\mathrm{req}}+2 \le 5r_1$. Finally $X \le 2N+1 \le 2r_1$, since $m, n_0 \le n$ and $N = n+\kappa$. Hence

$$\rho_{\mathrm{traj}} \le r_1 + 100\,r_1\cdot r_1\cdot(2r_1)^2 + 10r_1^2 \le 411\,r_1^4 \le 512\,r_1^4.$$

And $Q(R)+1 \ge 64r_1^2$, so $Q(Q(R)) \ge 64(Q(R)+1)^2 \ge 64\cdot 4096\,r_1^4$. □

The positioning uses the payload address paddr of Lemma I.71 and the loads of Lemma I.68(c):

$$\mathsf{Pos} = \mathsf{paddr}; \mathsf{load}_{2,8}; \mathsf{load}_{3,9}.$$

Let c_{num} be the constant with $V(u) \le c_{\mathrm{num}} X$ of Section I.7, and put $A_{\mathrm{p}} = 4 \cdot 10^{12}(c_{\mathrm{num}}+1)^4$ and $C_{\mathrm{pos}} = A_{\mathrm{p}} + 220000 A_{\mathrm{p}}^2$.

Lemma I.105 (The first frame of y_0)**.** *Let τ carry the saved request, hold the archive (S, σ, N, W, m) within R rows and be a workspace of R rows with origin marks up to R. Then Pos runs from $(-1, \tau)$ to $(-1, \tau')$ in some t units, where for some $R' \ge R$*

(a) τ' carries the saved request, holds the same archive within R' rows, and is a workspace of R' rows with origin marks up to R';

(b) track 5 carries the row of the frame of u_0, tracks 8 and 9 carry the counters N and W, and track 14 carries the counter d;

(c) $t + R' + 1 \le C_{\mathrm{pos}}(X + R + 1)^8$.

Proof. Put $Y = X+R+1$. By Lemma I.71(a), paddr runs in some t_1 units to a tape within R' rows that keeps the saved request, carries on track 5 the row p of the first payload frame, which is the frame of u_0, and holds the value d on track 14; and $t_1 + R' + 1 \le 4 \cdot 10^{12}(R+V(u)+1)^4 \le A_{\mathrm{p}} Y^4$, since $R + V(u) + 1 \le (c_{\mathrm{num}}+1)Y$ (the number D of that lemma is $V(u)$). By the same lemma $R \le R'$, and no cell of tracks 3, 4 and 15 changes, so the archive is kept. In the archive (S, σ, N, W, m), numbered from 0, N is entry 2 and W entry 3. By Lemma I.68(c), $\mathsf{load}_{2,8}$ and $\mathsf{load}_{3,9}$ make tracks 8 and 9 hold N and W, within $(5+6) \cdot 20000(R'+1)^2 \le 220000 A_{\mathrm{p}}^2 Y^8$ units, and change only tracks 8, 9, 12 and 13. So tracks 5 and 14 keep p and d, and $t + R' + 1 \le A_{\mathrm{p}} Y^4 + 220000 A_{\mathrm{p}}^2 Y^8 \le C_{\mathrm{pos}} Y^8$. □

After the last coordinate the controls go back where the loop reads them:

$$\mathsf{Rest} = \left[\mathsf{load}_{0,11}, \mathsf{load}_{1,10}, \mathsf{load}_{2,8}, \mathsf{load}_{3,9}, \mathsf{load}_{4,5}\right]; \mathsf{cc}_{11\to 14}; \mathsf{zero}_2.$$

Lemma I.106 (Restoring the controls)**.** *Let τ carry the saved request, hold the archive (S, σ, N, W, m) within r rows, be a workspace of r rows with origin marks up to r, let $r \ge \rho_{\mathrm{traj}}$, and let the binary stream hold $\mathrm{sw}_W(Z)$ for an integer vector Z of length d. Then Rest runs from $(-1, \tau)$ to $(-1, \tau')$ in some t units, where τ' holds the stored vector Z on the same r rows, track 2 carries the counter 0, track 14 carries a retained word of length S from row 0, and $t + r + 1 \le 2 \cdot 10^6 (r+1)^2$.*

Proof. The five loads make tracks 11, 10, 8, 9 and 5 hold S, σ, N, W and m; each changes only tracks 12, 13 and its destination (Lemma I.68(c)), so the binary stream and the earlier destinations survive, and they take at most $(3+4+5+6+7) \cdot 20000(r+1)^2 + 1$ units. $\mathsf{cc}_{11\to 14}$ (at most $300(r+1)$) makes track 14 hold the value S, which is a retained word of length S from row 0, and zero_2 (11 units) sets $(0, 2)$ to 0. Tracks 3, 4, 15, 0 and 1 are not written, so the saved request, the workspace and the origin marks are kept, and the reserve holds by hypothesis. So τ' satisfies (a) to (e) of Definition I.101, and $t + r + 1 \le 500000(r+1)^2 + 300(r+1) + 12 + (r+1) \le 2 \cdot 10^6 (r+1)^2$. □

I.10.4 One coordinate

The loop over the coordinates keeps the following state between two runs of Coord. Write $Z_0 = (Z_{0,0}, \dots, Z_{0,d-1})$, so that $Z_{0,j} = \mathrm{near}(2^N u_j / e_j)$. In the payload the frame of u_j is followed by that of e_j, and the frame of e_{d-1} by the frame of the first coefficient of the field.

Definition I.107 (The prefix state)**.** Let $k \le d$ and $r \in \mathbb{N}$. A tape τ is in the *prefix state k with r rows* if

(a) τ carries the saved request, holds the archive (S, σ, N, W, m) within r rows, is a workspace of r rows with origin marks up to r, and $r \ge \rho_{\mathrm{traj}}$;

(b) track 5 carries the row of the frame of u_k (for $k = d$, of the frame after that of e_{d-1});

(c) tracks 8 and 9 carry the counters N and W, and track 14 carries the counter $d - k$;

(d) the binary stream holds $\mathrm{sw}_W(Z_{0,0}) \cdots \mathrm{sw}_W(Z_{0,k-1})$, and track 11 carries its length $k(W+2)$.

For the rest of this subsection fix $k < d$ and a tape in the prefix state k with r rows, and write $u = u_k$, $e = e_k$, $z = Z_{0,k}$,

$$a = \lfloor r/2 \rfloor, \qquad \rho = 400(W+2)^2, \qquad D = 2u2^N + e.$$

Three facts are used throughout. First, $2\rho \le r$, so that $\rho \le a$ and $a + \rho \le r$: since $d \ge 1$ and $N = n + \kappa \ge 3$ (the definition of κ gives $\kappa \ge 3$), $(d+1)(N+1) \ge 8$ and $r \ge \rho_{\mathrm{traj}} \ge 800(W+2)^2$. Second, $y_{0,k}$ has width s_0 (Section H.1), so $|u| \le 2^{s_0}$ and $e \le 2^{s_0}$, and $s_0 + N + 3 \le \mathscr{B}(N)$ by (H.1), so $s_0 + N + 2 \le W$. Hence

$$|D| \le 2^{s_0+N+1} + 2^{s_0} < 2^W, \qquad 0 < 2e \le 2^W, \qquad 2^{N+1}|u| < 2^W,$$

and $|u|$ and e have at most W binary digits. Third, $z = \mathrm{near}(2^N u/e) = \lfloor D/(2e) \rfloor$.

The arithmetic area. The arithmetic of one coordinate runs on track 13 around the row a. The *view at a* of a tape τ is the virtual tape $\sigma_\tau(j) = \tau(\mathrm{cell}(a, 13) + 16j)$, $j \in \mathbb{Z}$; for $|j| \le a$ its cell j is the cell $(a - j, 13)$. Twelve-cell rows at the virtual position 1 occupy the cells $(a - 1 - 12t - c, 13)$: column c of row t. The virtual cell 0, that is $(a, 13)$, holds a sign. Put

$$\mathsf{call}(P) = \mathsf{seek}_{12}; \mathsf{left}^1; P^{\uparrow 16}; \mathsf{home}_{13}.$$

Lemma I.108 (Running on the arithmetic area)**.** *Let τ satisfy (a), (c) and (d) of Definition I.107 with r rows, and let track 12 carry a. Let a program P run on σ_τ from the position 0 in t units to a position f with $0 \le f \le \rho$ and a virtual tape σ' that agrees with σ_τ outside $[-\rho, \rho]$. Then* call(P) *runs from $(-1, \tau)$ to $(-1, \tau')$ within $17t + 36r + 40$ units, where $\tau'(\mathrm{cell}(a, 13) + 16j) = \sigma'(j)$ for every j, τ' agrees with τ off track 13, and τ' again satisfies (a), (c) and (d).*

Proof. seek_{12} ($18a + 15$ units) reaches $(a, 12)$ and left^1 (2) the cell $o = \mathrm{cell}(a, 13)$. The configuration carries $(0, \sigma_\tau)$ for the stride 16 and the origin o, so by Lemma I.8 $P^{\uparrow 16}$ runs within $17t$

units to the cell $o + 16f = \mathrm{cell}(a - f, 13)$ and a tape that carries σ' and agrees with τ off the cells $o + 16j$. The changed cells are $(a - j, 13)$ with $|j| \le \rho$, which lie in the rows $a - \rho, \dots, a + \rho$ of $[0, r]$, on track 13; so the workspace and the origin marks are kept, and the other conditions do not involve track 13. home_{13} from row $a - f$ takes $18(a - f) + 17$ units. In all at most $17t + 36a + 34$. □

The centre and the marks. Put $\mathsf{flag}_b = \mathsf{left}^{11}; \mathsf{write}\, b; \mathsf{home}_{10}$, $\mathsf{up} = \mathsf{left}^{1}; \mathsf{home}_{1}$, $\mathsf{wbit}_b = \mathsf{seek}_{12}; \mathsf{left}^{1}; \mathsf{write}\, b; \mathsf{home}_{13}$, and

$$\begin{aligned}
\mathsf{half} &= \mathsf{zero}_2; \mathsf{zero}_{12}; \mathsf{flag}_0; \mathsf{peek}_{2\to 0}; \mathsf{loop}(\mathsf{up}; \mathsf{par}; \mathsf{inc}_2; \mathsf{peek}_{2\to 0}); \mathsf{up},\\
\mathsf{par} &= \mathsf{left}^{11}; \mathsf{branch}(\mathsf{write}\,1; \mathsf{home}_{10}; \mathsf{skip},\ \mathsf{write}\,0; \mathsf{home}_{10}; \mathsf{inc}_{12}),\\
\mathsf{marks} &= \mathsf{left}^{3}; \mathsf{loop}(\mathsf{home}_2; \mathsf{wbit}_1; \mathsf{pred}_{12}^{12}; \mathsf{pred}_2; \mathsf{left}^{3}); \mathsf{home}_2,\\
\mathsf{Prep} &= [\mathsf{clear}_{13}, \mathsf{half}, \mathsf{dup}_{12\to 10}, \mathsf{dup}_{9\to 2}, \mathsf{inc}_2, \mathsf{inc}_2, \mathsf{pred}_{12},\\
&\qquad \mathsf{marks}, \mathsf{dup}_{10\to 12}, \mathsf{dup}_{12\to 2}],
\end{aligned}$$

where pred_k^c is c copies of pred_k followed by skip; when track k carries $b + c$ and there are origin marks up to $b + c$, it takes $\sum_{j<c}(36(b + j) + 2k + 43) + 1$ units and leaves the counter b (Lemma I.127).

Lemma I.109 (The centre and the marks)**.** *Let τ be in the prefix state k with r rows.*

(a) half *runs from $(-1, \tau)$ to $(-1, \tau')$ within $1000(r + 1)^2$ units; track 2 of τ' carries r, track 12 carries $\lfloor r/2 \rfloor$, and τ' differs from τ only on tracks 2, 10 and 12, in rows $j \le r$; so it is still in the prefix state k.*

(b) If track 12 carries b, track 2 carries n, $12n \le b \le r$ and track 13 is blank, then marks *runs from $(-1, \tau)$ to $(-1, \tau')$ within $1500(n + 1)(r + 1)$ units, where $\tau'(b - 12j, 13) = 1$ for $j < n$, every other cell of track 13 is 0, track 12 carries $b - 12n$, track 2 carries 0, and only tracks 2, 12 and 13 have changed.*

(c) Prep *runs from $(-1, \tau)$ within $50000(r + 1)^2$ units to a tape τ_1 in the prefix state k with r rows on which tracks 2 and 12 carry a, $(a - 1 - 12t, 13) = 1$ for $t < W + 2$, and every other cell of track 13 is 0. In the view at a, the twelve-cell rows at 1 have $W + 2$ marked rows, are closed on the left, and all their other columns hold 0. Only tracks 2, 10, 12 and 13 have changed.*

Proof. (a) The first three parts take $11 + 31 + 27 = 69$ units and leave the counter 0 on tracks 2 and 12 and 0 in $(0, 10)$; $\mathsf{peek}_{2\to 0}$ (8) reaches the header $(0, 0)$. For $j \le r$ let I_j be the configuration at $(j, 0)$ on which track 2 carries j, track 12 carries $\lfloor j/2 \rfloor$, $(0, 10)$ holds $[j \text{ odd}]$, and nothing else has changed. For $j < r$ the header is 1; the pass returns to the root $(18j + 7)$, flips the parity cell and, if j is odd, advances track 12 (at most $18j + 96$), advances track 2 $(36j + 48)$ and peeks at the header of row $j + 1$ $(18j + 26)$: at most $400(r + 1)$ units with its test, ending in I_{j+1}, since $\lfloor (j + 1)/2 \rfloor = \lfloor j/2 \rfloor + [j \text{ odd}]$. At I_r the sentinel header stops the loop, and up takes $18r + 7$. In all at most $69 + 8 + r(400(r + 1) + 1) + 1 + 18r + 7 \le 1000(r + 1)^2$.

(b) Let J_j, $j \le n$, be the configuration at $(0, 2)$ on which track 2 carries $n - j$, track 12 carries $b - 12j$, and the marks $(b - 12j', 13)$, $j' < j$, have been written; left^3 (4 units) reaches J_0. The scanned

cell $(0,2)$ is 1 exactly when $j < n$. A pass from J_j returns to the root (6), writes the mark at row $b-12j$ ($36(b-12j)+35$), steps track 12 back twelve times (at most $12(36r+67)+1$), steps track 2 back ($36(n-j-1)+47$) and returns to $(0,2)$ (4): at most $1500(r+1)$ units with its test. With the final test and home_2 (6), Lemma I.6 gives at most $n \cdot 1500(r+1) + 11 \le 1500(n+1)(r+1)$.

(c) clear_{13} takes $65r+35$ units with its skip, and half leaves a on track 12. The two copies of Lemma I.126(b) (at most $102r+76$ units each) put a on track 10 and W on track 2; two increments ($72W+132$ units) make track 2 carry $W+2$, and pred_{12} ($36a+31$) makes track 12 carry $a-1$. Since $12(W+2)+1 \le \rho \le a$, part (b) applies with $b = a-1$ and $n = W+2$, within $1500(W+3)(r+1)$ units. The last two copies put a back on track 12 and then on track 2. The prefix state involves none of the tracks 2, 10, 12 and 13. In the view at a, the presence cell of row t is $(a-1-12t, 13)$, which is 1 for $t < W+2$ and 0 for $t \ge W+2$ and for $t = -1$, the cell $(a+11, 13)$. Since $W+3 \le r+1$ the total is at most $50000(r+1)^2$. □

Loading the numerator and the denominator. With src and probe of Lemma I.45, put

$$\begin{aligned}
\mathsf{sbit} &= \mathsf{seek}_5; \mathsf{right}^1; \mathsf{branch}(\mathsf{home}_4; \mathsf{wbit}_0,\ \mathsf{home}_4; \mathsf{wbit}_1),\\
\mathsf{lcol} &= \mathsf{src}; \mathsf{probe}; \mathsf{loop}(\mathsf{home}_{10}; \mathsf{sbit}; \mathsf{inc}_5; \mathsf{pred}_{12}^{12}; \mathsf{src}; \mathsf{probe}); \mathsf{home}_{10},\\
\mathsf{lsign} &= \mathsf{sbit}; \mathsf{inc}_5; \mathsf{pred}_{12}^{2}; \mathsf{lcol},\\
\mathsf{Load} &= \big[\mathsf{lsign}, \mathsf{dup}_{2\to12}, \mathsf{pred}_{12}^{3}, \mathsf{lsign}, \mathsf{dup}_{2\to12}\big].
\end{aligned}$$

Lemma I.110 (Loading a rational)**.** *Let τ be a workspace of r rows with origin marks up to r.*

(a) If track 5 carries $s \le r$ and track 12 carries $b \le r$, then sbit *runs from the root to the root in $36s+36b+54$ units and sets $(b,13)$ to $\tau(s,4)$; nothing else changes.*

(b) Let the saved tracks lay out the frame of an integer x, the bit $[x<0]$ followed by the $\ell = \mathrm{bl}(|x|)+1$ lowest binary digits $x_0,\dots,x_{\ell-1}$ of $|x|$, possibly followed by further frames, from row s (Definition I.43), with $s+\ell+1 \le r$; let track 5 carry s and track 12 carry b, with $2+12\ell \le b \le r$. Then lsign *runs from the root to the root within $12000(r+1)^2$ units; it sets $(b,13)$ to $[x<0]$ and $(b-2-12t,13)$ to x_t for $t<\ell$, leaves the counter $s+\ell+1$ on track 5 and $b-2-12\ell$ on track 12, and changes nothing else outside tracks 10 and 12.*

(c) From the tape τ_1 of Lemma I.109(c), Load *runs within $50000(r+1)^2$ units to a tape τ_2 on which, in the view at a, the cell 0 holds $[u<0]$, column 1 of the twelve-cell rows at 1 holds the $W+2$ lowest binary digits of $|u|$, column 4 holds those of e, and the other columns are as in τ_1; tracks 2 and 12 carry a; track 5 carries the row of the frame of u_{k+1} (for $k+1=d$, of the frame after that of e_{d-1}); and τ_2 agrees with τ_1 off tracks 5, 10, 12 and 13.*

Proof. (a) seek_5 ($18s+8$) and right^1 (2) reach $(s,4)$; the branch (1) reads it, home_4 ($18s+8$) returns, and wbit writes $(b,13)$ in $36b+35$ units.

(b) By (a), sbit copies the sign cell $(s,4) = [x<0]$ into $(b,13)$; inc_5 ($36s+54$) and pred_{12}^2 (at most $72r+135$) leave $s+1$ on track 5 and $b-2$ on track 12. In lcol, src ($18(s+1)+11$) reaches $(s+1,3)$ and probe (22) writes into $(s+1,10)$ whether the frame goes on at row $s+1$, which it does. For $t \le \ell$ let K_t be the configuration at $(s+1+t,10)$ on which track 5 carries $s+1+t$,

track 12 carries $b-2-12t$, the digits $x_0,\dots,x_{t-1}$ have been written, and the flag holds $[t<\ell]$: by the layout the rows $s+1,\dots,s+\ell-1$ continue the frame and row $s+1+\ell$ does not. A pass from K_t, $t<\ell$, returns to the root, copies $x_t=\tau(s+1+t,4)$ into $(b-2-12t,13)$, advances track 5, steps track 12 back twelve times and probes the next row: at most $1000(r+1)$ units with its test, ending in K_{t+1}. With $\ell\le r$, the last test and home_{10}, lcol takes at most $1100(r+1)^2$ units and lsign at most $12000(r+1)^2$. The probes write track 10; nothing else outside track 12 and the named cells of track 13 is written.

(c) By Definition I.107(b) track 5 carries the row of the frame of u, and the frame of e follows it. Both have at most W digits, so $2+12W+3\le\rho\le a$ gives the room for (b), and the frames end before $|w_u|\le r$. The first lsign, with $b=a$, writes $[u<0]$ into $(a,13)$, the virtual cell 0, and the digits of $|u|$ into $(a-2-12t,13)$, which is column 1 of row t. Track 2 still carries a, so $\mathsf{dup}_{2\to12}$ puts a back on track 12, and pred^3_{12} makes it $a-3$. The second lsign, with $b=a-3$, writes $[e<0]=0$ into column 2 of row 0 and the digits of e into $(a-5-12t,13)$, column 4 of row t; the last copy puts a back on track 12. Prep left these columns 0, so above the digits they hold 0, and the columns hold the $W+2$ lowest digits. Track 5 now carries the row after the frame of e. The total is at most $24000(r+1)^2+204(r+1)+3(36r+67)+2\le50000(r+1)^2$. □

The dividend. Let $\overline{\mathsf{cp}}_{s\to t}$ be $\mathsf{cp}_{s\to t}$ of Lemma I.25 with the two parts of its branch exchanged; it writes the complement of column s into column t, in the same number of units. Put $\mathsf{c}_b=\mathsf{right}^6;\mathsf{write}\,b;\mathsf{left}^6$ and

$$\mathsf{Copy}=\mathsf{call}(\mathsf{right};\mathsf{cp}_{1\to2};\mathsf{back}),$$
$$\mathsf{Scale}=\big[\mathsf{zero}_{10},\ \mathsf{rep}_{10,8}(\mathsf{twice}),\ \mathsf{twice}\big],\qquad \mathsf{twice}=\mathsf{call}(\mathsf{right};\mathsf{z}_{10};\mathsf{dbl};\mathsf{back});\mathsf{inc}_{10},$$
$$\mathsf{Add}=\mathsf{call}(\mathsf{right};\mathsf{madd};\mathsf{back}),$$
$$\mathsf{madd}=\mathsf{left};\mathsf{branch}\big(\mathsf{right};\mathsf{c}_0;\mathsf{add}^{\uparrow2},\ \mathsf{right};\overline{\mathsf{cp}}_{2\to2};\mathsf{back};\mathsf{c}_1;\mathsf{add}^{\uparrow2}\big),$$

with rep of Lemma I.126.

Lemma I.111 (The dividend). *From the tape τ_2 of Lemma I.110(c), the programs* Copy, Scale *and* Add, *run in this order, take at most $100000(r+1)^2$ units and lead to a tape τ_3 on which, in the view at a, column 8 of the $W+2$ marked rows holds a word x with $\mathrm{sval}_{W+2}(x)=D$, column 4 still holds the digits of e, the cell 0 holds $[u<0]$, and the marks are kept; τ_3 agrees with τ_2 off tracks 10 and 13.*

Proof. Write $n=W+2$ and $h=1$. Each virtual program starts at the cell 0, steps to the presence cell h of row 0 and ends there after back; it moves and writes only in $[-12,12(n+1)]\subseteq[-\rho,\rho]$, so Lemma I.108 applies.

Copy: the virtual program takes $1+(26n+1)+(14n+27)$ units (Lemma I.25) and copies the digits of $|u|$ into column 2; with the call, at most $1000(r+1)$ units, since $n\le r$.

Scale: zero_{10} (27 units) makes track 10 carry 0, and track 8 carries N. For $j\le N+1$ let R_j say that column 2 holds the n lowest digits of $2^j|u|$ and track 10 carries j. The virtual program of twice clears column 10 of row 0 and doubles column 2 with the incoming bit 0 (Lemma I.26), in $1+23+(62n+1)+(14n+27)$ units. Since $2^{j+1}|u|\le2^{N+1}|u|<2^n$ for $j\le N$, there is no overflow, and inc_{10} $(36j+64)$ makes track 10 carry $j+1$: twice runs from R_j to R_{j+1} within $2000(r+1)$ units. By Lemma I.126(c) with $c=10$ and $g=8$, $\mathsf{rep}_{10,8}(\mathsf{twice})$ runs from R_0 to

R_N within $(N+1)\cdot 2200(r+1) \le 2200(r+1)^2$ units, and the last twice reaches R_{N+1}: column 2 holds $2^{N+1}|u|$.

Add: the virtual program steps back to the cell 0, reads $[u<0]$ and returns to h. The adder $\mathsf{add}^{\uparrow 2}$ works on the even columns, so its operands are columns 2 and 4, its carries column 6, its sum column 8, and c_b sets its carry-in, column 6 of row 0, to b. If $u \ge 0$, the sum of $2^{N+1}|u|$ and e is $D < 2^{n-1}$, so it is $\mathrm{val} = \mathrm{sval}_n$ of the sum (Lemma I.21). If $u<0$, column 2 is first complemented and the carry-in is 1; addition is symmetric in its two operand columns, so Corollary I.22(b) gives $\mathrm{sval}_n = e - 2^{N+1}|u| = D$, since e and $2^{N+1}|u|$ are below 2^{n-1} and $|D| < 2^{n-1}$. The virtual program takes at most $3+(28n+1)+(14n+27)+15+3(20n+1)+(14n+27) \le 120n+80$ units; with the call, at most $3000(r+1)$.

The three parts write only track 13 inside the area and track 10; the total is at most $1000(r+1)+2200(r+1)^2+2000(r+1)+28+3000(r+1) \le 100000(r+1)^2$. □

The division. Put $\mathsf{c}^- = \mathsf{left}^6;\mathsf{write}\,0;\mathsf{right}^6$ and, for twelve-cell rows,

$$\begin{aligned}
\mathsf{abs} &= \mathsf{cp}_{8\to 6};\mathsf{left}^6;\mathsf{branch}(A_0,A_1),\\
A_0 &= \mathsf{right}^6;\mathsf{back};\mathsf{skip};\mathsf{cp}_{6\to 1};\mathsf{back};\mathsf{left};\mathsf{write}\,0;\mathsf{right},\\
A_1 &= \mathsf{right}^6;\mathsf{back};\mathsf{neg}^{\uparrow 6};\mathsf{back};\mathsf{cp}_{6\to 1};\mathsf{back};\mathsf{left};\mathsf{write}\,1;\mathsf{right},\\
\mathsf{trim} &= \mathsf{fwd};\mathsf{left}^{12};\mathsf{write}\,0;\mathsf{back}, \qquad \mathsf{ddiv} = \mathsf{cp}_{4\to 2};\mathsf{back};\mathsf{z}_{10};\mathsf{dbl};\mathsf{back};\overline{\mathsf{cp}}_{2\to 4};\mathsf{back},\\
\mathsf{Div} &= \mathsf{call}(\mathsf{right};\mathsf{c}^-;\mathsf{abs};\mathsf{trim};\mathsf{ddiv};\mathsf{sdiv}),
\end{aligned}$$

with neg of Lemma I.24 and sdiv of Lemma I.30.

Lemma I.112 (Magnitude, trimming and the divisor)**.** *Let the twelve-cell rows at h have $n \ge 1$ marked rows and be closed on the left.*

(a) If column 8 holds a word x with $\mathrm{sval}_n(x) = Z$ and $\sigma(h-6) = 0$, then abs runs from h to h within $400(n+1)$ units, leaves in column 1 the n lowest binary digits of $|Z|$ and in the cell $h-1$ the bit $[Z<0]$, and writes only columns 1 and 6 and the cell $h-1$.

(b) trim runs from h to h in $28n+28$ units and sets column 0 of row $n-1$ to 0, so that $n-1$ rows remain marked; nothing else changes.

(c) If column 4 holds a word y with $2\,\mathrm{val}(y) < 2^n$, then ddiv runs from h to h within $200(n+1)$ units and leaves in column 4 the complement of the n lowest digits of $2\,\mathrm{val}(y)$; it writes only columns 2, 4 and 10.

Proof. (a) $\mathsf{cp}_{8\to 6}$ ($48n+1$ units) copies x into column 6 and ends at the end row; left^6 (7) reaches column 6 of row $n-1$, the top bit of x, which is 1 exactly when $Z<0$, because $\mathrm{sval}_n(x) = \mathrm{val}(x) - 2^n x_{n-1}$ and $0 \le \mathrm{val}(x) < 2^n$. After the branch, right^6 and back return to h ($7+14n+27$). If $Z<0$, the cells $h+6i$ form a tape of stride 6 whose two-cell rows at h are columns 0 and 6, and the cell before them, $h-6$, holds 0; by Lemmas I.24 and I.8, $\mathsf{neg}^{\uparrow 6}$ replaces column 6, within $7\cdot 30(n+1)$ units, by a word of value $2^n - \mathrm{val}(x) = -Z = |Z|$; then back. If $Z \ge 0$, column 6 already holds $\mathrm{val}(x) = |Z|$. Then $\mathsf{cp}_{6\to 1}$ ($34n+1$), back ($14n+27$),

and the last three primitives write $[Z < 0]$ into $h - 1$. In all at most $334n + 311 \le 400(n + 1)$ units.

(b) fwd $(14n + 1)$ reaches the end row, left^{12} (13) the presence cell of row $n - 1$, which is set to 0 (1), and back over the $n - 1$ remaining rows takes $14(n - 1) + 27$.

(c) $\mathsf{cp}_{4\to 2}$ $(32n+1)$ and back $(14n+27)$ copy y into column 2; z_{10} (23), dbl $(62n+1)$ and back double it without overflow; $\overline{\mathsf{cp}}_{2\to 4}$ $(32n + 1)$ and back write its complement into column 4: in all $168n + 107$ units. □

Lemma I.113 (The rounded quotient)**.** *From the tape τ_3 of Lemma I.111,* Div *runs within $20000(r + 1)^2$ units to a tape τ_4 on which, in the view at a, the cell 0 holds $[z < 0]$ and column 8 of the first $W + 1$ twelve-cell rows at 1 holds the $W + 1$ binary digits of $|z|$; so the cell 0 followed by column 8 is $\mathrm{sw}_W(z)$. Track 12 carries a, and τ_4 agrees with τ_3 off track 13.*

Proof. The virtual program steps to $h = 1$ and clears the cell $h-6$ (15 units). By Lemma I.112(a) with $n = W + 2$ and $Z = D$, column 1 then holds the digits of $|D|$ and the cell 0 the bit $[D < 0]$; column 4 still holds e. trim leaves $n' = W + 1$ marked rows, and since $|D| < 2^W$ and $e \le 2^{s_0}$, the first n' rows of columns 1 and 4 still hold $|D|$ and e. By Lemma I.112(c), column 4 then holds the complement of $y = 2e$, with $0 < y \le 2^W = 2^{n'-1}$. These are the hypotheses of Lemma I.30 with n' rows and $|D| < 2^{n'}$: sdiv leaves in the cell $h - 1$, the virtual cell 0, the bit $[\lfloor D/y \rfloor < 0]$ and in column 8 the n' digits of $|\lfloor D/y \rfloor|$, and $\lfloor D/(2e) \rfloor = z$. The virtual program takes at most $1 + 15 + 400(W + 3) + (28W + 84) + 200(W + 2) + 945(W + 2)^2 \le 2000(W + 3)^2$ units and stays in $[-12, 12(W + 3)]$. With $(W + 3)^2 \le 4(W + 2)^2 \le r/100$, Lemma I.108 bounds Div by $340r + 36r + 40 \le 20000(r + 1)^2$ units. □

Appending the word. Put

$$\begin{aligned}
\mathsf{app}_{11}(b) &= \big[\mathsf{seek}_{11}, \mathsf{right}^5, \mathsf{write}\,1, \mathsf{left}, \mathsf{write}\,b, \mathsf{left}^4, \mathsf{next},\\
&\qquad \mathsf{right}^5, \mathsf{write}\,0, \mathsf{left}^5, \mathsf{home}_{11}\big],\\
\mathsf{obit} &= \mathsf{seek}_{12}; \mathsf{left}^1; \mathsf{branch}\big(\mathsf{home}_{13}; \mathsf{app}_{11}(0),\\
&\qquad \mathsf{home}_{13}; \mathsf{app}_{11}(1)\big),\\
\mathsf{Emit} &= \mathsf{obit}; \mathsf{pred}^9_{12}; \mathsf{zero}_{10}; \mathsf{rep}_{10,9}(\mathsf{ebit}); \mathsf{ebit},\\
\mathsf{ebit} &= \mathsf{obit}; \mathsf{pred}^{12}_{12}; \mathsf{inc}_{10}.
\end{aligned}$$

Lemma I.114 (Appending the signed word)**.** *Let τ be a workspace of r rows with origin marks up to r.*

(a) If track 11 carries ℓ with $\ell + 1 \le r$, then $\mathsf{app}_{11}(b)$ runs from the root to the root in $36\ell + 95$ units; it sets $(\ell, 6)$ to 1, $(\ell, 7)$ to b and $(\ell + 1, 6)$ to 0, and advances the counter on track 11 to $\ell + 1$. So if the binary stream holds a word w of length ℓ, it then holds wb.

(b) If moreover track 12 carries $b' \le r$, then obit runs from the root to the root in $36b' + 36\ell + 130$ units and appends $\tau(b', 13)$ in the same way.

(c) From the tape τ_4 of Lemma I.113, Emit *runs within* $20000(r+1)^2$ *units to a tape on which the binary stream holds* $\mathrm{sw}_W(Z_{0,0})\cdots\mathrm{sw}_W(Z_{0,k})$ *and track* 11 *carries its length* $(k+1)(W+2)$*; only tracks* 6, 7, 10, 11 *and* 12 *change.*

Proof. (a) seek_{11} $(18\ell+14)$ reaches $(\ell,11)$; right^5 (6) the presence cell $(\ell,6)$; the writes and moves (3) set the presence and value cells; left^4 (5) returns to $(\ell,11)$; next (20) advances the counter; right^5, the write of the new terminator $(\ell+1,6)$ and left^5 take 13; and home_{11} from row $\ell+1$ takes $18\ell+33$; the list adds 1. (b) seek_{12} $(18b'+15)$, left^1 (2), the branch (1) and home_{13} $(18b'+17)$, then (a).

(c) Let $\ell = k(W+2)$; then $\ell+W+3 \le d(W+2)+1 < r$. In the view at a the cell 0 is $(a,13)$ and column 8 of row t is $(a-9-12t,13)$. The first obit appends $[z<0]$; pred^9_{12} (at most $9(36r+67)+1$) leaves $a-9$ on track 12, and zero_{10} (27) the counter 0 on track 10. For $t \le W+1$ let R_t say that the stream holds the old word, the sign and the digits $|z|_0,\dots,|z|_{t-1}$, track 11 carries $\ell+1+t$, track 12 carries $a-9-12t$, and track 10 carries t. Then ebit runs from R_t to R_{t+1} within $2500(r+1)$ units: it appends $|z|_t$, steps track 12 back twelve rows and advances track 10. Track 9 carries W, so by Lemma I.126(c) $\mathsf{rep}_{10,9}(\mathsf{ebit})$ runs from R_0 to R_W within $(W+1)\cdot 2700(r+1)$ units, and the last ebit reaches R_{W+1}: $W+2$ bits, $\mathrm{sw}_W(z)$, have been appended. In all at most $72r+130+9(36r+67)+1+27+2700(r+1)^2+2500(r+1) \le 20000(r+1)^2$ units. □

Lemma I.115 (One coordinate)**.** *Let $k<d$. From every tape in the prefix state k with r rows,* Coord *runs from the root to the root within* $250000(r+1)^2$ *units to a tape in the prefix state* $k+1$ *with the same r rows.*

Proof. Lemmas I.109(c), I.110(c), I.111, I.113 and I.114(c) take the tape through $\tau_1,\dots,\tau_4$ to a tape whose binary stream holds $\mathrm{sw}_W(Z_{0,0})\cdots\mathrm{sw}_W(Z_{0,k})$ with its length on track 11. Then pred_{14} $(36(d-k-1)+71$ units) leaves the counter $d-k-1$ on track 14. None of the parts writes tracks 0, 1, 3, 4, 8, 9 or 15, and only Load writes track 5, which then carries the row of the frame of u_{k+1}. So the tape is in the prefix state $k+1$. The parts take at most $(50000+50000+100000+20000+20000)(r+1)^2+36r+72 \le 250000(r+1)^2$ units. □

Lemma I.116 (All coordinates)**.**

(a) Let $\mathsf{Begin} = \mathsf{zero}_6;\mathsf{zero}_{11}$*. From the tape of Lemma I.105 with $R' \ge \rho_{\mathrm{traj}}$,* Begin *runs in* 48 *units to a tape in the prefix state* 0 *with R' rows.*

(b) From every tape in the prefix state 0 *with r rows,* Coords *runs from the root to the root in some t units to a tape in the prefix state d with r rows, and*

$$t+r+1 \le \big(250080(d+1)+2\big)(r+1)^3.$$

Proof. (a) zero_6 (19 units) writes 0 into $(0,6)$, so the binary stream is empty, and zero_{11} (29) makes track 11 carry 0; nothing else changes, and Lemma I.105 supplies the rest of the prefix state 0.

(b) For $k \le d$ let I_k be the set of configurations at $(0,14)$ whose tape is in the prefix state k with r rows; left^{15} (16 units) goes from the root to $(0,14)$. The scanned cell $(0,14)$ holds 1

exactly when the counter $d-k$ is positive. A pass from I_k, $k<d$, returns to the root (18 units), runs Coord (at most $250000(r+1)^2$ units, Lemma I.115) and steps back to $(0,14)$ (16). By Lemma I.6 the loop takes at most $d(250000(r+1)^2+35)+1$ units, and home_{14} adds 18. So $t+r+1 \le 250000d(r+1)^2+35d+36+(r+1) \le (250080(d+1)+2)(r+1)^3$. □

Lemma I.117 (Packing the first vector)**.** *Let τ carry the saved request, hold the archive (S,σ,N,W,m) within r rows and be a workspace of r rows with origin marks up to r. Put $A'=2^{10}\cdot 10^{22}$, $B'=A'+(C_{\mathrm{pos}}+48)(A'+1)^8$, $K_{\mathrm{c}}=250080(d+1)+2$,*

$$K_{\mathrm{pk}}=B'+K_{\mathrm{c}}(B'+1)^3, \qquad K_{\mathrm{pp}}=C_{\mathrm{pos}}+K_{\mathrm{pk}}(C_{\mathrm{pos}}+1)^{360}.$$

(a) Pack *runs from $(-1,\tau)$ to $(-1,\tau')$ in some t units, where for some $r'\ge r$ the tape τ' carries the saved request, holds the archive within r' rows, is a workspace of r' rows with origin marks up to r', $r'\ge\rho_{\mathrm{traj}}$, the binary stream holds $\mathrm{sw}_W(Z_0)$, and*

$$t+r'+1 \le K_{\mathrm{pk}}(X+r+1)^{360}.$$

(b) Pos; Pack *runs to a tape with the same properties, and $t+r'+1\le K_{\mathrm{pp}}(X+r+1)^{2888}$.*

Proof. (a) Put $Y=X+r+1$. By Lemma I.104, Res ends on $r_1\ge\rho_{\mathrm{traj}}$ rows, and $t_1+r_1+1\le 10^{22}(r+2)^{10}\le A'Y^{10}$, since $r+2\le 2Y$. By Lemmas I.105 and I.116(a), Pos; Begin runs in t_2+48 units to a tape in the prefix state 0 with $r_2\ge r_1$ rows, and $(t_2+48)+r_2+1\le(C_{\mathrm{pos}}+48)(Y+r_1+1)^8$. Lemma 15.36(a) with Y for its N, $e=10$ and $g=8$ bounds the first three parts and r_2+1 by $B'Y^{90}$. By Lemma I.116(b), Coords ends in the prefix state d with r_2 rows, whose binary stream holds $\mathrm{sw}_W(Z_0)$, and $t_3+r_2+1\le K_{\mathrm{c}}(Y+r_2+1)^3$. Lemma 15.36(a) with $e=90$ and $g=3$ gives the bound with $r'=r_2$ and the exponent $90\cdot 4=360$.

(b) By Lemma I.105, Pos runs in t_0 units to a tape with the hypotheses of (a) on $R\ge r$ rows, and $t_0+R+1\le C_{\mathrm{pos}}Y^8$; by (a) from there, $t+r'+1\le K_{\mathrm{pk}}(Y+R+1)^{360}$. Lemma 15.36(a) with $e=8$ and $g=360$ gives the exponent $8\cdot 361=2888$. □

Proof of Theorem I.102. Put $Y=X+r+1$. By Lemma I.103, Arch runs in t_1 units to a tape with the hypotheses of Lemma I.104 on $r_1\ge r$ rows, and $t_1+r_1+1\le 10^{10}Y^2$. By Lemma I.104, Res runs in t_2 units to $r_2\ge\rho_{\mathrm{traj}}$ rows, and $t_2+r_2+1\le 10^{22}(Y+r_1+1)^{10}$; Lemma 15.36(a) with $e=2$ and $g=10$ gives $t_1+t_2+r_2+1\le L_1Y^{22}$ with $L_1=10^{10}+10^{22}(10^{10}+1)^{10}$. By Lemma I.117(b), Pos; Pack runs in t_3 units to $r_3\ge r_2\ge\rho_{\mathrm{traj}}$ rows with $\mathrm{sw}_W(Z_0)$ on the binary stream, and $t_3+r_3+1\le K_{\mathrm{pp}}(Y+r_2+1)^{2888}$; with $e=22$ and $g=2888$, $t_1+t_2+t_3+r_3+1\le L_2Y^{63558}$, $L_2=L_1+K_{\mathrm{pp}}(L_1+1)^{2888}$, since $22\cdot 2889=63558$. By Lemma I.106, Rest runs in t_4 units to a tape that holds the stored vector Z_0 on $r'=r_3$ rows, with the counter 0 on track 2 and the retained word of length S on track 14, and $t_4+r'+1\le 2\cdot 10^6(Y+r_3+1)^2$. With $e=63558$ and $g=2$ the total satisfies

$$t+r'+1\le K_{\mathrm{i}}Y^{190674}, \qquad K_{\mathrm{i}}=L_2+2\cdot 10^6(L_2+1)^2,$$

because $63558\cdot 3=190674$. The constants depend only on the problem and n_0: on d, and on c_{num} through C_{pos}. □

I.11 One coefficient of the Taylor table

How does the machine find the coefficient of t^3 in the Taylor series of $\sin t$? Take the oscillator $y_0' = y_1$, $y_1' = -y_0$ as a coefficient field: $c = 0$, the coordinate 0 has the single term $(1, 1)$ of A and the coordinate 1 the single term $(-1, 0)$, and there are no terms of B. For illustration let $N = 3$, so $s = 2^N = 8$, and let the stored vector be $Z = (0, 8)$, the point $(0, 1)$ at precision 2^{-3}. The rows of the table are $r_0 = (0, 8)$, $r_1 = (8, 0)$, $r_2 = (0, -4)$, and the stage is about to append the first entry of r_3. The output buffer then holds six signed words, $0, 8, 8, 0, 0, -4$. From its length the machine finds the order $l = 2$ and the coordinate $j = 0$. It reads from the saved request that the coordinate 0 has the constant $0 = 0/1$ and the coefficient $1 = 1/1$, so the common denominator is $D = 1 \cdot 1 = 1$; it reads the index 1 of the term and finds $r_{2,1} = -4$ as the word number $2 \cdot 2 + 1 = 5$ of the buffer. The integer numerator of $(Af_2)_0 = f_{2,1}$ over Ds^2 is $U = D \cdot 1 \cdot r_{2,1} \cdot s = -32$. One division with rounding finishes the entry:

$$r_{3,0} = \left\lfloor \frac{2U + Ds(l+1)}{2Ds(l+1)} \right\rfloor = \left\lfloor \frac{-40}{48} \right\rfloor = -1 = \operatorname{near}\Big(\frac{-4}{3}\Big),$$

and $-1/8$ is the coefficient $-\frac{1}{6}$ of t^3 in $\sin t$, rounded to precision 2^{-3}. The machine appends the signed word of -1 to the buffer and sets two flags that tell the two enclosing loops whether the row and the table are complete.

This section constructs that computation for every coefficient field. It gives the three programs of the stage (one entry, one row, the whole table), proves their contracts, and proves the step bound of each with its exponent. The exponent of one entry is 118, of one row 118 and of the whole table 120. Section I.11.1 states the results and proves the two loops; the routines follow; the proof of the bound for one entry closes the section.

I.11.1 The table, the three programs and their contracts

Throughout this section a problem with a coefficient field of dimension d is fixed, with level n_0, radius M and the constants of Section 15.9. For a request with coordinate $i < d$ and precision m put $n = \max(m, n_0)$, $N = N(n)$, $s = 2^N$ and $W = W_m$, and let $X = m + n_0 + \kappa + 1$. Since $N = n + \kappa$, we have $N < X$.

Definition I.118 (The table in the buffer)**.** Let $Z = (Z_0, \dots, Z_{d-1})$ be an integer vector. Put $r_0 = Z$ and, for $l < N$,

$$r_{l+1,j} = \operatorname{near}\big(s\,\operatorname{next}(f, l)_j\big), \qquad f_i = r_i/s,$$

the rows of Lemma 15.35. For $l < N$ and $j \le d$ the *table prefix* $T_{l,j}(Z)$ is the list of integers

$$r_{0,0}, \dots, r_{0,d-1},\ r_{1,0}, \dots, r_{l,d-1},\ r_{l+1,0}, \dots, r_{l+1,j-1}\ :$$

the rows $r_0, \dots, r_l$ followed by the first j entries of r_{l+1}. So $T_{l,d}(Z) = T_{l+1,0}(Z)$ for $l + 1 < N$, and the *table* is $T(Z) = T_{N-1,d}(Z)$, the rows $r_0, \dots, r_N$. We say that the output buffer *holds the table prefix* (l, j) of Z if it holds the word $\operatorname{sw}_W(T_{l,j}(Z))$ with capacity r, the number of rows in use (Definition I.3(b)). This word has $((l + 1)d + j)(W + 2)$ bits.

If $\|Z/s\| \le M$, every entry of every r_l fits W, by Proposition I.32(a), so the signed words are defined. The stored vector is kept between steps as in Definition I.101: the saved request on

tracks 3, 4 and 15, the counters m, N, W_m and σ on tracks 5, 8, 9 and 10, the word $\mathrm{sw}_W(Z)$ on the binary stream, origin marks and a workspace of r rows, and a reserve of rows; in particular $r \geq 100(d+1)(N+1)(W+2)^2$. The coefficient stage uses tracks 11, 12 and 13 of every row and, as scratch that it restores, the tracks 2, 5 to 10 and 14 and the positive half of the tape.

The programs. The stage is three nested programs. Let $\mathsf{sent} = \mathsf{left}^1; \mathsf{scanL}; \mathsf{left}^{13}$; from the root of a tape whose track 0 carries the counter r it walks along the headers to the sentinel row and stops at cell$(r, 13)$, in $2 + (18r + 1) + 14 = 18r + 17$ units (Lemma I.10). The two sentinel cells $(r, 13)$ and $(r, 11)$ are the flags of the two loops: the buffer occupies the rows below its length, which is less than r, so these cells are free. Put

$$\begin{aligned} \mathsf{Build} &= \mathsf{seed}; \mathsf{sent}; \mathsf{write}\,1; \mathsf{loop}(\mathsf{Row}); \mathsf{home}_{13}, \\ \mathsf{Row} &= \mathsf{right}^2; \mathsf{write}\,1; \mathsf{loop}(\mathsf{Append}); \mathsf{left}^2, \\ \mathsf{Append} &= \big[\mathsf{home}_{11},\ \mathsf{Archive},\ \mathsf{Indices},\ \mathsf{dup}_{5\to10},\ \mathsf{dup}_{8\to7},\ \mathsf{pred}_7,\ \mathsf{Width}, \\ &\qquad \mathsf{BankInit},\ \mathsf{zero}_{14},\ \mathsf{Den},\ \mathsf{Num},\ \mathsf{Ops},\ \mathsf{Quot},\ \mathsf{Finish}\big]. \end{aligned}$$

seed copies the stored vector into the empty output buffer as row r_0 (Lemma I.125). Build then repeats Row while the flag $(r, 13)$ holds 1, and Row repeats Append while the flag $(r, 11)$ holds 1. Each run of Append appends one entry and rewrites both flags. Its parts are constructed in the rest of the section; here is what they do.

(1) home_{11} returns from the flag to the root. $\mathsf{Archive}$ copies every cell of rows $0, \dots, r$ into the positive half of the tape (Lemma I.130), so that the stage can use the registers freely and restore them at the end.

(2) $\mathsf{Indices}$ recovers $l+1$ and j from the length $((l+1)d+j)(W+2)$ of the buffer, by counting words and dividing by d in unary (Lemma I.142). The track copies, the decrement and Width put l on track 7, j on track 10 and W on track 9.

(3) $\mathsf{BankInit}$ lays out an arithmetic area of $H = 3W$ twelve-cell rows on track 13, below the sentinel row and above the buffer (Lemma I.139).

(4) Den forms the common denominator D_j of the coefficients of coordinate j, Num the integer numerator

$$U = [l = 0]\, D_j c_j s^2 + \sum_{(a,u)} D_j a\, r_{l,u}\, s + \sum_{(b,u,v)} \sum_{p \leq l} D_j b\, r_{p,u}\, r_{l-p,v}$$

of Proposition I.32(b), reading every coefficient from the saved request and every $r_{p,u}$ from the buffer, and Ops the two operands $2U + D_j s(l+1)$ and $2D_j s(l+1)$ (Lemmas I.151, I.153 and I.154).

(5) Quot divides once, rounding down (Lemma I.155); by Proposition I.32(b) the quotient is $r_{l+1,j}$.

(6) Finish computes the two flags, appends the signed word of the quotient to the buffer, restores every borrowed track from the archive, clears the archive and writes the flags (Lemma I.156).

Theorem I.119 (One entry of the table). *Put $K_{\mathrm{a}} = 2\,000\,000 + 114\,744\,020 \cdot 17^{118}$. Let $r, l < N$ and $j < d$, and let Z be an integer vector with $\|Z/s\| \le M$. Let τ be a tape that holds the stored vector Z on r rows (Definition I.101), on which track 2 carries a counter $c < S$ and track 14 a retained word of length S from row 0, whose output buffer holds the table prefix (l, j) of Z, and with $\tau(r, 11) = 1$. Then* Append *runs from $(\mathrm{cell}(r, 11), \tau)$ to $(\mathrm{cell}(r, 11), \tau')$ in some number t of units, where*

(a) τ' holds the stored vector Z on the same r rows;

(b) the output buffer of τ' holds the table prefix $(l, j + 1)$ of Z;

(c) $\tau'(r, 11) = [j + 1 < d]$ and $\tau'(r, 13) = [l + 1 < N]$;

(d) $\tau'(q, 2) = \tau(q, 2)$ and $\tau'(q, 14) = \tau(q, 14)$ for every $q \le S$;

(e) $t \le K_{\mathrm{a}}(X + r + 1)^{118}$.

The constant K_{a} is a numeral: it depends on nothing, not even on the problem. The exponent is $118 = g_D + g_F + g_R + g_Q + 3$ with the exponents $g_D = 24$, $g_F = 78$, $g_R = 8$ and $g_Q = 5$ of the four arithmetic phases; Table I.4 lists how each arises. The proof is at the end of the section.

Theorem I.120 (One row of the table). *Let $r, l < N$, Z, c and τ be as in Theorem I.119, except that the output buffer holds the table prefix $(l, 0)$ of Z, that is, the rows $r_0, \dots, r_l$, and that $\tau(r, 13) = 1$. Then* Row *runs from $(\mathrm{cell}(r, 13), \tau)$ to $(\mathrm{cell}(r, 13), \tau')$ in t units, where τ' holds the stored vector Z on r rows, its output buffer holds the rows $r_0, \dots, r_{l+1}$, $\tau'(r, 13) = [l + 1 < N]$, τ' agrees with τ on the cells $(q, 2)$ and $(q, 14)$, $q \le S$, and*

$$t \le (dK_{\mathrm{a}} + d + 8)(X + r + 1)^{118}.$$

Proof. Put $Y = X + r + 1$ and $b = K_{\mathrm{a}} Y^{118}$. For $j \le d$ let I_j be the set of configurations $(\mathrm{cell}(r, 11), \sigma)$ such that σ holds the stored vector Z on r rows, its buffer holds the table prefix (l, j), $\sigma(r, 11) = [j < d]$, $\sigma(r, 13)$ is 1 if $j = 0$ and $[l + 1 < N]$ if $j \ge 1$, and σ agrees with τ on the cells $(q, 2)$ and $(q, 14)$, $q \le S$. The program right^2 takes 3 units from $\mathrm{cell}(r, 13)$ to $\mathrm{cell}(r, 13) + 2 = \mathrm{cell}(r, 11)$, and write 1 one unit; since $d \ge 1$, the configuration is in I_0. Let $j < d$ and let a configuration in I_j be given. It scans $\sigma(r, 11) = 1$. Track 2 still carries c and track 14 the retained word, because these depend only on the cells $(q, 2)$, $q \le c < S$, and $(q, 14)$, $q \le S$. So Theorem I.119 applies: Append runs within b units to a configuration in I_{j+1}. Each configuration in I_d scans $[d < d] = 0$. By Lemma I.6, loop(Append) runs within $d(b + 1) + 1$ units from I_0 to I_d, and left^2 returns to $\mathrm{cell}(r, 13)$ in 3 units. In I_d the buffer holds the prefix (l, d), the rows $r_0, \dots, r_{l+1}$, and since $d \ge 1$ the flag $(r, 13)$ holds $[l + 1 < N]$. In all $t \le 3 + 1 + d(b + 1) + 1 + 3 = dK_{\mathrm{a}} Y^{118} + d + 8 \le (dK_{\mathrm{a}} + d + 8)Y^{118}$, because $Y \ge 1$. □

Theorem I.121 (The whole table). *Let r and Z with $\|Z/s\| \le M$ be given, and let τ hold the stored vector Z on r rows, with a counter $c < S$ on track 2 and a retained word of length S on track 14 from row 0. Then* Build *runs from $(-1, \tau)$ to $(-1, \tau')$ in t units, where τ' holds the stored vector Z on the same r rows, its output buffer holds the word $\mathrm{sw}_W(r_0, \dots, r_N)$ of the whole table with capacity r, τ' agrees with τ on the cells $(q, 2)$ and $(q, 14)$, $q \le S$, and*

$$t \le (dK_{\mathrm{a}} + d + 1008)(X + r + 1)^{120}.$$

The rows in use do not change, so in the sense of Definition I.7 this is a contract whose bound counts the units alone, with exponent 120 *and the constant* $dK_{\mathrm{a}} + d + 1008$*, which depends on the problem only through* d*.*

Proof. Put $Y = X + r + 1$ and $K_{\mathrm{r}} = dK_{\mathrm{a}} + d + 8$. By Lemma I.125, seed runs from $(-1, \tau)$ within $600(r+1)^2$ units to $(-1, \tau_1)$, where the buffer of τ_1 holds $\mathrm{sw}_W(Z)$, the prefix $(0, 0)$, and τ_1 differs from τ only on tracks 11, 12 and 13 of rows $j \le r$; the hypothesis $d(W+2) \le r$ of that lemma is part of the reserve. So τ_1 still holds the stored vector Z, which involves none of these tracks. sent takes $18r + 17$ units to $\mathrm{cell}(r, 13)$, and $\mathsf{write}\,1$ one unit; the buffer is not affected, since its length $d(W+2)$ is less than r.

For $l \le N$ let J_l be the set of configurations $(\mathrm{cell}(r, 13), \sigma)$ such that σ holds the stored vector Z on r rows, its buffer holds the rows $r_0, \dots, r_l$, $\sigma(r, 13) = [l < N]$, and σ agrees with τ on the cells $(q, 2)$ and $(q, 14)$, $q \le S$. The configuration reached is in J_0, because $N \ge 1$. From J_l with $l < N$ the scanned cell holds 1, and Theorem I.120 gives a run of Row within $K_{\mathrm{r}} Y^{118}$ units to a configuration in J_{l+1}; each configuration in J_N scans 0. By Lemma I.6 the loop takes at most $N(K_{\mathrm{r}} Y^{118} + 1) + 1$ units, and home_{13} from row r takes $18r + 17$ units (Lemma I.11). In J_N the buffer holds the whole table.

Since $N \le X \le Y$ and $r + 1 \le Y$,

$$t \le 600(r+1)^2 + 2(18r+17) + 1 + N(K_{\mathrm{r}} Y^{118} + 1) + 1 \le 600Y^2 + 36Y + K_{\mathrm{r}} Y^{119} + Y \le (K_{\mathrm{r}} + 1000) Y^{120},$$

and $K_{\mathrm{r}} + 1000 = dK_{\mathrm{a}} + d + 1008$. □

I.11.2 Packed lists, the output buffer and natural numbers

The stage keeps one more kind of record, in the positive half of the tape: a list of bits written as pairs of cells.

Definition I.122 (Packed lists)**.** A tape τ holds the *packed list* $w = w_0 \cdots w_{n-1}$ at h if $\tau(h+2i) = 1$ and $\tau(h + 2i + 1) = w_i$ for $i < n$, and $\tau(h + 2n) = 0$. The cell $h + 2i$ is the *presence* cell and $h + 2i + 1$ the *value* cell of the entry i.

Lemma I.123 (Packed lists)**.** *Let* τ *hold the packed list* w *of length* n *at* h*. Put*

$$\mathsf{scanP} = \mathsf{loop}(\mathsf{right}; \mathsf{right}), \qquad \mathsf{emitP}(b) = \mathsf{write}\,1; \mathsf{right}; \mathsf{write}\,b; \mathsf{right}; \mathsf{write}\,0,$$
$$\mathsf{appP}(b) = \mathsf{scanP}; \mathsf{emitP}(b), \qquad \mathsf{rewP} = \mathsf{left}^2; \mathsf{loop}(\mathsf{left}^2).$$

(a) scanP *runs from* (h, τ) *to* $(h + 2n, \tau)$ *in* $3n + 1$ *units.*

(b) $\mathsf{emitP}(b)$ *runs from* (x, τ) *in* 5 *units to* $x + 2$*, writing* 1*,* b *and* 0 *into the cells* x*,* $x + 1$ *and* $x + 2$*.*

(c) $\mathsf{appP}(b)$ *runs from* (h, τ) *in* $3n + 6$ *units to* $(h + 2n + 2, \tau')$*, where* τ' *holds the packed list* wb *at* h *and differs from* τ *only in the cells* $h + 2n$*,* $h + 2n + 1$ *and* $h + 2n + 2$*.*

(d) If $\tau(h - 2) = 0$*,* rewP *runs from* $(h + 2n, \tau)$ *to* $(h - 2, \tau)$ *in* $4n + 4$ *units.*

Table I.4. The bounds of the coefficient stage. Here $H = 3W$ is the width of the arithmetic area and $Y = 17(r+1)$. A routine's exponent is the one its proof composes; none is the least possible.

Proof. (a) Lemma I.6 with $I_i = \{(h+2i, \tau)\}$: a pass costs 3 units with its test, and the cell $h+2n$ stops the loop. (b) Five primitives. (c) is (a) and (b) with $x = h+2n$; the new end cell $h+2n+2$ receives 0. (d) left^2 (3 units) reaches $h+2n-2$; the loop then passes over the presence cells $h+2n-2, \dots, h$, 4 units each with its test, and stops at $h-2$ (1 unit). □

The output buffer grows one bit at a time.

Lemma I.124 (Appending to the buffer)**.** *Let*

$$\mathsf{put}_{11}(b) = [\mathsf{seek}_{11}, \mathsf{left}^2, \mathsf{write}\, b, \mathsf{right}, \mathsf{write}\, 1, \mathsf{right}, \mathsf{next}, \mathsf{home}_{11}].$$

If track 11 *carries the counter* ℓ *and* τ *has origin marks up to* $\ell+1$*, then* $\mathsf{put}_{11}(b)$ *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *in* $36\ell+75$ *units, where* τ' *is* τ *with* $(\ell,13)$ *set to* b*,* $(\ell,12)$ *and* $(\ell,11)$ *set to* 1 *and* $(\ell+1,11)$ *set to* 0*. In particular, if the output buffer holds* w *with capacity* $R > |w| = \ell$*, then it holds* wb *with capacity* R *afterwards.*

Proof. seek_{11} ($18\ell+14$) reaches $(\ell,11)$, left^2 (3) the cell $(\ell,13)$; the writes and moves (4) set $(\ell,13)$ and $(\ell,12)$ and return to $(\ell,11)$; next (20) advances the counter (Lemma I.13); home_{11}

from row $\ell+1$ takes $18\ell+33$; and the list adds 1. The sum is $36\ell+75$. The presence cells $(j,12)$ with $\ell<j\le R$ are unchanged, so they still hold 0. □

Lemma I.125 (Emptying the buffer, and the seed row)**.** *Let τ be a workspace of r rows with origin marks up to r. Put* $\mathsf{empty}=\mathsf{clear}_{11,12}$ *and*

$$\mathsf{seed}=\mathsf{empty};\mathsf{rep}_{11,6}(\mathsf{cbit}),$$
$$\mathsf{cbit}=\mathsf{peek}_{11\to7};\mathsf{branch}\big(\mathsf{home}_7;\mathsf{put}_{11}(0),\ \mathsf{home}_7;\mathsf{put}_{11}(1)\big),$$

with peek *and* rep *as in Lemma I.126 below.*

(a) empty *runs from $(-1,\tau)$ to $(-1,\tau')$ in $124r+63$ units; τ' is τ with tracks 11 and 12 set to 0 in rows $j\le r$, so its output buffer holds the empty word with capacity r.*

(b) If the binary stream of τ holds w with $|w|\le r$, then seed *runs from $(-1,\tau)$ to $(-1,\tau'')$ within $600(r+1)^2$ units, where the output buffer of τ'' holds w with capacity r, τ'' is a workspace of r rows, and τ'' differs from τ only on tracks 11, 12 and 13 of rows $j\le r$.*

Proof. (a) By Lemma I.16 the two clears take $(61r+30)+(63r+32)$ units, and the list adds 1. (b) After empty, let R_q ($q\le|w|$) say that the buffer holds $w_0\cdots w_{q-1}$ and that the tape is otherwise as after empty. Track 11 then carries q, and the guard track 6 carries the counter $|w|$, the presence marks of the stream. A run of cbit from R_q, $q<|w|$, goes to $(q,11)$ and over to $(q,7)$ ($18q+14+5$ units), branches on w_q, returns along the origin marks ($18q+11$) and appends w_q with Lemma I.124 ($36q+75$): at most $200(r+1)$ units, ending in R_{q+1}. By Lemma I.126(c), $\mathsf{rep}_{11,6}(\mathsf{cbit})$ takes at most $(|w|+1)(200(r+1)+200(r+1))\le400(r+1)^2$ units, and with (a) the total is at most $600(r+1)^2$. Only tracks 11, 12 and 13 of rows below $|w|+1\le r+1$ were written. □

Several stages move a whole track, or repeat a body while a column holds marks. The next lemma gives these routines, and the one after it the decrement of a counter.

Lemma I.126 (Tracks and columns)**.** *Let $k,l,c,g<16$. Put* $\mathsf{peek}_{c\to g}=\mathsf{seek}_c;\mathsf{shift}_{c\to g}$,

$$\mathsf{dup}_{k\to l}=\mathsf{left}^1;\mathsf{loop}(\mathsf{row}_{k\to l};\mathsf{left}^{16});\mathsf{row}_{k\to l};\mathsf{left}^1;\mathsf{home}_1,$$
$$\mathsf{row}_{k\to l}=\mathsf{left}^k;\mathsf{branch}(E_0,E_1),\qquad E_b=\mathsf{right}^k;\mathsf{left}^l;\mathsf{write}\,b;\mathsf{right}^l,$$
$$\mathsf{rep}_{c,g}(P)=\mathsf{peek}_{c\to g};\mathsf{loop}(\mathsf{home}_g;P;\mathsf{peek}_{c\to g});\mathsf{home}_g.$$

(a) If track c carries the counter q, $\mathsf{peek}_{c\to g}$ *runs from $(-1,\tau)$ to $(\mathrm{cell}(q,g),\tau)$ in $18q+c+4+|c-g|$ units.*

(b) If track 0 of τ carries the counter r, τ has origin marks up to r and $2\le l$, then $\mathsf{dup}_{k\to l}$ *runs from $(-1,\tau)$ to $(-1,\tau')$ in exactly $(2k+2l+42)r+2k+2l+16$ units, where τ' is τ with (j,l) set to $\tau(j,k)$ for every $j\le r$.*

(c) Let $1\le g,n\le r$, and let $\mathrm{R}_0,\dots,\mathrm{R}_n$ be properties of tapes such that on every tape with R_q track c carries q, track g carries n, and there are origin marks up to r. If for every $q<n$ the program P runs from $(-1,\sigma)$ within b units to some $(-1,\sigma')$ with R_{q+1} whenever σ has R_q, then $\mathsf{rep}_{c,g}(P)$ *runs from every tape with R_0 to a tape with R_n within $(n+1)(b+200(r+1))$ units.*

Proof. (a) Lemma I.11(a) and (c). (b) left^1 (2 units) reaches the header $(0,0)$. For $j < r$ the pass at the header $(j,0) = 1$ reads (j,k), writes it into (j,l), returns to the header and moves to $(j+1,0)$: $1+(k+1)+1+(k+1)+(l+1)+1+(l+1)+17 = 2k+2l+24$ units with its test. At the sentinel $(r,0) = 0$ the test fails (1 unit), $\mathsf{row}_{k\to l}$ copies the cell of row r ($2k+2l+6$), left^1 (2) reaches $(r,1)$ and home_1 takes $18r+5$. The sum is the stated count. (c) Let I_q be the set of configurations at cell(q,g) whose tape has R_q. The first peek ($18\cdot 0 + c + 4 + |c-g| \le 36$ units) reaches I_0. A pass from I_q, $q < n$, scans $(q,g) = 1$ (1 unit), returns ($18q+g+4$), runs P (at most b) and peeks again ($18(q+1)+c+4+|c-g|$): at most $b + 100(r+1)$ units, ending in I_{q+1}. At I_n the cell (n,g) is the hole of track g. With the final test and home_g ($18n+g+4$), Lemma I.6 gives at most $36 + n(b+100(r+1)+1) + 1 + 18n + 20 \le (n+1)(b+200(r+1))$ units. □

Lemma I.127 (Decrementing a counter). *Let* $2 \le k < 16$ *and*

$$\mathsf{pred}_k = \mathsf{seek}_k; \mathsf{right}^{16}; \mathsf{write}\ 0; \mathsf{home}_k.$$

If track k *carries the counter* $a+1$ *and* τ *has origin marks up to* $a+1$*, then* pred_k *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *in* $36a+2k+43$ *units, where* τ' *is* τ *with* (a,k) *set to* 0*; track* k *then carries* a*.*

Proof. seek_k ($18(a+1)+k+3$) reaches the hole in row $a+1$, right^{16} (17) the cell (a,k), which is set to 0 (1), and home_k from row a takes $18a+k+4$. □

The coefficients of the field are read from the saved request, one framed number at a time, with the frame reader of Section I.7. By Lemma I.44 the saved request lays out the frames $f_0, f_1, \dots, f_F$ of the request from row 0 (Definition I.43); so every frame f_k, followed by the later frames, is laid out from its first row s_k, and we call s_k the *row of* f_k. The program skipf of Lemma I.46 moves the counter on track 5 from the row of a frame g to the row of the next one, in $36a + 70|g| + 16$ units if track 5 carried a, and fetch of Lemma I.45 copies the frame whose row track 5 carries onto tracks 6 and 7 from the row o that track 8 carries, within $1000(a+o+|g|+1)^2$ units. Both write only tracks 5 to 8 and 10. The test probe used there writes into $(a,10)$ whether the frame goes on at row a.

Lemma I.128 (Reading a natural number). *Let* $\mathsf{nat} = \mathsf{fetch}; \mathsf{reset}_8; \mathsf{toUnary}$*, with* $\mathsf{toUnary}$ *of Lemma I.31. Let* τ *have origin marks up to* r*, let track* 5 *carry* s*, track* 8 *the counter* 0*, and track* 9 *hold* 0 *in every row, and let the binary digits* $\beta(v)$ *of a natural number* v *(as the request writes them) be the frame whose row is* s*, with* $s + |\beta(v)| \le r$ *and* $v+1 \le r$*. Then* nat *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *within* $10\,000(r+1)^2$ *units, where track* 8 *of* τ' *carries* v*, track* 9 *holds the value* v*, track* 5 *carries* $s+|\beta(v)|$*, only tracks* 5 *to* 10 *have changed, and every cell* $x \ge -1$ *and every cell of a row beyond* r *is kept. With* $\mathsf{clear}_{8,9}$ *in front, the same holds without the hypotheses on tracks* 8 *and* 9*, within* $11\,000(r+1)^2$ *units, provided track* 0 *carries the counter* r *and every cell of a row beyond* r *holds* 0*.*

Proof. By Lemma I.45 with $o = 0$, fetch puts $\beta(v)$ on the binary stream within $1000(s + |\beta(v)| + 1)^2 \le 1000(r+1)^2$ units, and track 8 then carries $|\beta(v)|$. reset_8 ($36|\beta(v)| + 48$ units, Lemma I.14(c)) makes it carry 0 again. By Lemma I.31 with the counter 0, $\mathsf{toUnary}$ takes at most $1000(|\beta(v)| + v + 1)^2 \le 4000(r+1)^2$ units and leaves the counter and the value v on tracks 8 and 9. The sum is at most $10\,000(r+1)^2$. The clears of tracks 8 and 9 take $(55r+24) + (57r+26) + 1 \le 1000(r+1)^2$ units. □

I.11.3 Snapshots of the rows

The coefficient stage needs more registers than the sixteen tracks offer while the stored vector, the step counter and the saved request must survive it. It therefore copies every cell of the rows in use into the positive half of the tape, which is blank between stages, uses the tracks freely, and restores them from that copy at the end. The same mechanism, nested, gives subroutines with call frames.

Definition I.129 (The archive of the rows)**.** Let σ be a tape and r a row count. The *archive* $A_r(\sigma)$ is the word of $16(r+1)$ bits that lists, for $j = 0, 1, \dots, r$ in turn, the bit $[j < r]$ followed by $\sigma(j,1), \dots, \sigma(j,15)$. Its entry $16j + k$ records the cell (j,k), $k \geq 1$, and the entry $16j$ the header of row j in a workspace of r rows.

Lemma I.130 (Taking a snapshot)**.** *Let*

$$\begin{aligned}
\mathsf{root} &= \mathsf{left}; \mathsf{home}_1, \qquad \mathsf{push}(b) = \mathsf{root}; \mathsf{right}^3; \mathsf{appP}(b); \mathsf{rewP}; \mathsf{left}^1; \mathsf{seek}_0, \\
\mathsf{Archive} &= \mathsf{left}^1; \mathsf{loop}(\mathsf{write}\,0; \mathsf{crow}(1); \mathsf{write}\,1; \mathsf{left}^{16}); \mathsf{crow}(0); \mathsf{root}, \\
\mathsf{crow}(b) &= \mathsf{push}(b); \mathsf{pk}_1; \mathsf{pk}_2; \cdots; \mathsf{pk}_{15}, \\
\mathsf{pk}_k &= \mathsf{left}^k; \mathsf{branch}\big(\mathsf{right}^k; \mathsf{push}(0),\ \mathsf{right}^k; \mathsf{push}(1)\big).
\end{aligned}$$

Let τ have origin marks up to r, $\tau(j,0) = 1$ for $j < r$, $\tau(r,0) = 0$, $\tau(0) = 0$, and let τ hold a packed list w at 2. Then Archive *runs from $(-1,\tau)$ to $(-1,\tau')$ within $10^6(|w| + r + 1)^2$ units, where τ' holds the packed list $wA_r(\tau)$ at 2 and differs from τ only in the cells x with $2 + 2|w| \leq x \leq 2 + 2(|w| + 16(r+1))$.*

Proof. The program keeps the header of the row it is copying at 0, so that seek_0 finds that row again after each trip to the positive half. Consider a configuration at cell$(j,0)$ in which the header of row j holds 0, the headers of rows $q < j$ hold 1, and the tape holds a packed list v at 2. Then $\mathsf{push}(b)$ returns to the root along the origin marks ($18j + 6$ units), steps to cell 2 (4), appends b ($3|v| + 6$, Lemma I.123), rewinds to the blank cell 0 ($4|v| + 8$), steps to the root (2) and finds the row again ($18j + 3$, Lemma I.11): at most $100(j + |v| + 1)$ units, and the list is now vb. The program pk_k reads (j,k) and pushes it, so $\mathsf{crow}(b)$ appends $b, \tau(j,1), \dots, \tau(j,15)$ within $16 \cdot 100(j + |v| + 17) + 15 \cdot 33 \leq 2000(j + |v| + 17)$ units. A pass of the loop at the header $(j,0) = 1$, $j < r$, sets it to 0, copies the row with the true header bit 1, restores the header and moves to row $j + 1$; at the sentinel $(r,0) = 0$ the loop stops and $\mathsf{crow}(0)$ copies row r with its header bit 0. So the list becomes $wA_r(\tau)$. At row j the list has length $|w| + 16j \leq |w| + 16r$, so each row costs at most $2000(17r + |w| + 17) + 20 \leq 34\,020(|w| + r + 1)$ units, and with left^1, the final test and root the total is at most $(r+1) \cdot 34\,020(|w| + r + 1) + 18r + 9 \leq 10^6(|w| + r + 1)^2$. Every header is restored, and only the cells of the new entries and the end cell of the list are written. $\square$

Lemma I.131 (Restoring from a snapshot). *For a set $\mathcal{S}$ of tracks with $1 \notin \mathcal{S}$ put*

$$\mathsf{pop}_k^{\mathcal{S}} = \mathsf{root}; \mathsf{right}^3; \mathsf{scanP}; \mathsf{left}^1; \mathsf{branch}\big(\mathsf{pa}_k(0), \mathsf{pa}_k(1)\big),$$
$$\mathsf{pa}_k(b) = \mathsf{write}\,0; \mathsf{left}; \mathsf{write}\,0; \mathsf{rewP}; \mathsf{left}^1; \mathsf{seek}_0; \mathsf{left}^k; W_k(b); \mathsf{right}^k,$$

where $W_k(b)$ is $\mathsf{write}\,b$ *if $k = 0$ or $k \in \mathcal{S}$ and* skip *otherwise. Let* $\mathsf{rrow}^{\mathcal{S}}$ *be* $\mathsf{pop}_{15}^{\mathcal{S}}; \cdots; \mathsf{pop}_1^{\mathcal{S}}; \mathsf{pop}_0^{\mathcal{S}}$ *and*

$$\mathsf{Restore}_{\mathcal{S}} = \mathsf{seek}_0; \mathsf{rrow}^{\mathcal{S}}; \mathsf{left}; \mathsf{loop}(\mathsf{right}^{17}; \mathsf{write}\,0; \mathsf{rrow}^{\mathcal{S}}; \mathsf{left}); \mathsf{right}^2.$$

Let τ have origin marks up to r, $\tau(j,0) = 1$ for $j < r$, $\tau(r,0) = 0$, $\tau(0) = 0$, and let τ hold the packed list $wA_r(\sigma)$ at 2 for some tape σ. Then $\mathsf{Restore}_{\mathcal{S}}$ *runs from $(-1,\tau)$ to $(-1,\tau')$ within $2 \cdot 10^6(|w| + r + 1)^2$ units, where $\tau'(j,k) = \sigma(j,k)$ for $j \le r$ and $k \in \mathcal{S}$, the cells x with $2 + 2|w| \le x < 2 + 2(|w| + 16(r+1))$ hold 0, and τ' agrees with τ on every other cell. In particular τ' holds the packed list w at 2. For the set $\mathcal{B} = \{2,5,6,7,8,9,10,14\}$ of the tracks the stage borrows we write* $\mathsf{Restore} = \mathsf{Restore}_{\mathcal{B}}$*; it takes at most $10^6(|w| + r + 1)^2$ units.*

Proof. $\mathsf{pop}_k^{\mathcal{S}}$, started at cell$(j,0)$ with the header of row j at 0 and the list v at 2, goes to the end of the list, reads the value b of its last entry, erases that entry, comes back to row j and writes b into (j,k) if $k = 0$ or $k \in \mathcal{S}$; as in the previous proof this costs at most $150(j + |v| + 1)$ units. The entries of row j are the last sixteen of the list, track 15 last, so $\mathsf{rrow}^{\mathcal{S}}$ at row j restores the selected cells of that row and finally its header, from the entry $16j$. The first seek_0 finds the sentinel row r, whose header is 0, and the archive ends with row r. After a row j is restored, left reads the origin mark $(j,1)$: it is 1 for $j \ge 1$, and then the pass moves to $(j-1,0)$, sets that header to 0 so that seek_0 finds the row, restores the row and steps to $(j-1,1)$; at row 0 the mark is 0 and right^2 returns to the root. The rows are thus restored from r down to 0, sixteen pops each, with lists of length at most $|w| + 16(r+1)$: at most $(r+1)(16 \cdot 150(17r + |w| + 18) + 40) + 18r + 6$ units, which is less than $10^6(|w| + r + 1)^2$; the bound $2 \cdot 10^6(|w| + r + 1)^2$ covers every $\mathcal{S}$. Erased entries hold 0 in both cells. □

Lemma I.132 (Call frames). *Let $\mathcal{S}$ be a set of tracks, $1 \notin \mathcal{S}$, $0 \notin \mathcal{S}$, and* $\mathsf{Call}_{\mathcal{S}}(P) = \mathsf{Archive}; P; \mathsf{Restore}_{\mathcal{S}}$*. Let τ be as in Lemma I.130, and let τ_A be the tape it produces. Suppose P runs from $(-1,\tau_A)$ in t_P units to some $(-1,\sigma)$ such that σ has origin marks up to r, $\sigma(j,0) = 1$ for $j < r$, $\sigma(r,0) = 0$, $\sigma(0) = 0$, and σ holds the list $wA_r(\tau)$ at 2. Then* $\mathsf{Call}_{\mathcal{S}}(P)$ *runs from $(-1,\tau)$ to $(-1,\tau')$ within $t_P + 3 \cdot 10^6(|w| + r + 1)^2$ units, where τ' agrees with τ on the cells (j,k), $j \le r$, $k \in \mathcal{S}$, holds 0 in the cells x with $2 + 2|w| \le x < 2 + 2(|w| + 16(r+1))$, and agrees with σ on every other cell.*

Proof. Lemmas I.130 and I.131 with the archived tape τ; the costs add. □

The *registers* of the stage are the tracks $\mathcal{R} = \{2,5,6,7,8,9,10,11,12,14\}$. For a set O of output tracks we write $\mathsf{frame}_O(P) = \mathsf{Call}_{\mathcal{R}\setminus O}(P)$: a subroutine P run in this frame may use every register as scratch, and afterwards every register except those in O is as before; the arithmetic area on track 13 and the outputs in O are as P left them.

The snapshot also serves as a record of the registers at the start of the stage, from which the stage reads back the order N and the width W when it needs them.

Lemma I.133 (Reading a counter from the snapshot)**.** *Let $1 \le u < 16$, $2 \le k < 16$, and put*

$$\mathsf{arch}_{k\leftarrow u} = \mathsf{right}^{3};\mathsf{write}\,0;\mathsf{right}^{1+2u};\mathsf{loop}(\mathsf{abody});\mathsf{left}^{1+2u};\mathsf{write}\,1;\mathsf{rewP};\mathsf{left}^{1},$$
$$\mathsf{abody} = \mathsf{left}^{1+2u};\mathsf{write}\,1;\mathsf{right}^{32};\mathsf{write}\,0;\mathsf{rewP};\mathsf{left}^{1};\mathsf{inc}_{k};\mathsf{right}^{3};\mathsf{scanP};\mathsf{right}^{1+2u}.$$

Let τ hold the packed list $A_r(\sigma)$ at 2, with $\tau(0) = 0$ and origin marks up to r, let track u of σ carry a counter $n < r$, and let track k of τ carry 0. Then $\mathsf{arch}_{k\leftarrow u}$ runs from $(-1,\tau)$ to $(-1,\tau')$ within $10^4(r+1)^2$ units, where track k of τ' carries n, and τ' agrees with τ on every cell $x \ge 0$ and on every cell $x < 0$ that is not on track k.

Proof. The entry of (q,u) in the archive has its value in cell $2+2(16q+u)+1 = (2+32q)+(1+2u)$. The program marks its place by setting the presence cell $2+32q$ of the header entry of row q to 0 (a bookmark). The first three parts set the bookmark for $q = 0$ and move to the value of $(0,u)$. A pass of the loop at the value of $(q,u) = 1$, that is $q < n$, clears the bookmark, sets the bookmark of row $q+1$ (which exists, since $q+1 \le n < r$), rewinds over the $16(q+1)$ entries before it to the blank cell 0 (Lemma I.123(d)), steps to the root, increments track k ($36q+2k+44$ units, Lemma I.14), and scans from cell 2 to the new bookmark and then to the value of $(q+1,u)$. With the rewind ($64(q+1)+4$ units) and the scan ($48(q+1)+1$) a pass costs at most $148q+2k+4u+207 \le 1000(r+1)$ units. At the value of $(n,u) = 0$, the hole, the loop stops, and the last four parts clear the bookmark and return to the root ($64n+2u+10$ units). By Lemma I.6 the total is at most $1000n(r+1)+64n+4u+50 \le 10^4(r+1)^2$. The positive half is as before, and of the scratch area only track k was written. □

With $\mathsf{Width} = \mathsf{zero}_9;\mathsf{arch}_{9\leftarrow 9}$ the width W returns to track 9 from the snapshot, within $25 + 10^4(r+1)^2 \le 11\,000(r+1)^2$ units; likewise $\mathsf{Order} = \mathsf{zero}_8;\mathsf{arch}_{8\leftarrow 8}$ brings back N.

I.11.4 The arithmetic area

The arithmetic of one entry is done in twelve-cell rows (Section I.5) laid along track 13, between the end of the buffer and the sentinel row, and read upwards, towards row 0.

Definition I.134 (The bank)**.** Let τ be a tape and a a row. The *bank view* of τ at a is the tape $\beta(x) = \tau(\mathrm{cell}(a,13)+16x)$, $x \in \mathbb{Z}$; for $x \le a$ this is the cell $(a-x,13)$. The *bank of width H* at a is the block of twelve-cell rows at 1 of β; it is *laid out* if it has H marked rows and is closed on the left (Definition I.20). The cell $\beta(0)$, that is $(a,13)$, is the *sign cell.* Column c of the bank *reads* the integer z if the word $\beta(1+12q+c)$, $q < H$, has a value congruent to z modulo 2^H. The *support* of the bank is the set of cells x with $-11 \le x \le 12H+24$ of β, that is, the cells of track 13 in the rows $a-12H-24,\dots,a+11$.

Reading modulo 2^H is what the ripple adder and the multiplier compute (Lemma I.21, Corollary I.22, Lemma I.27), so sums and products of columns are read correctly whatever the signs. Only two readings need more: the common denominator, which is read as a natural number, and the two final operands, which are read in two's complement; Proposition I.32(b) puts both below 2^{H-1} for $H = 3W$. The columns have fixed roles: 1 holds the operand just loaded, 3 a second factor, 7 the common denominator, 9 the weight of the current coefficient and 11 the numerator; 2, 4, 5, 6, 8 and 10 are the working columns of the routines of Section I.5.

Definition I.135 (The working state)**.** Fix r, $l < N$, $j < d$ and Z as in Theorem I.119, let τ_0 be the tape with which Append starts, $H = 3W$, $a = r - 12$ and $\ell = ((l+1)d + j)(W+2)$. A tape τ is in the *working state with indices* (q, p) if

(i) $12H + 25 \le a$ and $\ell \le a - 12H - 25$;

(ii) track 0 carries the counter r, there are origin marks up to r, and the output buffer holds the table prefix (l, j) of Z with capacity r;

(iii) the root holds 1, the cells 0 and 1 hold 0, τ holds the packed list $A_r(\tau_0)$ at 2, and every cell beyond it holds 0;

(iv) tracks 7, 10, 8, 14, 9 and 6 carry the counters l, j, p, q, W and H;

(v) the bank of width H at a is laid out;

(vi) τ agrees with τ_0 on tracks 0, 1, 3, 4 and 15, and every cell of a row $j' > r$ holds 0.

The index q counts the terms of a sum, p the pairs of a Cauchy sum.

By (vi) the saved request of τ_0 is kept, and by (i) and (ii) the buffer lies in rows below $a - 12H - 25$, outside the support of the bank. The first condition holds for every tape the stage meets.

Lemma I.136 (Room for the bank)**.** *If $r \ge 100(d+1)(N+1)(W+2)^2$ and $W \ge 4$, then for $l < N$ and $j \le d$ we have $((l+1)d + j)(W+2) + 12(3W+4) \le r$; hence $12H + 25 \le r - 12$ and $\ell < r - 12 - (12H + 25)$.*

Proof. Put $F = (d+1)(N+1)$. Then $(l+1)d + j \le (N+1)d + d \le F$, so the prefix has at most $F(W+2) \le F(W+2)^2$ bits, and $12(3W+4) \le 10(W+2)^2 \le 10F(W+2)^2$. The sum is at most $11F(W+2)^2 \le r$. Since $12(3W+4) = 12H + 48$, the remaining claims follow. Also $W = 4\mathscr{B}(N) + 4 \ge 4$. □

Lemma I.137 (Calling the bank)**.** *Let*

$$\mathsf{bcall}(P) = \mathsf{sent}; \mathsf{right}^{192}; P^{\uparrow 16}; \mathsf{home}_{13}, \qquad \mathsf{bank}(P) = \mathsf{bcall}(\mathsf{right}; P; \mathsf{left}).$$

Let τ have origin marks up to r, $\tau(j', 0) = 1$ for $j' < r$, $\tau(r, 0) = 0$, and let $a = r - 12$ and $12H + 25 \le a$. Let β be the bank view of τ at a, and suppose P runs on the tape β from $(0, \beta)$ in t units to (f, β'), where $0 \le f \le a$ and β' agrees with β outside the support. Then $\mathsf{bcall}(P)$ runs from $(-1, \tau)$ to $(-1, \tau')$ within $17t + 36r + 300$ units, where the bank view of τ' at a is β' and τ' agrees with τ on every cell that is not in the support. If P runs from $(1, \beta)$ to $(1, \beta')$ in t units, $\mathsf{bank}(P)$ does the same within $17t + 36r + 334$ units.

Proof. sent $(18r+17)$ reaches $\mathrm{cell}(r, 13)$ and right^{192} (193) the cell $\mathrm{cell}(r, 13) + 192 = \mathrm{cell}(a, 13)$. With $o = \mathrm{cell}(a, 13)$ and stride 16 we have $o + 16x = \mathrm{cell}(a - x, 13)$, so the configuration carries $(0, \beta)$ in the sense of Lemma I.8, and $P^{\uparrow 16}$ runs within $17t$ units to a configuration that carries (f, β') and has changed no cell off track 13; its head is on $\mathrm{cell}(a - f, 13)$, in row $a - f \le a$. home_{13} then takes $18(a - f) + 17 \le 18r$ units. For $\mathsf{bank}(P)$ the two extra moves add 2 units to t. □

Lemma I.138 (Bank routines)**.** *Let the twelve-cell rows at h have $H \geq 1$ marked rows and be closed on the left, and let $1 \leq s, t, c < 12$. Put*

$$\begin{aligned} \mathsf{bcp}_{s\to t} &= \mathsf{cp}_{s\to t};\mathsf{back}, \qquad \mathsf{bz}_t = \mathsf{cl}_t;\mathsf{back}, \qquad \mathsf{bmul} = \mathsf{mul};\mathsf{back},\\ \mathsf{bone}_t &= \mathsf{bz}_t;\mathsf{right}^t;\mathsf{write}\,1;\mathsf{left}^t,\\ \mathsf{bsign}_c &= \mathsf{loop}(\mathsf{right}^{12});\mathsf{left}^{12-c};\mathsf{branch}(E_0,E_1),\\ E_b &= \mathsf{right}^{12-c};\mathsf{back};\mathsf{left};\mathsf{write}\,b;\mathsf{right}, \end{aligned}$$

and, with $\Sigma = \mathsf{z}_6;\mathsf{add}^{\uparrow 2};\mathsf{back};\mathsf{cp}_{8\to 4};\mathsf{back}$ of Lemma I.27,

$$\begin{aligned} \mathsf{bacc} &= [\mathsf{bcp}_{4\to 2},\mathsf{bcp}_{11\to 4},\Sigma,\mathsf{bcp}_{4\to 11}], \qquad \mathsf{bdbl}_c = [\mathsf{bcp}_{c\to 2},\mathsf{bcp}_{c\to 4},\Sigma,\mathsf{bcp}_{4\to c}],\\ \mathsf{binc} &= [\mathsf{bcp}_{1\to 2},\mathsf{bcp}_{9\to 4},\Sigma,\mathsf{bcp}_{4\to 9}]. \end{aligned}$$

Each runs from h to h, keeps the presence marks and writes only the columns named below, the cell $h-1$ for bsign*, and cells of the end row.*

(a) $\mathsf{bcp}_{s\to t}$ *copies column s into column t in $(2s+2t+20)H+1+(14H+27)$ units;* bz_t *clears column t in $(2t+17)H+1+(14H+27)$ units;* bone_t *makes column t read 1 within $(2t+31)H+2t+31$ units.*

(b) bsign_c *copies the last bit of column c, its two's complement sign, into the cell $h-1$, within $28H+80$ units.*

(c) If columns 1 and 3 read x and y, bmul *makes column 4 read xy within $441(H+1)^3$ units, writing columns 2, 4, 5, 6, 8 and 10.*

(d) Σ makes column 4 read the sum of what columns 2 and 4 read, within $132H+73$ units, writing columns 4, 6 and 8. Hence bacc *adds column 4 to column 11 within $400H+160$ units,* bdbl_c *doubles column c ($c \neq 2, 4$) and* binc *adds column 1 to column 9, each within $400H+161$ units.*

Proof. (a) Lemma I.25(a) and (b); bone_t adds $(t+1)+1+(t+1)$ units and sets the least significant bit. (b) The loop walks to the end row ($14H+1$ units), left^{12-c} reaches column c of row $H-1$ and the branch reads it; E_b returns to the end row, walks back to row 0 ($14H+27$) and writes b into $h-1$: at most $28H+58$ units. (c) Lemma I.27 gives column 4 the H lowest bits of $\mathrm{val}(x)\,\mathrm{val}(y)$ within $400(H+1)^2$ units, and back adds $14H+27$; the low H bits of a product are determined by the factors modulo 2^H, and $400(H+1)^2+14H+27 \leq 441(H+1)^3$. (d) The count of Σ is part of the proof of Lemma I.27; by Lemma I.21 the sum is correct modulo 2^H. The three copies of each composite cost at most $(2\cdot 11+2\cdot 4+34)H+28$ each, and the sums are as stated. □

Lemma I.139 (Laying out the bank). *Put* $\mathsf{BankInit} = \mathsf{ext}; \mathsf{lay}$, *where*

$$\mathsf{ext} = \mathsf{zero}_6; \mathsf{acc}^{14}_{9\to 6}; \mathsf{acc}^{14}_{9\to 6}; \mathsf{acc}^{14}_{9\to 6}; \mathsf{reset}_{14},$$
$$\mathsf{lay} = \mathsf{dup}_{0\to 2}; \mathsf{pred}_2; \mathsf{zc}^{12}; \mathsf{rep}_{14,6}(\mathsf{wr}(1); \mathsf{pred}_2; \mathsf{zc}^{11}; \mathsf{inc}_{14}); \mathsf{zc}^{12},$$

$\mathsf{wr}(b) = \mathsf{seek}_2; \mathsf{left}^{11}; \mathsf{write}\, b; \mathsf{home}_{13}$ *writes* b *into* $(a', 13)$ *when track* 2 *carries* a', *and* zc^n *is* n *copies of* $\mathsf{wr}(0); \mathsf{pred}_2$. *Let track* 0 *of* τ *carry* r, *track* 9 *carry* W, *let the output buffer hold a word* v *with capacity* r, $36W + 37 \le r$ *and* $|v| \le r - 25 - 36W$. *Then* $\mathsf{BankInit}$ *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $12\,000(r+1)^2$ *units, where the bank of width* $H = 3W$ *at* $a = r - 12$ *is laid out in* τ' *with its sign cell and all its columns* 0, *tracks* 6 *and* 14 *carry* H, *track* 2 *carries* $r - 25 - 12H$, *track* 9 *still carries* W, *the buffer still holds* v, *and only tracks* 2, 6, 14 *and the rows* $r - 25 - 12H < j' < r$ *of track* 13 *have changed.*

Proof. ext adds the counter W three times to the empty track 6, using track 14 as scratch (Lemma I.15(b), at most $500(3W+1)^2$ units each), and resets track 14: at most $2000(r+1)^2$ units. In lay, the copy of the headers puts the counter r on track 2 ($46r + 20$ units), and one decrement makes it $r - 1$, the row of the cell $x = -11$ of the bank view. The program $\mathsf{wr}(b)$ takes $36a' + 35$ units and pred_2 at most $100(r+1) + 1$, so zc^{12} clears the cells $x = -11, \dots, 0$ within $2400(r+1) + 1$ units. A pass of the repetition, with track 14 carrying $q < H$ and track 2 carrying the row of the cell $x = 1 + 12q$, writes the presence mark of the bank row q, clears its eleven columns and advances track 14, within $3000(r+1)$ units; by Lemma I.126(c) with the guard track 6 carrying H, the H passes take at most $(H+1) \cdot 3200(r+1)$ units. The last zc^{12} clears the end row. Since $H \le r$, lay takes at most $10\,000(r+1)^2$ units. The written cells of track 13 are those of the rows $r - 1$ down to $r - 24 - 12H$, all above the buffer. □

I.11.5 Reading the indices and the operands

The stage receives no numbers from outside: it reads l and j off the buffer, every coefficient off the saved request and every entry of the table off the buffer. This subsection gives the readers.

Dividing in unary. The order and the coordinate come from a division of the number of words in the buffer by d. The divider below reads its dividend on track 4, which in this stage belongs to the saved request; it is therefore run with tracks 4 and 7 exchanged, by a transformation of the program like the dilation of Lemma I.8.

Lemma I.140 (Exchanging two tracks). *Let* $\tau^{\times}$ *be* τ *with tracks* 4 *and* 7 *exchanged:* $\tau^{\times}(j,4) = \tau(j,7)$, $\tau^{\times}(j,7) = \tau(j,4)$, *and* $\tau^{\times} = \tau$ *elsewhere. Let* P *be a program in which both parts of every branch end on the same track and every loop body ends on the track on which it starts, so that the track of the head before each primitive is determined by the program text when* P *starts at the root. Let* $P^{\times}$ *replace each move of* P *by the moves that the exchange requires: a move from track* k *to track* $k \pm 1$ *becomes the move, of at most four cells, between the images of the two cells. If* P *runs from* $(-1, \tau^{\times})$ *to* $(-1, \sigma)$ *in* t *units, then* $P^{\times}$ *runs from* $(-1, \tau)$ *to* $(-1, \sigma^{\times})$ *within* $5t$ *units.*

Proof. The exchange maps the cell of (j,k) to that of (j,k'), where k' is k with 4 and 7 swapped; it fixes the root and every cell off tracks 4 and 7, and it is its own inverse. Induction on the execution of P: a test or a write at the image cell sees or changes the image of the cell that P

sees or changes, so the same branch is taken, and a move of P becomes at most four moves and a skip, at most 5 units. The static track is what makes the replacement of a move a fixed piece of program text. □

Lemma I.141 (Unary division)**.** *Let*

$$\mathsf{udiv} = [\mathsf{val}_2,\ \mathsf{loop}(D),\ \mathsf{home}_4],$$
$$D = [\mathsf{home}_4, \mathsf{inc}_2, \mathsf{inc}_5, \mathsf{pres}_5, \mathsf{branch}(\mathsf{home}_6; \mathsf{reset}_5; \mathsf{mark}_8,\ \mathsf{home}_6), \mathsf{val}_2].$$

Let track 4 *hold the value* u*, track* 6 *the value* $b \geq 1$*, tracks* 2, 5 *and* 8 *carry* 0*, track* 9 *hold the value* 0*, and let* τ *have origin marks up to* R *with* $u + 1 \leq R$ *and* $b \leq R$*. Then* udiv *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $1000(u + b + 1)^2$ *units; in* τ' *track* 8 *carries* $\lfloor u/b \rfloor$*, track* 9 *holds the value* $\lfloor u/b \rfloor$*, track* 5 *carries* $u \bmod b$ *and track* 2 *carries* u*, and only tracks* 2, 5, 8 *and* 9 *have changed. The program* $\mathsf{udiv}^{\times}$ *does the same with the dividend on track* 7 *instead of* 4*, within* $5000(u + b + 1)^2$ *units.*

Proof. Let $I_{j'}$ be the configuration at $(j', 4)$ in which tracks 2, 5 and 8 carry j', ρ and q with $j' = qb + \rho$ and $\rho < b$, and track 9 holds the value q. val_2 reaches I_0. A pass from $I_{j'}$, $j' < u$, reads the mark $(j', 4) = 1$, returns, advances tracks 2 and 5 and reads $(\rho + 1, 6)$. If $\rho + 1 < b$ this is 1 and the pass returns; if $\rho + 1 = b$ it is the hole of track 6, and the pass resets track 5 to 0 and appends a mark to the quotient (Lemma I.14(c) and (e)). Then val_2 moves to $(j' + 1, 4)$. By Lemmas I.11 and I.14 a pass costs at most $72j' + 108\rho + 36q + 334 \leq 108(u + b) + 334$ units, and I_u scans the hole of track 4. Lemma I.6 and the two moves to and from the root give at most $u(108(u + b) + 335) + 18u + 40 \leq 1000(u + b + 1)^2$ units. The second claim is Lemma I.140: every loop body and branch of udiv ends on the track it starts from. □

The order and the coordinate. The buffer holding the prefix (l, j) has $\ell = ((l+1)d+j)(W+2)$ bits, so the number of its words is $w = (l + 1)d + j$, with $j < d$, and $l + 1 = \lfloor w/d \rfloor$, $j = w \bmod d$. The dimension d is the first frame of the saved request.

Lemma I.142 (Recovering l and j)**.** *Let*

$$\mathsf{Dim} = \mathsf{clear}_{5,8,9}; \mathsf{nat}, \qquad \mathsf{skipW} = \mathsf{zero}_6; \mathsf{rep}_{6,9}(\mathsf{inc}_2; \mathsf{inc}_6); \mathsf{inc}_2; \mathsf{inc}_6; \mathsf{inc}_2; \mathsf{inc}_6,$$
$$\mathsf{Words} = \mathsf{zero}_2; \mathsf{zero}_5; \mathsf{peek}_{2\to 11}; \mathsf{loop}(\mathsf{home}_{11}; \mathsf{skipW}; \mathsf{inc}_5; \mathsf{peek}_{2\to 11}); \mathsf{home}_{11},$$
$$\mathsf{Prep} = \mathsf{clear}_{6,7,9}; \mathsf{copy}_{8\to 6}; \mathsf{copy}_{5\to 7}; \mathsf{zero}_2; \mathsf{zero}_5; \mathsf{zero}_8,$$
$$\mathsf{Indices} = \mathsf{dup}_{9\to 2}; \mathsf{Dim}; \mathsf{dup}_{2\to 9}; \mathsf{Words}; \mathsf{Prep}; \mathsf{udiv}^{\times}.$$

Let τ *hold the saved request (Definition I.41), have origin marks up to* r*, track* 0 *carrying the counter* r *and every cell of a row beyond* r *equal to* 0*, let its buffer hold the table prefix* (l, j) *of* Z *with capacity* r*,* $l < N$*,* $j < d$*, let track* 9 *carry* W*, and let the reserve of Definition I.101 hold. Then* $\mathsf{Indices}$ *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $40\,000(r + 1)^3$ *units, where track* 8 *of* τ' *carries* $l + 1$*, track* 5 *carries* j*, track* 6 *holds the value* d*, and* τ' *differs from* τ *only on tracks* 2 *and* 5 *to* 10 *of the scratch area.*

Proof. $\mathsf{dup}_{9\to 2}$ saves W on track 2; each dup costs at most $102(r + 1)$ units (Lemma I.126(b)). Dim reads the first frame of the saved request, the binary digits of d at row 0, onto track 8

(Lemma I.128, within $11\,000(r+1)^2$ units), and $\mathsf{dup}_{2\to 9}$ puts W back on track 9. In Words, skipW advances the counter on track 2 by $W+2$: the repetition, guarded by track 9 which carries W, advances tracks 2 and 6 W times, and two more steps follow; it costs at most $500(r+1)^2$ units. The loop of Words runs while the cell of track 11 in the row given by track 2 holds 1, that is, while the counter p on track 2 is less than ℓ; since ℓ is a multiple of $W+2$, it stops with $p=\ell$ after w passes, each of which also advances track 5. So track 5 carries w, within $2000(r+1)^3$ units. Prep puts the values d and w on tracks 6 and 7 and empties the registers of the divider, within $1000(r+1)^2$ units, and $\mathsf{udiv}^{\times}$ (Lemma I.141) leaves $\lfloor w/d\rfloor = l+1$ on track 8 and $w \bmod d = j$ on track 5, within $5000(w+d+1)^2 \le 20\,000(r+1)^2$ units, since $w+1\le r$ and $d\le r$ by the reserve. The total is at most $14\,000(r+1)^3+1000(r+1)^2+20\,000(r+1)^2 \le 40\,000(r+1)^3$. □

At the end of the stage the same computation yields the two flags. For tracks p, b and f let

$$\mathsf{cmp}_{p,b,f} = \mathsf{peek}_{p\to b};\mathsf{branch}(\mathsf{cf}(0),\mathsf{cf}(1)),$$
$$\mathsf{cf}(x) = \mathsf{home}_b;\mathsf{sent};\mathsf{shift}_{13\to f};\mathsf{write}\,x;\mathsf{home}_f.$$

If track p carries v and track b carries $\beta \ge v$, the cell (v,b) holds $[v<\beta]$, so $\mathsf{cmp}_{p,b,f}$ writes $[v<\beta]$ into the sentinel cell (r,f), within $200(r+1)$ units, and writes nothing else.

Lemma I.143 (The flags)**.** *Let*

$$\mathsf{Flags} = \mathsf{dup}_{8\to 14};\mathsf{Indices};\mathsf{dup}_{14\to 9};\mathsf{inc}_5;\mathsf{cmp}_{5,6,7};\mathsf{pred}_5;\mathsf{cmp}_{8,9,6}.$$

Under the hypotheses of Lemma I.142, if moreover track 8 *carries N, then* Flags *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *within* $42\,000(r+1)^3$ *units, where* $\tau'(r,7)=[j+1<d]$, $\tau'(r,6)=[l+1<N]$, *tracks* 8, 5, 6 *and* 9 *carry* $l+1$, *j, d and N, and only tracks* 2, 5 *to* 10 *and* 14 *have changed.*

Proof. The order N is kept on track 14 while $\mathsf{Indices}$ runs and then moved to track 9. Then inc_5 makes track 5 carry $j+1\le d$, and $\mathsf{cmp}_{5,6,7}$ writes $[j+1<d]$; pred_5 returns to j, and $\mathsf{cmp}_{8,9,6}$ compares $l+1\le N$ with N. The four last parts take at most $1000(r+1)$ units, the copies $204(r+1)$, and Lemma I.142 the rest. □

Where a coefficient is. By Definition 15.32 the saved request holds, after the frame of d: for each coordinate a *linear row*, the number of its A-terms followed by their indices; for each coordinate a *bilinear row*, the number of its B-terms followed by their index pairs; the payload length; and the payload, the numerator and the denominator of every coordinate of y_0, every c_i, every A-coefficient (coordinate by coordinate, term by term) and every B-coefficient, each a framed integer. So the rational with *ordinal* o in the payload is

$$o = \begin{cases} d+j & \text{for } c_j,\\ 2d+L_A(j)+q & \text{for the term } q \text{ of } A_j,\\ 2d+L_A+L_B(j)+q & \text{for the term } q \text{ of } B_j, \end{cases} \tag{I.1}$$

where $L_A(j)$ and $L_B(j)$ count the terms of A and of B of the coordinates before j and $L_A = L_A(d)$; its numerator and denominator are the frames number $2o$ and $2o+1$ of the payload.

Lemma I.144 (Addresses in the saved request)**.** *There are fixed programs* $\mathsf{coefA}(\kappa, e)$*, for the three kinds* κ *of coefficient (c, A, B) and* $e \in \{0, 1\}$*, and* $\mathsf{idxA}(\kappa, e)$ *for* $\kappa \in \{A, B\}$*, with the following property. Let* τ *hold the saved request, have origin marks up to r, track* 0 *carrying r, every cell of a row beyond r equal to* 0*, and the reserve; let track* 5 *carry* $j < d$ *and track* 14 *carry q, less than the number of terms of the kind* κ *of coordinate j (no condition on q for* $\kappa = c$*).*

(a) $\mathsf{coefA}(\kappa, e)$ *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $150\,000(r+1)^4$ *units, where track* 5 *of* τ' *carries a row* s' *which is the row of the frame of the numerator (*$e = 0$*) or the denominator (*$e = 1$*) of the selected coefficient, with* $s' + (\text{its length}) \le r$*.*

(b) $\mathsf{idxA}(\kappa, e)$ *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *within* $80\,000(r+1)^4$ *units, where track* 8 *of* τ' *carries the index of the term q: the index u of* (a, u) *for* $\kappa = A$*, and u (*$e = 0$*) or v (*$e = 1$*) of* (b, u, v) *for* $\kappa = B$*.*

(c) For $\kappa \in \{A, B\}$ *the program* $\mathsf{rowA}(\kappa)$ *below runs within* $60\,000(r+1)^4$ *units and leaves on track* 8 *the number of terms of the kind* κ *of coordinate j.*

In each case only tracks 2 *and* 5 *to* 12 *change, the saved request and every cell* $x \ge -1$ *and every cell below row* $r+1$ *are kept, and track* 14 *still carries q.*

Proof. All programs are built from nat, skipf, counter copies and additions and the following countdown. For a track p let

$$\mathsf{cp1}_p = \mathsf{peek}_{p\to 1}; \mathsf{branch}(\mathsf{shift}_{1\to 10}; \mathsf{write}\,0,\ \mathsf{shift}_{1\to 10}; \mathsf{write}\,1),$$
$$\mathsf{down}_p(P) = \mathsf{cp1}_p; \mathsf{loop}(\mathsf{home}_{10}; P; \mathsf{pred}_p; \mathsf{cp1}_p); \mathsf{home}_{10}.$$

With track p carrying n, $\mathsf{cp1}_p$ writes into $(n, 10)$ the origin mark $(n, 1) = [n \ge 1]$ and stops there, and $\mathsf{down}_p(P)$ runs P exactly n times, counting track p down to 0, within $(n+1)(b+400(r+1))$ units if each run of P; pred_p takes at most b (Lemma I.6 with the invariant that track p carries $n - i$ after i passes).

Write $\mathsf{natC} = \mathsf{clear}_{8,9}; \mathsf{nat}$; it reads the natural number at the row on track 5 onto track 8 and moves track 5 past its frame (Lemma I.128, $11\,000(r+1)^2$ units). Put

$$\mathsf{terms}_p(\alpha, x) = \mathsf{down}_p(\mathsf{skipf}^{\alpha}; [\mathsf{inc}_{11} \text{ if } x = 1]), \qquad \mathsf{srow}(\alpha, x) = \mathsf{natC}; \mathsf{terms}_8(\alpha, x),$$

where skipf^{α} is α copies of skipf: $\mathsf{terms}_p(\alpha, x)$ skips as many terms of arity α as track p counts, adding one to track 11 per term if $x = 1$, within $2000(r+1)^3$ units, and $\mathsf{srow}(\alpha, x)$ skips one whole row of the shape whose terms have α indices, within $13\,000(r+1)^3$ units (Lemma I.46 for each frame; at most r frames are skipped in all). Next,

$$\mathsf{rowA}(A) = \mathsf{pos}; \mathsf{down}_2(\mathsf{srow}(1, 1)); \mathsf{natC}, \qquad \mathsf{pos} = \mathsf{dup}_{5\to 2}; \mathsf{zero}_{11}; \mathsf{Dim}; \mathsf{dup}_{8\to 12},$$
$$\mathsf{rowA}(B) = \mathsf{pos}; \mathsf{down}_{12}(\mathsf{srow}(1, 1)); \mathsf{down}_2(\mathsf{srow}(2, 1)); \mathsf{natC}.$$

pos puts j on track 2, 0 on track 11, d on track 12 and moves track 5 past the frame of d. $\mathsf{rowA}(A)$ skips the linear rows of the coordinates before j, counting their terms on track 11, and reads the term count of the linear row of j; $\mathsf{rowA}(B)$ first skips all d linear rows, counting their terms, and then the bilinear rows before j. So track 11 carries $L_A(j)$, respectively $L_A + L_B(j)$,

track 8 the number of terms of row j, and track 5 the row of the first index frame of that row. The bounds of (c) follow from the parts: at most $12\,000(r+1)^2$ for pos and, for each countdown, at most $(r+1)(14\,000(r+1)^3 + 400(r+1)) \le 15\,000(r+1)^4$.

For the term q put $\mathsf{tail}(\alpha) = \mathsf{dup}_{14\to12};\mathsf{terms}_{12}(\alpha,1)$, which skips the first q terms of the row and adds q to track 11 (within $2200(r+1)^3$ units), and $\mathsf{termA}(\kappa) = \mathsf{rowA}(\kappa);\mathsf{tail}(\alpha_\kappa)$ with $\alpha_A = 1$, $\alpha_B = 2$ (within $65\,000(r+1)^4$). Then $\mathsf{idxA}(\kappa,e) = \mathsf{termA}(\kappa);[\mathsf{skipf}\text{ if }\kappa = B, e = 1];\mathsf{natC}$ reads the first or second index of the term onto track 8, within $65\,000(r+1)^4 + 1000(r+1)^2 + 11\,000(r+1)^2 \le 80\,000(r+1)^4$ units, which is (b).

For (a), the ordinal (I.1) is formed on track 11: for $\kappa = c$ by $\mathsf{dup}_{5\to11}$ and one addition of d, and for $\kappa = A, B$ by $\mathsf{termA}(\kappa)$ and two additions of d; the additions are Dim followed by one or two copies of $\mathsf{acc}^{12}_{8\to11}$, within $13\,000(r+1)^2$ units. Call this part $\mathsf{ordA}(\kappa)$; it takes at most $80\,000(r+1)^4$ units. Then

$$\mathsf{payA}(e) = \mathsf{pos}';\mathsf{down}_{12}(\mathsf{srow}(1,0));\mathsf{dup}_{2\to12};\mathsf{down}_{12}(\mathsf{srow}(2,0));\mathsf{skipf};\\ \mathsf{zero}_2;\mathsf{acc}^{12}_{11\to2};\mathsf{acc}^{12}_{11\to2};\mathsf{down}_2(\mathsf{skipf});[\mathsf{skipf}\text{ if }e=1],$$

with $\mathsf{pos}' = \mathsf{Dim};\mathsf{dup}_{8\to2};\mathsf{dup}_{8\to12}$, skips the d linear and the d bilinear rows and the payload length, then $2o$ integer frames, and for $e = 1$ one more: track 5 then carries the row of the numerator or the denominator of the rational o. Its parts cost at most $50\,000(r+1)^4$ (the position of the payload) and $3000(r+1)^3 + 1000(r+1)^2$ (the skips), so at most $60\,000(r+1)^4$, and $\mathsf{coefA}(\kappa,e) = \mathsf{ordA}(\kappa);\mathsf{payA}(e)$ takes at most $150\,000(r+1)^4$ units. Every routine used writes only the tracks named, and the frames read lie below row r by the reserve. □

Where an entry of the table is. The entry $r_{p,u}$ is word number $pd+u$ of the buffer, so its signed word starts at row $(pd+u)(W+2)$ of track 13. Let

$$\mathsf{adv} = \mathsf{inc}_5;\mathsf{inc}_{10}, \qquad \mathsf{lw} = \mathsf{zero}_{10};\mathsf{rep}_{10,9}(\mathsf{adv});\mathsf{adv};\mathsf{adv},\\ \mathsf{lws}_g = \mathsf{zero}_8;\mathsf{rep}_{8,g}(\mathsf{lw};\mathsf{inc}_8),\\ \mathsf{Look} = \mathsf{dup}_{5\to2};\mathsf{dup}_{8\to12};\mathsf{dup}_{9\to14};\mathsf{Dim};\mathsf{dup}_{8\to6};\mathsf{dup}_{14\to9};\\ \mathsf{zero}_5;\mathsf{zero}_7;\mathsf{rep}_{7,12}(\mathsf{lws}_6;\mathsf{inc}_7);\mathsf{lws}_2.$$

Lemma I.145 (Locating an entry)**.** *Let τ be as in Lemma I.144, with track 5 carrying $u < d$, track 8 carrying $p \le r$, track 9 carrying W, and $(pd+u)(W+2) \le r$. Then* Look *runs from $(-1,\tau)$ to $(-1,\tau')$ within $20\,000(r+1)^4$ units, where track 5 of τ' carries $(pd+u)(W+2)$; it writes only tracks 2 and 5 to 14 other than 11 and 13.*

Proof. The copies keep u, p and W while Dim reads d, which is moved to track 6. lw advances track 5 by $W+2$ (as skipW above, within $1000(r+1)^2$ units); lws_g advances it by $W+2$ as many times as track g counts, within $2000(r+1)^3$ units; and the outer repetition, guarded by track 12 carrying p, advances it by $d(W+2)$ p times, within $3000(r+1)^4$ units. The last lws_2 adds $u(W+2)$. With the copies and Dim the total is at most $20\,000(r+1)^4$. □

Loading an operand. An operand enters the bank as a magnitude in column 1 and a sign in the sign cell, and is then converted to two's complement. Track 2 serves as the write pointer

into the bank: $\mathsf{bptr} = \mathsf{dup}_{0\to 2};\mathsf{pred}_2^{12}$ makes it carry $r-12=a$, the row of the sign cell, within $1500(r+1)$ units. With $\mathsf{wr}(b)$ of Lemma I.139, put

$$\begin{aligned}\mathsf{ldS} &= \mathsf{cb}_4;\mathsf{inc}_5;\mathsf{pred}_2;\mathsf{sv};\mathsf{loop}(\mathsf{home}_7;\mathsf{wr}(1);\mathsf{pred}_2;\mathsf{cb}_4;\mathsf{inc}_5;\mathsf{pred}_2^{11};\mathsf{inc}_{10};\mathsf{sv});\\ &\qquad \mathsf{home}_7,\\ \mathsf{ldT} &= \mathsf{cb}_{13};\mathsf{inc}_5;\mathsf{pred}_2;\mathsf{rep}_{10,9}(\mathsf{mg});\mathsf{mg};\mathsf{wr}(0);\mathsf{peek}_{10\to 6};\\ &\qquad \mathsf{branch}(\mathsf{home}_6;\mathsf{wr}(0),\ \mathsf{home}_6;\mathsf{wr}(1)),\\ \mathsf{mg} &= \mathsf{wr}(1);\mathsf{pred}_2;\mathsf{cb}_{13};\mathsf{inc}_5;\mathsf{pred}_2^{11};\mathsf{inc}_{10},\end{aligned}$$

where $\mathsf{cb}_k = \mathsf{peek}_{5\to k};\mathsf{branch}(\mathsf{home}_k;\mathsf{wr}(0),\ \mathsf{home}_k;\mathsf{wr}(1))$ copies the cell of track k in the row given by track 5 into the cell of track 13 in the row given by track 2, and $\mathsf{sv} = \mathsf{seek}_5;\mathsf{right}^2;\mathsf{probe}'$, where probe' is the test probe of Lemma I.45 with its flag written into track 7 instead of 10 (left^4 and right^8 in place of left^7 and right^5). Finally let $\mathsf{sgn} = \mathsf{bcall}([\mathsf{right},\mathsf{bcp}_{9\to 5},\mathsf{left},\mathsf{neg}',\mathsf{back},\mathsf{bcp}_{5\to 9},\mathsf{bcp}_{8\to 1},\mathsf{left}])$, where neg' branches on the sign cell and either copies column 1 into column 8 or writes into column 8 the complement of column 1 plus one (through column 9 and the ripple adder).

Lemma I.146 (Loading operands)**.** *Let τ be in the working state with indices (q,p), and let*

$$\mathsf{loadS} = \mathsf{frame}_{\varnothing}([\mathsf{bank}(\mathsf{bz}_1),\mathsf{bptr},\mathsf{zero}_{10},\mathsf{ldS},\mathsf{sgn}]),$$
$$\mathsf{loadT} = \mathsf{frame}_{\varnothing}([\mathsf{bank}(\mathsf{bz}_1),\mathsf{bptr},\mathsf{zero}_{10},\mathsf{ldT},\mathsf{sgn}]).$$

Put $Y = 17(r+1)$.

(a) If track 5 carries the row s' of the frame of an integer z (its sign bit followed by the binary digits of $|z|$, at most H of them), with $s'+(\text{its length})\le r$, then loadS runs from $(-1,\tau)$ to $(-1,\tau')$ within $3\,100\,000\,Y^2$ units, and column 1 of the bank of τ' reads z.

(b) If track 5 carries the first row of the signed word $\mathrm{sw}_W(z)$ of an entry z of the buffer, then loadT does the same within $3\,100\,000\,Y^2$ units.

In both cases τ' is in the working state with indices (q,p), columns 3, 7, 9 and 11 of the bank are unchanged, and τ' differs from τ only on track 13, inside the support of the bank.

Proof. Inside the frame, $\mathsf{bank}(\mathsf{bz}_1)$ clears column 1 (at most $2000(r+1)$ units, Lemmas I.137 and I.138). (a) cb_4 copies the sign bit, the first bit of the frame, into the sign cell $(a,13)$, and the loop of ldS copies the following bits of the frame, one per bank row, into column 1: a pass rewrites the presence mark of the bank row, copies the bit into column 1 of that row ($x=2+12i$), advances the read pointer, moves the write pointer down twelve rows and counts on track 10; sv sets the flag $(s'',7)$ to 1 exactly while the frame continues. A pass costs at most $4500(r+1)$ units, and the frame has at most r bits, so ldS takes at most $50\,000(r+1)^2$ units. The rest of column 1 is 0, so column 1 holds $|z|$, and the sign cell holds $[z<0]$. (b) ldT copies the sign cell of the word and its $W+1$ magnitude bits in the same way (the repetition guarded by track 9 copies W bits and mg one more), writes a presence 0 after them, and then restores that presence mark from the comparison $[W+1<H]=1$ of track 10 with track 6; within $51\,000(r+1)^2$ units. In both cases sgn (within $25\,000(r+1)$ units, since neg' takes at most $210H+112$ virtual units) leaves in column 1 the H-bit word $|z|$ or $2^H-|z|$ according

to the sign, which reads z; it saves and restores column 9, which neg' uses. So the body of the frame takes at most $85\,000(r+1)^2$ units, and by Lemma I.132 with the archive of length $16(r+1)$ the frame adds at most $3 \cdot 10^6(17(r+1))^2$: in all at most $3\,100\,000\,Y^2$. The frame restores every register, and the bank lies on track 13, which no frame restores. □

The operand programs of the arithmetic combine an address with a load:

$$\begin{aligned}
\mathsf{coef}(\kappa,e) &= \mathsf{frame}_{\{5\}}(\mathsf{dup}_{10\to5};\mathsf{coefA}(\kappa,e));\mathsf{loadS},\\
\mathsf{idx}(\kappa,e) &= \mathsf{frame}_{\{5\}}(\mathsf{dup}_{10\to5};\mathsf{idxA}(\kappa,e);\mathsf{dup}_{8\to5}),\\
\mathsf{at} &= \mathsf{frame}_{\{5\}}(\mathsf{Look}), \qquad \mathsf{atL} = \mathsf{frame}_{\{5\}}(\mathsf{dup}_{7\to8};\mathsf{Look}),\\
\mathsf{atC} &= \mathsf{frame}_{\{5\}}([\mathsf{dup}_{5\to10},\mathsf{dup}_{8\to2},\mathsf{dup}_{7\to8},\mathsf{zero}_5,\\
&\qquad \mathsf{rep}_{5,2}(\mathsf{pred}_8;\mathsf{inc}_5),\mathsf{dup}_{10\to5},\mathsf{Look}]).
\end{aligned}$$

Lemma I.147 (Operands of the arithmetic)**.** *Let τ be in the working state with indices (q,p) and $Y = 17(r+1)$.*

(a) $\mathsf{coef}(\kappa,e)$ *runs within $6\,300\,000\,Y^4$ units to a tape in the same working state in which column 1 reads the numerator ($e=0$) or the denominator ($e=1$) of the coefficient of kind κ of coordinate j (the term q for $\kappa \neq c$), with columns 3, 7, 9 and 11 unchanged.*

(b) $\mathsf{idx}(\kappa,e)$, at, atL *and* atC *run within $3\,100\,000\,Y^4$ units each and change only the counter on track 5:* $\mathsf{idx}(\kappa,e)$ *makes it the index of Lemma I.144(b); if track 5 carries an index $u<d$, then* at, atL *and* atC *make it the first row of the word of $r_{p,u}$, $r_{l,u}$ and $r_{l-p,u}$ respectively ($p \le l$ for* atC*).*

Proof. Each frame restores every register but track 5 and runs its body on the archived tape, which holds the saved request, carries the counter r on track 0, has origin marks up to r and holds 0 in every row beyond r, so that the lemmas of this subsection apply to it. (a) The body $\mathsf{dup}_{10\to5};\mathsf{coefA}(\kappa,e)$ takes at most $102(r+1)+150\,000(r+1)^4$ units (Lemma I.144(a)), so the address costs at most $3\,200\,000\,Y^4$ with the frame, and Lemma I.146(a) adds $3\,100\,000\,Y^2$. Every coefficient of the field has width s (Section H.1), so its numerator and denominator have at most $s+1$ binary digits, and $s+1 \le \mathscr{B}(N) < W \le H$ by (H.1). (b) The bodies take at most $81\,000(r+1)^4$ (index) and $21\,000(r+1)^4$ or $22\,000(r+1)^4$ units (lookups; Lemmas I.144(b) and I.145); the repetition of atC decrements the copy of l on track 8 p times, within $1000(r+1)^2$ units. With the frame each is at most $3\,100\,000\,Y^4$. The words lie in the buffer since $p \le l$ and $u<d$. □

Loops over the terms. Two guards drive the loops of the arithmetic; both write the flag into the sentinel cell $(r,13)$, which is free while the stage runs, and stop there:

$$\begin{aligned}
\mathsf{tg}(\kappa) &= \mathsf{frame}_{\varnothing}([\mathsf{dup}_{10\to5},\mathsf{rowA}(\kappa),\mathsf{cmp}_{14,8,13}]);\mathsf{sent},\\
\mathsf{cg} &= \mathsf{frame}_{\varnothing}([\mathsf{dup}_{7\to5},\mathsf{inc}_5,\mathsf{cmp}_{8,5,13}]);\mathsf{sent}.
\end{aligned}$$

For a program Q put

$$\begin{aligned}
\mathsf{terms}(\kappa,Q) &= [\mathsf{zero}_{14},\mathsf{tg}(\kappa),\mathsf{loop}([\mathsf{home}_{13},Q,\mathsf{inc}_{14},\mathsf{tg}(\kappa)]),\mathsf{home}_{13}],\\
\mathsf{pairs}(Q) &= [\mathsf{zero}_8,\mathsf{cg},\mathsf{loop}([\mathsf{home}_{13},Q,\mathsf{inc}_8,\mathsf{cg}]),\mathsf{home}_{13}].
\end{aligned}$$

Lemma I.148 (Term loops). *Let $Y = 17(r+1)$ and $\kappa \in \{A, B\}$, and let n_κ be the number of terms of the kind κ of coordinate j.*

(a) $\mathsf{tg}(\kappa)$*, from the working state with indices (q, p), $q \le n_\kappa$, ends at* $\mathrm{cell}(r, 13)$ *within $4\,000\,000\,Y^4$ units, with $(r, 13)$ set to $[q < n_\kappa]$ and nothing else changed;* cg*, with $p \le l + 1$, does the same within $4\,000\,000\,Y^2$ units with the flag $[p < l + 1]$.*

(b) Let $\mathrm{I}_0, \dots, \mathrm{I}_{n_\kappa}$ be properties of tapes that do not depend on track 14 or on the cell $(r, 13)$. Suppose that for every $q < n_\kappa$, Q runs from every tape in the working state with term index q that has I_q, within b units, to a tape in the working state with the same term index q that has I_{q+1}. Then $\mathsf{terms}(\kappa, Q)$ *runs from every tape in the working state that has I_0 to a tape in the working state with term index n_κ that has I_{n_κ}, within $(n_\kappa + 1)(b + 5\,000\,000\,Y^4)$ units. The same holds for* $\mathsf{pairs}(Q)$ *with the Cauchy index on track 8 in place of the term index, $l + 1$ in place of n_κ, and the bound $(l + 2)(b + 5\,000\,000\,Y^2)$.*

Proof. (a) Inside the frame, $\mathsf{rowA}(\kappa)$ puts n_κ on track 8 (Lemma I.144(c), with j copied to track 5), and $\mathsf{cmp}_{14,8,13}$ compares the term index with it; for cg, track 5 receives $l + 1$ and the Cauchy index is compared with it. The bodies take at most $61\,000(r + 1)^4$ and $1000(r + 1)$ units, the frame at most $3 \cdot 10^6 Y^2$ more, and sent $18r + 17$. The frame restores the registers; the flag is on track 13, which it does not restore, and it lies outside the buffer and the bank. (b) Lemma I.6 with the invariant that the head is at $\mathrm{cell}(r, 13)$, the tape is in the working state with term index q, has I_q, and $(r, 13) = [q < n_\kappa]$: a pass returns to the root $(18r + 17)$, runs Q, increments the term index $(36q + 72)$ and runs the guard, within $b + 5 \cdot 10^6 Y^4$ units with its test; the first guard, the reset of track 14 and the final return add at most another $5 \cdot 10^6 Y^4$. For pairs the guard is the smaller one. □

I.11.6 The five phases of one entry

Throughout this subsection r, $l < N$, $j < d$, Z with $\|Z/s\| \le M$ and the tape τ_0 are as in Theorem I.119, $H = 3W$, $a = r - 12$, and $Y = 17(r + 1)$, the length of the archive plus $r + 1$. We write $\mathsf{rpt}(P) = [\mathsf{zero}_2, \mathsf{arch}_{2\leftarrow 8}, \mathsf{zero}_5, \mathsf{rep}_{5,2}(P; \mathsf{inc}_5)]$; it reads N from the snapshot onto track 2 and runs P exactly N times.

Lemma I.149 (Doubling N times). *Let τ be in the working state and let column $c \notin \{0, 2, 4\}$ of the bank read z. Then* $\mathsf{rpt}(\mathsf{bank}(\mathsf{bdbl}_c))$ *runs within $22\,000(r + 1)^2$ units to a tape in the same working state in which column c reads $2^N z$; only columns 2, 4, 6, 8 and c of the bank and tracks 2 and 5 change.*

Proof. $\mathsf{arch}_{2\leftarrow 8}$ copies N from the snapshot, where track 8 carries $N < r$ (Definition I.101), within $10^4(r+1)^2$ units (Lemma I.133). A pass of the repetition doubles column c (Lemmas I.137 and I.138(d), at most $17(400H+161)+36r+334$ units) and advances track 5: at most $10\,000(r+1)$ units. By Lemma I.126(c) the N passes take at most $(N + 1) \cdot 10\,200(r + 1)$, and with the two zeroings the total is at most $22\,000(r + 1)^2$, since $N \le r$. □

Lemma I.150 (The start)**.** *The list*

$$\mathsf{Start} = [\mathsf{home}_{11}, \mathsf{Archive}, \mathsf{Indices}, \mathsf{dup}_{5\to10}, \mathsf{dup}_{8\to7}, \mathsf{pred}_7, \mathsf{Width}, \mathsf{BankInit}, \mathsf{zero}_{14}]$$

of the first nine parts of Append *runs from* $(\mathrm{cell}(r, 11), \tau_0)$ *within* $2 \cdot 10^6(r+1)^3$ *units to a tape in the working state with indices* $(0, l+1)$ *in which every column of the bank reads* 0 *and every cell below row* $r+1$ *holds* 0*.*

Proof. home_{11} takes $18r + 15$ units. Archive with the empty list takes at most $10^6(r+1)^2$ (Lemma I.130); Indices at most $40\,000(r+1)^3$ and leaves $l+1$ on track 8 and j on track 5 (Lemma I.142); the two copies and the decrement put j on track 10 and l on track 7, within $300(r+1)$; Width restores W on track 9 within $11\,000(r+1)^2$; BankInit lays out the bank within $12\,000(r+1)^2$ (Lemma I.139, whose hypotheses hold by Lemma I.136); and zero_{14} sets the term index to 0. The sum is at most $2 \cdot 10^6(r+1)^3$. None of these parts writes track 0, 1, 3, 4 or 15, a cell below row $r+1$, or the buffer. □

Lemma I.151 (The common denominator)**.** *Let*

$$\begin{aligned} \mathsf{mulD} &= \mathsf{bank}([\mathsf{bcp}_{7\to3}, \mathsf{bmul}, \mathsf{bcp}_{4\to7}]), \\ \mathsf{Den} &= [\mathsf{bank}(\mathsf{bone}_7),\ \mathsf{coef}(c, 1),\ \mathsf{mulD},\ \mathsf{terms}(A, \mathsf{coef}(A, 1); \mathsf{mulD}), \\ &\qquad \mathsf{terms}(B, \mathsf{coef}(B, 1); \mathsf{mulD})]. \end{aligned}$$

From a tape in the working state, Den *runs within* $K_D Y^{24}$ *units,* $K_D = 28\,935\,892$*, to a tape in the working state with the same Cauchy index in which column* 7 *holds the binary digits of the product* D_j *of the denominators of* c_j*, of the A-coefficients and of the B-coefficients of coordinate* j*, and columns* 9 *and* 11 *are unchanged.*

Proof. $\mathsf{bank}(\mathsf{bone}_7)$ sets column 7 to 1 within $17(45H+45)+36r+334 \le 2000(r+1)$ units. The body of mulD takes $(54H+28)+441(H+1)^3+(56H+28)+1 \le 641(H+1)^4$ units and replaces what column 7 reads by its product with column 1; with Lemma I.137 and $H \le r$, mulD takes at most $17 \cdot 641(H+1)^4 + 36r + 334 \le 11\,297(r+1)^5$ units. So one factor, $\mathsf{coef}(\kappa, 1); \mathsf{mulD}$, takes at most $6\,300\,000\,Y^4 + 11\,297(r+1)^5 \le 6\,311\,297\,Y^9$ (Lemma I.147(a)). Each loop over terms runs at most r times, so by Lemma I.148(b) with the invariant "column 7 reads the product of the first q denominators, after the earlier ones" it takes at most $(r+1)(6\,311\,297\,Y^9 + 5 \cdot 10^6 Y^4) \le 11\,311\,297\,Y^{14}$ units. The total is at most $2000(r+1)+6\,311\,297\,Y^9+2 \cdot 11\,311\,297\,Y^{14}+1 \le K_D Y^{24}$. Every denominator is positive, and $D_j < 2^s \le 2^H$ (the proof of Proposition I.32), so the word that reads D_j modulo 2^H is its binary expansion. □

Lemma I.152 (The weight of a coefficient)**.** *Let*

$$\begin{aligned} \mathsf{fac} &= \mathsf{bcall}([\mathsf{right}, \overline{\mathsf{cp}}_{1\to4}, \mathsf{back}, \mathsf{bcp}_{7\to1}, \mathsf{sdiv}, \mathsf{back}, \mathsf{bcp}_{8\to3}, \mathsf{left}]), \\ \mathsf{wgt}(\kappa) &= [\mathsf{coef}(\kappa, 1),\ \mathsf{fac},\ \mathsf{coef}(\kappa, 0),\ \mathsf{bank}(\mathsf{bmul}; \mathsf{bcp}_{4\to9})], \end{aligned}$$

where $\overline{\mathsf{cp}}_{1\to4}$ *is* $\mathsf{cp}_{1\to4}$ *with the two parts of its branch exchanged, so that it writes the complement of column* 1 *into column* 4 *in the same number of units. Let* τ *be in the working state with column* 7 *holding the binary digits of* D_j*. Then* $\mathsf{wgt}(\kappa)$ *runs within* $12\,631\,163\,Y^{14}$ *units to a tape in the same working state in which column* 9 *reads* $D_j q$*, where* q *is the selected coefficient of kind* κ*, and columns* 7 *and* 11 *are unchanged.*

Proof. After $\mathsf{coef}(\kappa, 1)$, column 1 holds the denominator e of q, a positive integer below $2^s \le 2^{H-1}$, and the sign cell holds 0. In fac, column 4 receives $\bar{e}$ and column 1 the binary digits of D_j, and sdiv (Lemma I.30) leaves $\lfloor D_j/e \rfloor = D_j/e$ in column 8, which is copied to column 3; e divides D_j. The virtual count is $1 + (30H + 1) + (14H + 27) + (50H + 28) + 945(H+1)^3 + (14H+27) + (56H+28) + 2 \le 1245(H+1)^4$, so fac takes at most $21\,565(r+1)^5$ units. Then column 1 receives the numerator of q, and the last part, whose body takes $1+441(H+1)^3+(60H+28)+1 \le 541(H+1)^4$ units, puts the product $(D_j/e)\cdot(\text{numerator}) = D_j q$ into column 9 within $9597(r+1)^5$ units. With the two reads ($6\,300\,000\,Y^4$ each) the total is at most $(12\,600\,001 + 21\,565 + 9597)Y^{14} = 12\,631\,163\,Y^{14}$. □

Lemma I.153 (The numerator)**.** *Let*

$$\begin{aligned}
\mathsf{cst} &= [\mathsf{wgt}(c), \mathsf{bank}(\mathsf{bcp}_{9\to 11}), \mathsf{rpt}(\mathsf{bank}(\mathsf{bdbl}_{11})), \mathsf{rpt}(\mathsf{bank}(\mathsf{bdbl}_{11}))],\\
\mathsf{cbr} &= \mathsf{left}^8; \mathsf{branch}(\mathsf{home}_7; \mathsf{cst},\ \mathsf{home}_7),\\
\mathsf{lin} &= [\mathsf{wgt}(A), \mathsf{idx}(A,0), \mathsf{atL}, \mathsf{loadT}, \mathsf{bank}([\mathsf{bcp}_{9\to 3}, \mathsf{bmul}, \mathsf{bcp}_{4\to 9}]),\\
&\qquad \mathsf{rpt}(\mathsf{bank}(\mathsf{bdbl}_9)), \mathsf{bank}([\mathsf{bcp}_{9\to 4}, \mathsf{bacc}])],\\
\mathsf{pr} &= [\mathsf{idx}(B,0), \mathsf{at}, \mathsf{loadT}, \mathsf{bank}([\mathsf{bcp}_{9\to 3}, \mathsf{bmul}, \mathsf{bcp}_{4\to 3}]),\\
&\qquad \mathsf{idx}(B,1), \mathsf{atC}, \mathsf{loadT}, \mathsf{bank}([\mathsf{bmul}, \mathsf{bacc}])],\\
\mathsf{bil} &= \mathsf{wgt}(B); \mathsf{pairs}(\mathsf{pr}),\\
\mathsf{Num} &= [\mathsf{bank}(\mathsf{bz}_{11}), \mathsf{cbr}, \mathsf{terms}(A, \mathsf{lin}), \mathsf{terms}(B, \mathsf{bil})].
\end{aligned}$$

From a tape in the working state whose column 7 holds the binary digits of D_j, Num *runs within $K_F Y^{78}$ units, $K_F = 80\,917\,448$, to a tape in the working state in which column 7 is unchanged and column 11 reads the numerator*

$$U = [l = 0]\, D_j c_j s^2 + \sum_{(a,u)} D_j a\, r_{l,u}\, s + \sum_{(b,u,v)} \sum_{p \le l} D_j b\, r_{p,u}\, r_{l-p,v}$$

of Proposition I.32(b), the sums running over the terms of A and of B of coordinate j in their order.

Proof. The constant part. Track 7 carries l, so the cell $(0,7)$ holds $[l \ge 1]$: cbr runs cst exactly when $l = 0$. cst puts $D_j c_j$ into column 9 (Lemma I.152), copies it into column 11 (at most $3000(r+1)$ units) and doubles column 11 $2N$ times (Lemma I.149): column 11 reads $D_j c_j s^2$. It takes at most $12\,631\,163\,Y^{14} + 3000(r+1) + 44\,000(r+1)^2 + 1 \le 12\,681\,163\,Y^{16}$ units, and cbr adds 21: at most $12\,681\,184\,Y^{16}$.

A linear term (a,u), the term q of A_j: $\mathsf{wgt}(A)$ puts $D_j a$ into column 9; $\mathsf{idx}(A,0)$, atL and loadT put $r_{l,u}$ into column 1 (Lemmas I.147 and I.146, at most $9\,300\,000\,Y^4$ units together); the product block replaces column 9 by $D_j a\, r_{l,u}$, within $17((58H+28) + 441(H+1)^3 + (60H + 28) + 1) + 36r + 334 \le 11\,284(r+1)^4$ units; rpt multiplies it by $s = 2^N$ (at most $22\,000(r+1)^2$); and the last block adds it to column 11 (at most $10\,000(r+1)$). So lin takes at most $(12\,631\,163 + 11\,284 + 9\,332\,001)Y^{22} = 21\,974\,448\,Y^{22}$ units.

A bilinear term (b,u,v): $\mathsf{wgt}(B)$ puts $D_j b$ into column 9. A run of pr with Cauchy index $p \le l$ loads $r_{p,u}$, puts $D_j b\, r_{p,u}$ into column 3, loads $r_{l-p,v}$ into column 1, and adds the product $D_j b\, r_{p,u} r_{l-p,v}$ to column 11; with the two bank blocks ($11\,284(r+1)^4$ and, for $\mathsf{bmul}; \mathsf{bacc}$, $17(441(H+1)^3 + 400H + 161) + 36r + 334 \le 16\,367(r+1)^4$) it takes at most $(11\,284 + 16\,367 +$

$18\,600\,001)Y^{12} = 18\,627\,652\,Y^{12}$ units. By Lemma I.148(b) with the invariant "column 11 has received the products for $p' < p$", $\mathsf{pairs}(\mathsf{pr})$ takes at most $(l+2)(18\,627\,652\,Y^{12} + 5\cdot 10^6 Y^2)$ units, and since $l+2 \le Y$, bil takes at most $(12\,631\,163+18\,627\,652+5\cdot 10^6)Y^{29} = 36\,258\,815\,Y^{29}$.

The sum. $\mathsf{bank}(\mathsf{bz}_{11})$ clears column 11 within $3000(r+1)$ units. Each loop over terms runs at most r times, and by Lemma I.148(b) with the invariant "column 11 reads the part of U formed by the earlier terms" the two loops take at most $(21\,974\,448+5\cdot 10^6)Y^{27}$ and $(36\,258\,815+5\cdot 10^6)Y^{34}$ units. Every part adds a term of U to column 11 in the order of the formula, modulo 2^H, and keeps column 7; the total is at most $(12\,681\,184 + 21\,974\,448 + 36\,258\,815 + 10\,003\,001)Y^{78} = K_F Y^{78}$. □

Lemma I.154 (The two operands)**.** *Let*

$$\begin{aligned}\mathsf{ordf} &= [\mathsf{bank}([\mathsf{bone}_1, \mathsf{bz}_9]), \mathsf{dup}_{7\to 2}, \mathsf{inc}_2, \mathsf{zero}_5, \mathsf{rep}_{5,2}(\mathsf{bank}(\mathsf{binc}); \mathsf{inc}_5),\\ &\qquad \mathsf{bank}([\mathsf{bcp}_{7\to 3}, \mathsf{bcp}_{9\to 1}, \mathsf{bmul}, \mathsf{bcp}_{4\to 7}])],\\ \mathsf{Ops} &= [\mathsf{rpt}(\mathsf{bank}(\mathsf{bdbl}_7)),\ \mathsf{ordf},\ \mathsf{bank}([\mathsf{bdbl}_{11}, \mathsf{bcp}_{7\to 4}, \mathsf{bacc}, \mathsf{bdbl}_7])].\end{aligned}$$

If columns 7 *and* 11 *read* D *and* U*, then* Ops *runs within* $K_R(r+1)^8$ *units,* $K_R = 91\,799$*, to a tape in the same working state in which column* 11 *reads* $2U + Ds(l+1)$ *and column* 7 *reads* $2Ds(l+1)$.

Proof. rpt makes column 7 read Ds (at most $22\,000(r+1)^2$ units). In ordf, columns 1 and 9 become 1 and 0, track 2 receives $l+1$, and the repetition adds column 1 to column 9 $l+1$ times, so column 9 reads $l+1$; this costs at most $15\,000(r+1)^2$ units. The last block multiplies column 7 by column 9, within $17((54H+28)+(54H+28)+441(H+1)^3+(56H+28)+1)+36r+334 \le 14\,797(r+1)^4$ units; so ordf takes at most $29\,798(r+1)^6$, and column 7 reads $Ds(l+1)$. The final block doubles column 11, adds column 7 to it and doubles column 7, within $17((400H+161)+(56H+28)+(400H+160)+(400H+161)+1)+36r+334 \le 40\,000(r+1)$ units. The total is at most $22\,000(r+1)^2+29\,798(r+1)^6+40\,000(r+1)+1 \le (62\,001+29\,798)(r+1)^8$. □

Lemma I.155 (The quotient)**.** *Let*

$$\begin{aligned}\mathsf{Quot} = \mathsf{bcall}([&\mathsf{right}, \mathsf{bcp}_{11\to 1}, \mathsf{bsign}_1, \mathsf{left}, \mathsf{neg}', \mathsf{back}, \mathsf{bcp}_{8\to 1},\\ &\overline{\mathsf{cp}}_{7\to 4}, \mathsf{back}, \mathsf{sdiv}, \mathsf{back}, \mathsf{left}]).\end{aligned}$$

If column 11 *reads an integer* u *and column* 7 *an integer* v *with* $|u| < 2^{H-1}$ *and* $0 < v < 2^{H-1}$*, then* Quot *runs within* $K_Q(r+1)^5$ *units,* $K_Q = 798\,880$*, to a tape in the same working state in which the sign cell holds* $[\lfloor u/v \rfloor < 0]$ *and column* 8 *holds the* H *binary digits of* $|\lfloor u/v \rfloor|$.

Proof. After the copy, column 1 holds the H-bit two's complement word of u, whose last bit is $[u < 0]$ because $|u| < 2^{H-1}$; bsign_1 puts it into the sign cell. neg' then writes $|u|$ into column 8 (Lemma I.146), which is copied into column 1, and column 4 receives $\bar{v}$. Now Lemma I.30 applies with $z = u$ and $y = v \le 2^{H-1}$. The virtual count is at most $945(H+1)^3 + 500(H+1) \le 1445(H+1)^4$, the parts other than sdiv being $1 + (58H+28) + (28H+80)+1+(210H+112)+(14H+27)+(52H+28)+(42H+1)+3(14H+27)+2$. Lemma I.137 gives at most $17\cdot 1445(H+1)^4 + 36r + 300 \le 24\,965(H+r+1)^5$, and $H+r+1 \le 2(r+1)$ gives $24\,965\cdot 2^5(r+1)^5 = K_Q(r+1)^5$. □

Lemma I.156 (The finish). *Let*

$$\begin{aligned}
\mathsf{rcp} &= \mathsf{peek}_{2\to 13};\mathsf{branch}(\mathsf{home}_{13};\mathsf{put}_{11}(0),\ \mathsf{home}_{13};\mathsf{put}_{11}(1)),\\
\mathsf{rmag} &= \mathsf{rcp};\mathsf{pred}_2^{12};\mathsf{inc}_5, \qquad \mathsf{Ret} = \mathsf{rcp};\mathsf{pred}_2^{9};\mathsf{rep}_{5,9}(\mathsf{rmag});\mathsf{rmag},\\
\mathsf{patch}_k &= \mathsf{seek}_0;\mathsf{left}^k;\mathsf{branch}(\mathsf{pt}_k(0),\mathsf{pt}_k(1)),\\
\mathsf{pt}_k(b) &= \mathsf{home}_k;\mathsf{right}^3;\mathsf{scanP};\mathsf{left}^{31-2k};\mathsf{write}\,b;\mathsf{right}^{31-2k};\mathsf{rewP};\mathsf{left}^1,\\
\mathsf{FRestore} &= \mathsf{patch}_6;\mathsf{patch}_7;\mathsf{Restore},\\
\mathsf{setfl} &= \mathsf{right}^4;\mathsf{branch}(\mathsf{left}^4;\mathsf{write}\,0,\ \mathsf{left}^4;\mathsf{write}\,1);\mathsf{right}^5;\\
&\qquad \mathsf{branch}(\mathsf{left}^7;\mathsf{write}\,0;\mathsf{right}^2,\ \mathsf{left}^7;\mathsf{write}\,1;\mathsf{right}^2),\\
\mathsf{Finish} &= [\mathsf{Order},\mathsf{Width},\mathsf{Flags},\mathsf{Width},\mathsf{bptr},\mathsf{zero}_5,\mathsf{Ret},\mathsf{FRestore},\\
&\qquad \mathsf{sent},\mathsf{right}^2,\mathsf{setfl}].
\end{aligned}$$

Let τ be in the working state, with the sign cell holding $[z<0]$ and column 8 holding the binary digits of $|z|$, where $z = r_{l+1,j}$. Then Finish *runs from $(-1,\tau)$ to $(\mathrm{cell}(r,11),\tau')$ within $4\cdot 10^6(r+1)^3$ units, and τ' has the properties (a) to (d) of Theorem I.119.*

Proof. Order and Width bring N and W back to tracks 8 and 9 from the snapshot (within $11\,000(r+1)^2$ each). The buffer still holds the prefix (l,j), so Flags writes $[j+1<d]$ into $(r,7)$ and $[l+1<N]$ into $(r,6)$, within $42\,000(r+1)^3$ units (Lemma I.143), and Width restores W again: at most $80\,000(r+1)^3$ units for these four parts. bptr puts a, the row of the sign cell, on track 2, and zero_5 empties track 5. In Ret, rcp appends to the buffer the bit of track 13 in the row given by track 2 (Lemma I.124): first the sign cell, then, after nine rows up, column 8 of the bank row 0 ($x=9$), and rmag moves twelve rows up after each bit. The repetition, guarded by track 9 which carries W, and the last rmag append the $W+1$ lowest binary digits of $|z|$, least significant first; since z fits W (Proposition I.32(a)), the higher digits are 0, and the buffer now holds $\mathrm{sw}_W(T_{l,j}(Z))\,\mathrm{sw}_W(z) = \mathrm{sw}_W(T_{l,j+1}(Z))$. This takes at most $5000(r+1)^2$ units, and the buffer and the bank are disjoint by Lemma I.136.

patch_k finds the sentinel row with seek_0, reads (r,k), goes to the end of the packed list, steps back $31-2k$ cells to the value of the entry $16r+k$ of the archive, the entry of (r,k), and writes the bit read there; within $150(17(r+1)+1)$ units. So after the two patches the archive records the flags in the cells $(r,6)$ and $(r,7)$. Restore (Lemma I.131, with the archive as the whole packed list) then restores the borrowed tracks 2, 5 to 10 and 14 of every row from the archive, within $10^6(r+1)^2$ units, and clears the archive; FRestore takes at most $2\cdot 10^6(r+1)^2$ units. The resulting tape agrees with τ_0 on tracks 0 to 10, 14 and 15 of every row, except the cells $(r,6)$ and $(r,7)$, which hold the flags, and the root and the positive half are as in τ_0. Tracks 6 and 7 of τ_0 hold the binary stream $\mathrm{sw}_W(Z)$, which ends before row r; so the tape holds the stored vector Z, which is (a), and (d) holds. sent and right^2 reach $\mathrm{cell}(r,11)$ ($18r+20$ units), and setfl (31 units) copies $(r,7)$ into $(r,11)$ and $(r,6)$ into $(r,13)$ and returns to $\mathrm{cell}(r,11)$, which is (c). The buffer occupies the rows below its length, so these writes leave it holding the prefix $(l,j+1)$, which is (b). The total is at most $80\,000(r+1)^3+1500(r+1)+17+5000(r+1)^2+2\cdot 10^6(r+1)^2+18r+52\le 4\cdot 10^6(r+1)^3$. □

I.11.7 Proof of the bound for one entry

The five phases are composed by adding their bounds after raising each exponent to a common one.

Lemma I.157 (Sums of bounds). *Let $Y \geq 1$, $t_i \leq K_i Y^{e_i}$ for $i \leq k$, and $e \geq \max_i e_i$. Then $t_1 + \cdots + t_k + 1 \leq (K_1 + \cdots + K_k + 1) Y^{e}$.*

Proof. $Y^{e_i} \leq Y^{e}$ and $1 \leq Y^{e}$. □

All composite bounds of this section are of this kind, with the exponent e that Table I.4 records; for a loop over at most r terms the factor $n + 1 \leq Y$ is absorbed by raising the exponent.

Proof of Theorem I.119. Put $Y = 17(r + 1)$. By Lemma I.150, the first nine parts of Append run from $(\mathrm{cell}(r, 11), \tau_0)$ within $t_S \leq 2 \cdot 10^6 (r + 1)^3$ units to a tape in the working state whose bank columns read 0. Then, by Lemmas I.151, I.153 and I.154, the parts Den, Num and Ops run within $t_D \leq K_D Y^{24}$, $t_F \leq K_F Y^{78}$ and $t_R \leq K_R (r + 1)^8$ units to a tape in the working state whose columns 11 and 7 read

$$u = 2U + D_j s(l + 1) \quad \text{and} \quad v = 2 D_j s(l + 1).$$

By Proposition I.32(b), $|u| < 2^{3W-1} = 2^{H-1}$ and $0 < v < 2^{H-1}$, and

$$\left\lfloor \frac{u}{v} \right\rfloor = \mathrm{near}\Big(\frac{U}{D_j s(l + 1)} \Big) = r_{l+1,j}.$$

So Quot (Lemma I.155) runs within $t_Q \leq K_Q (r + 1)^5$ units to a tape in which the sign cell and column 8 hold the sign and the binary digits of $|r_{l+1,j}|$, and Finish (Lemma I.156) runs within $t_E \leq 4 \cdot 10^6 (r + 1)^3$ units to $(\mathrm{cell}(r, 11), \tau')$ with (a) to (d). The hypotheses of every lemma used along the way are kept by the working state, which each part preserves.

For (e): the list adds one unit, so $t = t_S + t_D + t_F + t_R + t_Q + t_E + 1$. Since $r + 1 \leq Y$, Lemma I.157 with $e = 24 + 78 + 8 + 5 + 3 = 118$ gives

$$t_D + t_F + t_R + t_Q + t_E + 1 \leq (K_D + K_F + K_R + K_Q + 4\,000\,001)\, Y^{118} = 114\,744\,020\, Y^{118}.$$

Finally $Y = 17(r + 1) \leq 17(X + r + 1)$ and $(r + 1)^3 \leq (X + r + 1)^{118}$, so

$$t \leq \big(2\,000\,000 + 114\,744\,020 \cdot 17^{118} \big) (X + r + 1)^{118} = K_{\mathrm{a}} (X + r + 1)^{118}.$$

The number of rows is r throughout. □

The exponent 118 is the sum $g_D + g_F + g_R + g_Q + 3$ of the exponents of the four arithmetic phases and of the finish, and each of these is itself a sum along the nested routines, as Table I.4 shows: for the denominator $24 = 9 + 14 + 1$, where $9 = 5 + 4$ is one factor (the bank multiplication, called, has exponent $5 = 3 + 1 + 1$, and reading a coefficient 4) and $14 = 9 + 5$ the loop over the terms; for the numerator $78 = 16 + 22 + 29 + 11$, the constant part, one linear term and one bilinear term, with 5 added for each loop over terms and 1 for the sum. None of these exponents depends on the problem, on i or on m, so the exponent 120 of the whole table in Theorem I.121 is a fixed number, as Theorem 15.33 requires.

I.12 The Taylor sum of a step

How does the machine add up a column of the Taylor table? Take one coordinate with $N = 2$, step $2^{-\sigma}$ with $\sigma = 1$, and table entries $z_0 = 5$, $z_1 = 3$, $z_2 = -7$. The new stored integer is $\mathrm{near}(z_0 + z_1/2 + z_2/4) = \mathrm{near}(4.75) = 5$. The machine never forms a fraction. It runs Horner's rule on the integers, $T = (5 \cdot 2 + 3) \cdot 2 - 7 = 19$, which is the sum times $2^{\sigma N} = 4$, and then divides by 4 with one rounding: it halves 19 twice, keeping the last bit it drops, $19 \mapsto 9$ (drops 1) $\mapsto 4$ (drops 1), and adds that bit, $4 + 1 = 5$. Only this one rounding is made, so the result is the nearest integer to the exact sum, as Lemma 15.35 requires.

This section constructs that computation on the tape for every coordinate of every stored vector, proves its contract and its step bound, and composes it with the coefficient stage of Section I.11 into one stored step of the trajectory. The Taylor sum has exponent 8 in its own size measure, and the stored step has exponent $g + 18 = 136$, where $g = 118$ is the exponent of one coefficient entry (Theorem I.119). Section I.12.1 proves the arithmetic; Section I.12.2 states the programs and contracts and proves the two theorems from the bound for one coordinate; the routines follow, and Section I.12.7 proves that bound.

I.12.1 One rounding of the whole sum

Lemma I.158 (The single rounding of a Taylor sum)**.** *Let $\sigma, N \in \mathbb{N}$, let $z_0, \dots, z_N$ be integers, put $E = \sigma N$, and define $T_0 = z_0$, $T_{k+1} = 2^{\sigma} T_k + z_{k+1}$, so that*

$$T = T_N = \sum_{l=0}^{N} 2^{\sigma(N-l)} z_l.$$

(a) $\mathrm{near}\big(\sum_{l \le N} 2^{-\sigma l} z_l\big) = \big\lfloor (2T + 2^E)/(2 \cdot 2^E) \big\rfloor$.

(b) The reverse doubled floor. *Put $R_N = 2z_N$ and $R_l = 2z_l + \lfloor R_{l+1}/2^{\sigma} \rfloor$ for $l < N$. Then $R_0 = \lfloor 2T/2^E \rfloor$ and $\lfloor (R_0 + 1)/2 \rfloor = \lfloor (2T + 2^E)/(2 \cdot 2^E) \rfloor$.*

(c) Rounding by shifts. *Put $q_k = \lfloor T/2^k \rfloor$. Then $q_{k+1} = \lfloor q_k/2 \rfloor$. If $E \ge 1$ and $g \in \{0, 1\}$ is $q_{E-1} \bmod 2$, then $\lfloor (2T + 2^E)/(2 \cdot 2^E) \rfloor = q_E + g$; if $E = 0$, it is T.*

(d) Sizes. *Let every z_l fit W and put $H = W + E + N + 4$. Then $|T_k| < (k+1)2^{W+1+\sigma k}$ for $k \le N$, and $|2^q T_k| < 2^{H-2}$ whenever $k \le N$ and $\sigma k + q \le E$. Moreover, with g as in (c) (and $g = 0$ if $E = 0$), $-2^{H-1} \le q_E + g < 2^{H-1}$, and $q_E + g$ fits $H - 1$.*

Proof. For integers u and $v > 0$, $\mathrm{near}(u/v) = \lfloor u/v + 1/2 \rfloor = \lfloor (2u + v)/(2v) \rfloor$, and $\lfloor \lfloor x/a \rfloor / b \rfloor = \lfloor x/(ab) \rfloor$ for integers x and $a, b > 0$.

(a) Multiplying by 2^E gives $\sum_l 2^{-\sigma l} z_l = T/2^E$.

(b) Put $T^{(l)} = \sum_{k=l}^{N} 2^{\sigma(N-k)} z_k$. We show $R_l = \lfloor 2T^{(l)}/2^{\sigma(N-l)} \rfloor$ by downward induction on l. For $l = N$ both sides are $2z_N$. For $l < N$, $T^{(l)} = 2^{\sigma(N-l)} z_l + T^{(l+1)}$, so

$$\left\lfloor \frac{2T^{(l)}}{2^{\sigma(N-l)}} \right\rfloor = 2z_l + \left\lfloor \frac{2T^{(l+1)}}{2^{\sigma(N-l-1)} 2^{\sigma}} \right\rfloor = 2z_l + \left\lfloor \frac{R_{l+1}}{2^{\sigma}} \right\rfloor = R_l.$$

With $l = 0$, $R_0 = \lfloor 2T/2^E \rfloor$, and $\lfloor (R_0 + 1)/2 \rfloor = \lfloor \lfloor (2T + 2^E)/2^E \rfloor / 2 \rfloor = \lfloor (2T + 2^E)/(2 \cdot 2^E) \rfloor$.

(c) The first claim is the rule for nested floors. If $E \geq 1$, then $q_{E-1} = 2q_E + g$ and $T = 2^{E-1}q_{E-1} + \rho$ with $0 \leq \rho < 2^{E-1}$, so $T = 2^E q_E + 2^{E-1}g + \rho$. Since $\lfloor (2T + 2^E)/(2 \cdot 2^E) \rfloor = \mathrm{near}(T/2^E)$, Corollary I.22(c) with $k = E - 1$ gives $q_E + g$. If $E = 0$, $\lfloor (2T + 1)/2 \rfloor = T$.

(d) $|T_0| = |z_0| < 2^{W+1}$, and

$$|T_{k+1}| \leq 2^{\sigma}|T_k| + |z_{k+1}| < (k+1)2^{W+1+\sigma(k+1)} + 2^{W+1} \leq (k+2)2^{W+1+\sigma(k+1)}.$$

If $\sigma k + q \leq E$, then $|2^q T_k| < (k+1)2^{W+1+E} \leq 2^N 2^{W+1+E} = 2^{H-3}$, because $k + 1 \leq N + 1 \leq 2^N$. For integers, $|\lfloor x/2^E \rfloor| \leq |x|$, so $|q_E| \leq |T| \leq 2^{H-2} - 1$ and $|q_E + g| \leq 2^{H-2}$, which gives both claims. □

The machine of this section computes the integer of (a) in the form (c): Horner's rule in a word of H bits, E halvings that record the last bit dropped, and one addition. By (d) every integer it forms fits that word (Proposition I.32(c)), and $H = W + \sigma N + N + 4$ is at most a constant depending on the problem times X^2. The reverse recurrence (b) gives the same integer; the machine does not use it.

By Lemma 15.35, the step from the stored vector Z_k takes the table rows $r_0 = Z_k, r_1, \ldots, r_N$ and returns $Z_{k+1} = \mathrm{near}(2^N S_N(f))$ with $f_l = r_l/2^N$, that is,

$$(Z_{k+1})_i = \mathrm{near}\Big(\sum_{l \leq N} 2^{-\sigma l} r_{l,i}\Big) \qquad (i < d).$$

So Lemma I.158(a) with $z_l = r_{l,i}$ is exactly the coordinate i of the next stored vector.

I.12.2 The stage, its contract and the stored step

The stage works on any table of integers, independently of where it came from. Let $d, \sigma, N, W, r \in \mathbb{N}$ and let $z_0, \ldots, z_N$ be integer vectors of length d (the rows of a table) whose entries all fit W. For $i < d$ put

$$V_i = \mathrm{near}\Big(\sum_{l \leq N} 2^{-\sigma l} z_{l,i}\Big), \qquad V = (V_0, \ldots, V_{d-1}),$$

and write $\mathrm{sw}_W(z_0, \ldots, z_N)$ for the signed words of the rows, row after row; its length is $\ell = (N+1)d(W+2)$. For an integer y that need not fit W, $\mathrm{sw}_W(y)$ denotes the same rule as in Definition I.3: the bit $[y < 0]$ followed by the $W + 1$ lowest binary digits of $|y|$. The size measure of the stage is

$$Y = d + \sigma + N + W + r + 1.$$

Definition I.159 (The stage after j coordinates)**.** Let Z be an integer vector of length d and $j \leq d$. A tape τ is in the *state* C_j if

(i) track 11 carries the counter $j(W+2)$;

(ii) the binary stream holds $\mathrm{sw}_W(Z)$, and tracks 8, 9 and 10 carry the counters N, W and σ;

(iii) $\tau(k, 12) = [k < \ell]$ for $k \leq r$, and $\ell \leq r$;

(iv) for $k < \ell$, $\tau(k, 13)$ is the bit k of $\mathrm{sw}_W(V)$ if $k < j(W+2)$, and the bit k of $\mathrm{sw}_W(z_0, \dots, z_N)$ otherwise;

(v) τ has origin marks up to r and is a workspace of r rows.

So in C_j the first j words of the first table row have been replaced by the first j coordinates of the answer. Since the first row has d words and the answer has d coordinates, the replacement never touches a word that a later coordinate still needs: coordinate j reads the words $kd + j$, $k \le N$, and only the word j of the first row is replaced when coordinate j is done. The *protected tracks* are 2, 3, 4, 5, 8, 9, 10, 14 and 15.

The programs. Let $\mathsf{rep}_{c,g}$ and $\mathsf{dup}_{k\to l}$ be the programs of Lemma I.126. The stage is

$$\mathsf{Sum} = \mathsf{zero}_{11}; \mathsf{rep}_{11,6}(\mathsf{Coord}); \mathsf{dup}_{13\to 7},$$
$$\mathsf{Coord} = \mathsf{Prep}; \mathsf{Horner}; \mathsf{Round}; \mathsf{zero}_2; \mathsf{cpre}; \mathsf{Wback}; \mathsf{Restore}.$$

Sum resets the cursor on track 11, runs Coord once for each coordinate, using the presence marks of the stored vector on track 6 as the guard, and finally copies the first row of the buffer, which now holds the answer, onto the value track 7 of the binary stream. One run of Coord treats the coordinate j whose word starts at the row $a = j(W+2)$ that track 11 carries:

(1) Prep saves a and the borrowed tracks on a stack in the positive half of the tape, adds rows to the workspace, computes $E = \sigma N$ and $H = W + E + N + 4$ in unary, and lays out an arithmetic area of H twelve-cell rows along track 7 (Lemma I.181);

(2) Horner computes $T = \sum_l 2^{\sigma(N-l)} z_{l,j}$ in that area by Horner's rule, reading each $z_{l,j}$ from the buffer (Lemma I.178);

(3) Round halves T E times, adds the last bit dropped and writes the signed word of the result V_j (Lemma I.179);

(4) zero_2 and cpre put a back on track 2, and Wback writes the first $W+2$ bits of that word, which are $\mathrm{sw}_W(V_j)$, into the buffer at row a (Lemmas I.169 and I.180);

(5) Restore clears the arithmetic area, restores every borrowed track from the stack, returns the workspace to its r rows and advances track 11 to $a + W + 2$ (Lemma I.182).

Theorem I.160 (One coordinate). *Let $j < d$ and let τ be in the state C_j. Then* Coord *runs from $(-1, \tau)$ to $(-1, \tau')$ in some t units, where τ' is in the state C_{j+1}, agrees with τ on every cell of the protected tracks, and*

$$t \le 10^{31}\, Y^6.$$

The proof is in Section I.12.7. The exponent 6 comes from words of $H \le 7Y^2$ bits handled by loops whose length and cost per pass are both at most a constant times Y^2.

Theorem I.161 (The Taylor sum). *Put $K_\Sigma = 10^{31}+1000$. Let d, σ, N, W, r and the table $z_0, \dots, z_N$ be as above, and let Z be an integer vector of length d. Let τ be a tape whose binary stream holds $\mathrm{sw}_W(Z)$, on which tracks 8, 9 and 10 carry the counters N, W and σ, whose output buffer holds $\mathrm{sw}_W(z_0, \dots, z_N)$ with capacity r, and which is a workspace of r rows. Then* Sum *runs from $(-1, \tau)$ to $(-1, \tau')$ in some number t of units, where*

(a) the binary stream of τ' holds $\mathrm{sw}_W(V)$;

(b) τ' has origin marks up to r and is a workspace of r rows;

(c) τ' agrees with τ on every cell of the tracks 2, 3, 4, 5, 8, 9, 10, 14 and 15;

(d) $t \le K_\Sigma\, Y^8$.

The rows in use do not change, so in the sense of Definition I.7 this is a contract whose bound counts the units alone, with exponent 8 in the size measure Y and a constant that does not depend on anything.

Proof. Put $K = 10^{31}$ and $\ell = (N+1)d(W+2)$. Since the buffer holds a word of length ℓ with capacity r, $\ell \le r$, and so $d(W+2) \le r$.

Start. By Lemma I.14(d), zero_{11} takes 29 units and sets $(0, 11)$ to 0; it changes no other cell. The tape is then in the state C_0: track 11 carries 0, conditions (ii) and (v) are inherited, and (iii) and (iv) with $j = 0$ restate that the buffer holds the table word.

The loop over the coordinates. Recall that

$$\mathsf{rep}_{11,6}(\mathsf{Coord}) = \mathsf{peek}_{11\to6}; \mathsf{loop}(\mathsf{home}_6; \mathsf{Coord}; \mathsf{peek}_{11\to6}); \mathsf{home}_6.$$

For $j \le d$ let I_j be the set of configurations $(\mathrm{cell}(j(W+2), 6), \sigma)$ such that σ is in the state C_j and agrees with τ on the protected tracks. The binary stream holds d words of $W+2$ bits, so the presence cell $(j(W+2), 6)$ holds 1 for $j < d$ and 0 for $j = d$. The first $\mathsf{peek}_{11\to6}$ takes 20 units (Lemma I.126(a)) and ends in I_0. From a configuration in I_j with $j < d$, home_6 returns to the root along the origin marks in $18j(W+2) + 10$ units (Lemma I.11(b)), Theorem I.160 runs Coord within KY^6 units to a tape in C_{j+1} that keeps the protected tracks, and $\mathsf{peek}_{11\to6}$ goes to $\mathrm{cell}((j+1)(W+2), 6)$ in $18(j+1)(W+2)+20$ units. As $(j+1)(W+2) \le r$, a pass ends in I_{j+1} within $KY^6 + 100(r+1)$ units. By Lemma I.6 the loop takes at most $d(KY^6 + 100(r+1) + 1) + 1$ units, and the final home_6 at most $18r + 10$. So $\mathsf{rep}_{11,6}(\mathsf{Coord})$ ends in C_d within $d(KY^6 + 100(r+1) + 1) + 100(r+1)$ units, with the protected tracks unchanged.

The copy. In C_d the cells $(k, 13)$, $k < d(W+2)$, hold $\mathrm{sw}_W(V)$, and track 6 still holds the presence marks of a stream of $d(W+2)$ bits. By Lemma I.126(b), $\mathsf{dup}_{13\to7}$ copies track 13 onto track 7 in the rows $k \le r$ in exactly $82r + 56$ units and changes nothing else. Afterwards the binary stream holds $\mathrm{sw}_W(V)$; the origin marks and the workspace are kept, because track 7 holds 0 beyond row r before and after; and track 7 is not protected. This proves (a)–(c).

The count. Since $Y \ge 1$, $d \le Y$ and $r + 1 \le Y$,

$$t \le 29 + d\big(KY^6 + 100(r+1) + 1\big) + 100(r+1) + 82r + 56 \le KY^7 + 100Y^2 + Y + 185Y \le (K+1000)Y^8. \qquad \square$$

The stored vector between steps is described by Definition I.101: the saved request on tracks 3, 4 and 15, the counters m, N, W and σ on tracks 5, 8, 9 and 10, the word $\mathrm{sw}_W(Z)$ on the binary stream, origin marks up to r, a workspace of r rows and the reserve of rows. The contract of one stored step is Definition I.183. The coefficient stage Build of Theorem I.121 fills the output buffer with the table; the Taylor sum then consumes it.

Theorem I.162 (One stored step)**.** *Put* Step $=$ Build; Sum*, let* $g = 118$ *be the exponent of Theorem I.119,* K_{a} *its constant,* $c_W = 4(q_P + l_P + c_P) + 4$ *the constant of Proposition I.32(e), and*

$$K_{\mathrm{s}} = dK_{\mathrm{a}} + d + 1008 + K_\Sigma c_\Sigma^8, \qquad c_\Sigma = d + \sigma + c_W + 2.$$

Let a problem with a coefficient field and a level n_0 *be given. Let* $i < d$*,* m*,* r *and* $c < S$*, let* Z *be an integer vector of length* d *with* $\|Z/2^N\| \le M$*, and let* τ *hold the stored vector* Z *on* r *rows (Definition I.101), with the counter* c *on track* 2 *and a retained word of length* S *on track* 14 *from row* 0*. Then* Step *runs from* $(-1, \tau)$ *to* $(-1, \tau')$ *in* t *units, where* τ' *holds the stored vector* Z^+ *of Definition I.183 on the same* r *rows,*

$$Z_i^+ = \mathrm{near}\Big(\sum_{l \le N} 2^{-\sigma l} r_{l,i}\Big) \qquad (i < d)$$

for the table rows $r_0 = Z, r_1, \dots, r_N$ *of Lemma 15.35 (so* $Z^+ = Z_{k+1}$ *when* $Z = Z_k$*),* τ' *agrees with* τ *on the cells* $(q, 2)$ *and* $(q, 14)$*,* $q \le S$*, and*

$$t \le K_{\mathrm{s}}\,(X + r + 1)^{g+18} = K_{\mathrm{s}}\,(X + r + 1)^{136}.$$

So Step *meets the contract of Definition I.183 with exponent* $g_{\mathrm{s}} = g + 18 = 136$*; its constant depends on the problem only through* d*,* σ *and* c_W*.*

Proof. Put $X' = X + r + 1$. By Theorem I.121, Build runs from $(-1, \tau)$ within $(dK_{\mathrm{a}} + d + 1008)X'^{120}$ units to a tape τ_1 that holds the stored vector Z on the same r rows, whose output buffer holds $\mathrm{sw}_W(r_0, \dots, r_N)$ with capacity r, and that agrees with τ on the cells $(q, 2)$ and $(q, 14)$, $q \le S$. By Proposition I.32(a) every entry of every r_l fits W. So τ_1 satisfies the hypotheses of Theorem I.161 with the head vector Z and the table $r_0, \dots, r_N$: its binary stream holds $\mathrm{sw}_W(Z)$, its tracks 8, 9 and 10 carry N, W and σ, and it is a workspace of r rows. Theorem I.161 gives a run of Sum from $(-1, \tau_1)$ to $(-1, \tau')$ within $K_\Sigma Y^8$ units, where the binary stream of τ' holds $\mathrm{sw}_W(Z^+)$, τ' has origin marks up to r, is a workspace of r rows and agrees with τ_1 on tracks $2, 3, 4, 5, 8, 9, 10, 14, 15$. These tracks carry the saved request (3, 4, 15), the counters m, N, W, σ (5, 8, 9, 10), the step counter and the retained step word (2, 14). The reserve concerns the row count r only. So τ' holds the stored vector Z^+ on r rows and agrees with τ on the cells $(q, 2)$ and $(q, 14)$. The formula for Z^+ is the last display of Section I.12.1.

For the count, $N < X$ and $W \le c_W X^2$ by Proposition I.32(e), and $X' \ge 1$, so

$$Y = d + \sigma + N + W + r + 1 \le (d + \sigma)X'^2 + c_W X'^2 + 2X'^2 = c_\Sigma X'^2.$$

Hence Sum takes at most $K_\Sigma c_\Sigma^8 X'^{16}$ units, and

$$t \le (dK_{\mathrm{a}} + d + 1008)X'^{120} + K_\Sigma c_\Sigma^8 X'^{16} \le K_{\mathrm{s}} X'^{136},$$

because $120 \le 136$ and $16 \le 136$. The exponent is $(g+2)+2\cdot 8$: the coefficient stage contributes $g + 2 = 120$, and the Taylor sum its exponent 8 doubled by the passage from Y to X'^2. □

I.12.3 Repetition, rows and a stack

A coordinate needs more room than the r rows it is given and more registers than the free tracks offer. It takes both for a while and gives them back: it adds rows to the workspace and removes them at the end, and it saves the borrowed tracks on a stack in the positive half of the tape. This subsection gives these tools. The repetition $\mathsf{rep}_{c,g}(P) = \mathsf{peek}_{c\to g};\mathsf{loop}(\mathsf{home}_g;P;\mathsf{peek}_{c\to g});\mathsf{home}_g$ of Lemma I.126 is used throughout, also when its cursor does not start at 0.

Lemma I.163 (Repeating from a start, and $W+2$ times)**.** *Let $c,g<16$ with $1\le g$, and let $s\le n\le r$.*

(a) Let $\mathrm{R}_s,\dots,\mathrm{R}_n$ be properties of tapes such that on every tape with R_q track c carries q, track g carries n and there are origin marks up to r. If for every q with $s\le q<n$ the program P runs from $(-1,\sigma)$ within b units to some $(-1,\sigma')$ with R_{q+1} whenever σ has R_q, then $\mathsf{rep}_{c,g}(P)$ runs from every tape with R_s to a tape with R_n within $(n-s+1)(b+200(r+1))$ units.

(b) Put $\mathsf{wp}(P)=\mathsf{rep}_{11,9}(P);P;P$. Let $W+2\le r$ and let $\mathrm{R}_0,\dots,\mathrm{R}_{W+2}$ be properties such that on every tape with R_q track 11 carries q, track 9 carries W and there are origin marks up to r. If P runs from every tape with R_q, $q<W+2$, within b units to a tape with R_{q+1}, then $\mathsf{wp}(P)$ runs from every tape with R_0 to a tape with R_{W+2} within $(W+3)(b+200(r+1))$ units.

Proof. (a) As in the proof of Lemma I.126(c), with the configurations I_q ($s\le q\le n$) at cell(q,g) whose tape has R_q. The first $\mathsf{peek}_{c\to g}$ takes $18s+c+4+|c-g|\le 18r+34$ units, each of the $n-s$ passes at most $b+100(r+1)$ units with its test, and the final test and home_g at most $18r+20$. Since $36r+55\le b+200(r+1)$, the total is at most $(n-s+1)(b+200(r+1))$. (b) By (a) with $s=0$ and $n=W$, $\mathsf{rep}_{11,9}(P)$ reaches R_W within $(W+1)(b+200(r+1))$ units; the two further runs of P reach R_{W+2} within $2b$ more. □

The program $\mathsf{wp}(P)$ runs P once for each bit of a signed word of width W; this section uses it to append a word's worth of marks and to write one word back.

While a coordinate is computed the workspace has more rows than usual and the positive half is not blank.

Definition I.164 (Working workspace)**.** A tape τ is a *working workspace of c rows* if $\tau(-1)=1$, track 0 carries the counter c, τ has origin marks up to c, and every cell of every row $j>c$ holds 0.

A workspace of r rows with origin marks up to r is a working workspace of r rows. Every counter on such a tape is at most $c+1$, as in Lemma I.4.

Lemma I.165 (Moving a counter back, and adding rows)**.** *Let $2 \le k < 16$ and put*

$$\begin{aligned} \mathsf{retr}_k &= \mathsf{seek}_k; \mathsf{write}\ 1; \mathsf{right}^{16}; \mathsf{write}\ 0; \mathsf{home}_k, \\ \mathsf{addrow} &= \mathsf{seek}_0; \mathsf{write}\ 1; \mathsf{left}^{16}; \mathsf{write}\ 0; \mathsf{left}; \mathsf{write}\ 1; \mathsf{home}_1, \\ \mathsf{ginc}_k &= \mathsf{addrow}; \mathsf{inc}_k. \end{aligned}$$

Each runs from $(-1, \tau)$ to $(-1, \tau')$.

(a) If track k carries $a+1$ and τ has origin marks up to $a+1$, retr_k takes $36a + 2k + 44$ units, and τ' is τ with $(a+1, k)$ set to 1 and (a, k) set to 0; track k carries a.

(b) If τ is a working workspace of c rows, addrow takes $36c + 47$ units, and τ' is τ with $(c, 0)$ and $(c+1, 1)$ set to 1 and $(c+1, 0)$ set to 0, a working workspace of $c+1$ rows.

(c) If moreover track k carries $a \le c$, ginc_k takes $36c + 47 + 36a + 2k + 44$ units and leaves a working workspace of $c+1$ rows on which track k carries $a+1$.

No other cell is written.

Proof. (a) seek_k ($18(a+1) + k + 3$) reaches the hole $(a+1, k)$, the two writes and right^{16} (19) set it and the cell (a, k) above it, and home_k from row a takes $18a + k + 4$ units (Lemma I.11). (b) seek_0 ($18c + 3$) reaches the sentinel header $(c, 0)$; the writes and moves (21 units) promote it, blank the header of row $c+1$ and set the origin mark $(c+1, 1)$; and home_1 from row $c+1$ takes $18c + 23$. Rows beyond $c+1$ are untouched, so they hold 0. (c) is (b) followed by Lemma I.14(a), which needs origin marks up to $a + 1 \le c + 1$. □

The stack lies on the cells $15 + 16i$, $i \ge 0$, of the positive half; these cells are blank between stages and are never used by any other routine of the stage.

Definition I.166 (The stack)**.** For a tape τ the *stack view* is the tape $\varsigma(i) = \tau(15 + 16i)$, $i \in \mathbb{Z}$; so $\varsigma(-1)$ is the root and $\varsigma(i)$, $i \ge 0$, are positive cells. The tape *holds the stack* $w = w_0 \cdots w_{n-1}$ if ς holds the packed list w at 2 (Definition I.122), $\varsigma(0) = \varsigma(1) = 0$, and $\varsigma(x) = 0$ for every $x \ge 2 + 2n$. The cells $\varsigma(2 + 2i)$ and $\varsigma(3 + 2i)$ are the cells of the *entry* i; the last entry is the *top*.

Lemma I.167 (Pushing and popping)**.** *Put*

$$\begin{aligned} \mathsf{spush}(b) &= \big(\mathsf{right}; \mathsf{right}; \mathsf{right}; \mathsf{appP}(b); \mathsf{left}; \mathsf{left}; \mathsf{loop}(\mathsf{left}; \mathsf{left}); \mathsf{left}\big)^{\uparrow 16}, \\ \mathsf{spop} &= \big(\mathsf{right}^3; \mathsf{scanP}; \mathsf{left}^2; \mathsf{write}\ 0; \mathsf{right}; \mathsf{write}\ 0; \mathsf{left}; \mathsf{rewP}; \mathsf{left}\big)^{\uparrow 16}, \\ \mathsf{top}(P_0, P_1) &= \big(\mathsf{right}^3; \mathsf{scanP}; \mathsf{left}\big)^{\uparrow 16}; \mathsf{branch}\big(\mathsf{bk}; P_0,\ \mathsf{bk}; P_1\big), \\ \mathsf{bk} &= (\mathsf{right}; \mathsf{rewP}; \mathsf{left})^{\uparrow 16}, \end{aligned}$$

with scanP, appP *and* rewP *of Lemma I.123. Let τ hold the stack w of length n.*

(a) $\mathsf{spush}(b)$ runs from $(-1, \tau)$ within $17(6n + 16)$ units to $(-1, \tau')$, where τ' holds the stack wb and differs from τ only in the cells $47 + 32n$, $63 + 32n$ and $79 + 32n$.

(b) If $w = w'b$, then spop *runs from $(-1,\tau)$ within $17(7n+13)$ units to $(-1,\tau')$, where τ' holds the stack w' and is τ with the cells $15+32n$ and $31+32n$ of the top set to 0.*

(c) If $w = w'b$ and P_b runs from $(-1,\tau)$ in t units to a configuration γ, then $\mathsf{top}(P_0,P_1)$ *runs from $(-1,\tau)$ to γ within $17(7n+12)+1+t$ units.*

Proof. We count on the stack view and apply Lemma I.8 with origin 15 and stride 16: the root is $\varsigma(-1)$, each unit of the virtual run becomes at most 17, and only cells $15+16x$ are written. (a) Three moves reach $\varsigma(2)$, $\mathsf{appP}(b)$ appends b in $3n+6$ units and stops at $2n+4$ (Lemma I.123(c)), two moves reach the presence cell $2n+2$ of the new entry, the loop passes the $n+1$ presence cells $2n+2,\dots,2$ (3 units each) and stops at $\varsigma(0)=0$, and a last move returns to -1: $6n+16$ units. The cells written are $2+2n$, $3+2n$ and $4+2n$ of the view. (b) right^3 and scanP $(4+3n+1)$ reach $2+2n$, left^2 (3) the presence cell $2n$ of the top; four units clear its two cells and return; rewP over the $n-1$ entries below $(4n)$ reaches 0, and left the root: $7n+13$ units. (c) The first part ($3n+6$ units) stops at the value cell $2n+1$ of the top, the branch reads b, and bk ($4n+6$ units) returns to the root without writing. □

For a tape σ, a track k and a row count c, the *snapshot* $\theta^c_k(\sigma)$ is the word $\sigma(0,k)\sigma(1,k)\cdots\sigma(c,k)$ of $c+1$ bits. The stage saves a track by pushing its snapshot and restores it by popping the snapshot back, last row first.

Lemma I.168 (Saving and restoring a track)**.** *Let $2\le k<16$, $k\neq 11$, and put*

$$\begin{aligned}
\mathsf{brd}_k &= \mathsf{peek}_{11\to k};\mathsf{branch}\big(\mathsf{home}_k;\mathsf{spush}(0),\ \mathsf{home}_k;\mathsf{spush}(1)\big),\\
\mathsf{save}_k &= \mathsf{peek}_{11\to 0};\mathsf{loop}(\mathsf{left};\mathsf{home}_1;\mathsf{brd}_k;\mathsf{inc}_{11};\mathsf{peek}_{11\to 0});\\
&\qquad \mathsf{left};\mathsf{home}_1;\mathsf{brd}_k;\mathsf{zero}_{11},\\
\mathsf{wcl}_k(b) &= \mathsf{peek}_{11\to k};\mathsf{write}\,b;\mathsf{home}_k,\\
\mathsf{rone}_k &= \mathsf{top}\big(\mathsf{spop};\mathsf{wcl}_k(0),\ \mathsf{spop};\mathsf{wcl}_k(1)\big),\\
\mathsf{rest}_k &= \mathsf{dup}_{3\to 11};\mathsf{left}^{12};\mathsf{loop}(\mathsf{right}^{12};\mathsf{rone}_k;\mathsf{retr}_{11};\mathsf{left}^{12});\\
&\qquad \mathsf{right}^{12};\mathsf{rone}_k.
\end{aligned}$$

(a) Let track 0 carry the counter c, let τ have origin marks up to c, let track 11 carry 0, and let τ hold the stack w. Then save_k *runs from $(-1,\tau)$ to $(-1,\tau')$ within $11\,000(c+|w|+1)^2$ units, where τ' holds the stack $w\theta^c_k(\tau)$, track 11 carries 0, and τ' agrees with τ on every cell of a row that is not on track 11. For a list $k_1,\dots,k_s$ of such tracks,* $\mathsf{save}_{k_1};\cdots;\mathsf{save}_{k_s};\mathsf{skip}$ *pushes $\theta^c_{k_1}(\tau)\cdots\theta^c_{k_s}(\tau)$ within $(11\,000s+1)(c+|w|+s(c+1)+1)^2$ units.*

(b) Let τ be a working workspace of R rows on which track 3 carries $c\le R$, and let τ hold the stack $w\theta$, where θ is $\theta^c_k(\sigma)$ for some tape σ. Then rest_k *runs from $(-1,\tau)$ to $(-1,\tau')$ within $30\,000(R+|w|+c+1)^2$ units, where τ' holds the stack w, track 11 carries 0, $\tau'(q,k)=\sigma(q,k)$ for $q\le c$, τ' agrees with τ on every cell of a row that is not on track 11 or k, and τ' is a working workspace of R rows. For a list $k_1,\dots,k_s$ of such tracks, all different from 3,* $\mathsf{skip};\mathsf{rest}_{k_s};\cdots;\mathsf{rest}_{k_1}$ *restores them from the stack $w\theta^c_{k_1}(\sigma)\cdots\theta^c_{k_s}(\sigma)$ within $(30\,000s+1)(R+|w|+s(c+1)+c+1)^2$ units.*

No stack cell outside the entries pushed or popped is written.

Proof. (a) When track 11 carries $q \le c$, $\mathsf{peek}_{11\to 0}$ reaches the header $(q,0)$, which holds 1 exactly when $q < c$. A pass at the header of row $q < c$ steps to $(q,1)$ and returns along the origin marks ($18q+6$ units), reads (q,k) and pushes it (brd_k: at most $36q+2k+30$ units for the walks and $17(6(|w|+q)+16)$ for the push, Lemma I.167(a)), advances track 11 to $q+1$ ($36q+66$) and peeks again ($18q+44$): at most $1000(c+|w|+1)$ units with its test. At the sentinel header $(c,0)=0$ the loop stops; the program pushes (c,k) the same way and zero_{11} (29 units) makes track 11 carry 0. By Lemma I.6, the c passes and the rest cost at most $11\,000(c+|w|+1)^2$ units. Only track 11 and the stack cells are written. The list follows by adding the bounds, the stack growing by $c+1$ entries each time.

(b) $\mathsf{dup}_{3\to 11}$ copies track 3 onto track 11 in the rows $q \le R$ ($70R+44$ units, Lemma I.126(b)), so track 11 carries c. left^{12} reaches cell$(0,11)$, which holds 1 exactly when the counter on track 11 is positive. Let the counter be $q \ge 1$, the stack $wb_0 \cdots b_q$, and the rows $q+1,\dots,c$ of track k already restored. A pass returns to the root, reads the top b_q and pops it (Lemma I.167(b),(c)), writes it into (q,k) with wcl_k ($36q+50$ units at most), moves the counter back to $q-1$ with retr_{11} (Lemma I.165(a)) and steps to cell$(0,11)$ again: at most $238(|w|+c+1)+72q+842$ units. When the counter is 0, the loop stops, right^{12} returns to the root and rone_k writes b_0 into $(0,k)$. So rows $c, c-1,\dots,0$ of track k receive $\sigma(c,k),\dots,\sigma(0,k)$, and the stack is w. By Lemma I.6 the total is at most $30\,000(R+|w|+c+1)^2$. The tracks 0 and 1 are not written (track $k \ne 1$, and $k=0$ is excluded), so the working workspace is kept. For the list, the snapshots come off in the reverse order of the pushes, and the restored tracks differ from 3, so track 3 still carries c for each of them. □

The address of the coordinate, the counter $a = j(W+2)$ on track 11, is kept on the stack too, as a entries 1 followed by a separator 0.

Lemma I.169 (The address)**.** *Put*

$$\begin{aligned}
\mathsf{sav} &= \mathsf{left}^{12};\mathsf{loop}(\mathsf{right}^{12};\mathsf{retr}_{11};\mathsf{spush}(1);\mathsf{left}^{12});\mathsf{right}^{12};\mathsf{spush}(0),\\
\mathsf{cpre} &= \mathsf{right}^{48};\mathsf{write}\,0;\mathsf{right}^{16};\mathsf{loop}(G^{\uparrow 16};\mathsf{inc}_2;F^{\uparrow 16});J^{\uparrow 16},\\
G &= \mathsf{left};\mathsf{rewP};\mathsf{left}, \qquad F = \mathsf{right}^{3};\mathsf{scanP};\mathsf{write}\,1;\mathsf{right}^{2};\mathsf{write}\,0;\mathsf{right},\\
J &= \mathsf{left};\mathsf{write}\,1;\mathsf{loop}(\mathsf{left};\mathsf{left});\mathsf{left},\\
\mathsf{fin} &= \mathsf{wp}(\mathsf{spush}(1);\mathsf{inc}_{11});\mathsf{zero}_{11};\mathsf{right}^{48};\\
&\qquad \mathsf{loop}(\mathsf{left}^{48};\mathsf{spop};\mathsf{inc}_{11};\mathsf{right}^{48});\mathsf{left}^{48}.
\end{aligned}$$

Let τ have origin marks up to c.

(a) If track 11 carries $n \le c$ and τ holds the stack w, then sav *runs from $(-1,\tau)$ to $(-1,\tau')$ within $5000(c+|w|+n+1)^2$ units; τ' holds the stack $w1^n0$, track 11 carries 0, and of the rows only track 11 was written.*

(b) If track 2 carries 0, τ holds a stack 1^n0v for some word v, and $n \le c$, then cpre *runs from $(-1,\tau)$ to $(-1,\tau')$ within $2000(c+n+1)^2$ units, where track 2 of τ' carries n, the stack and every cell $x \ge 0$ are unchanged, and of the rows only track 2 was written.*

(c) If track 11 carries 0, track 9 carries W, τ holds the stack 1^a and $a+W+2 \le c$, then fin *runs from $(-1,\tau)$ to $(-1,\tau')$ within $7000(c+a+W+3)^2$ units, where track 11 of τ' carries*

$a + W + 2$, every cell $\varsigma(x)$, $x \geq 0$, of the stack view holds 0, and of the rows only track 11 was written.

Proof. (a) left^{12} reaches cell$(0, 11)$, which holds 1 while the counter on track 11 is positive. A pass with the counter $q+1$ returns to the root (13), moves the counter back to q ($36q+66$), pushes 1 ($\leq 17(6|w'|+16)$ with $|w'| \leq |w|+n$) and steps back (13): at most $36q+102(|w|+n)+364$ units. After n passes the counter is 0 and the loop stops; right^{12} and $\mathsf{spush}(0)$ finish. Lemma I.6 bounds the whole by $5000(c + |w| + n + 1)^2$.

(b) right^{48} reaches $\varsigma(2)$, the presence cell of the entry 0, and sets it to 0, a *hole*; right^{16} reaches its value cell $\varsigma(3)$. Let I_q ($q \leq n$) be the configuration at the value cell $\varsigma(3 + 2q)$ in which the presence cell of the entry q is a hole, the other cells of the stack are as before, and track 2 carries q. The scanned value is 1 for $q < n$ and the separator 0 for $q = n$. A pass from I_q, $q < n$, steps to the hole and rewinds over the q entries before it to $\varsigma(0)$ and the root (G: $4q + 6$ virtual units), increments track 2 ($36q + 48$), then walks right over those q entries, which stop at the hole, fills the hole, makes a hole of the next presence cell and steps to its value (F: $3q + 11$ virtual units). By Lemma I.8 a pass costs at most $155q + 337$ units and ends in I_{q+1}. At I_n the loop stops and J fills the last hole, rewinds to $\varsigma(0)$ and returns to the root ($3n + 7$ virtual units). The total is at most $2000(c + n + 1)^2$.

(c) By Lemma I.163(b), with the property that the stack is 1^{a+q} and track 11 carries q, $\mathsf{wp}(\mathsf{spush}(1); \mathsf{inc}_{11})$ pushes $W + 2$ entries 1 within $(W + 3) \cdot 1200(c + a + W + 3)$ units (a run of the body costs at most $102(a + W + 2) + 272 + 36c + 66$), and zero_{11} resets track 11. Then right^{48} reaches $\varsigma(2)$, which holds 1 while the stack is not empty. A pass returns to the root, pops the top, increments track 11 and returns to $\varsigma(2)$; after $a + W + 2$ passes the stack is empty, track 11 carries $a + W + 2$, and the loop stops on $\varsigma(2) = 0$. Every popped entry was cleared, and $\varsigma(0)$, $\varsigma(1)$ and the cells beyond the stack were already 0. The bound follows from Lemmas I.167 and I.6. □

The parameters of the arithmetic are computed in unary, each mark of a growing counter paid for by one new row, so that every counter always fits the workspace.

Lemma I.170 (The parameters and the rows)**.** *For tracks $2 \leq g, k, u < 16$, all different, and $p \in \mathbb{N}$ put*

$$

&\qquad \mathsf{left}; \mathsf{findR}^{\uparrow 16}; \mathsf{home}_1,
\end{aligned}
$$

with put *of Lemma I.12 and* findR *of Lemma I.34.*

(a) *If τ is a working workspace of C rows on which track k carries $a \le C$ and track g carries $n \le C$, then* $\mathsf{gadd}^{u}_{g\to k}$ *runs from $(-1,\tau)$ within $10\,000(C+a+n+1)^2$ units to a working workspace of $C+n$ rows on which tracks k, u and g carry $a+n$, n and n; only tracks 0, 1, k and u are written.*

(b) *Let τ be a working workspace of r rows on which tracks 8, 9 and 10 carry N, W and σ, all at most $r+1$. Put $E=\sigma N$, $H=W+E+N+4$ and $R=r+1+E+H+1000(H+1)+20$. Then* Par *runs from $(-1,\tau)$ to $(-1,\tau')$ within*

$$\Gamma_{\mathrm{par}} = (48r+22)+(36r+47)+10^6(r+1+\sigma(N+1)+N+1)^3 + 10^6(r+1+2E+W+N+5)^2+10^9(R+H+1)^2$$

units, where τ' is a working workspace of R rows, tracks 3, 12 and 4 carry r, E and H, tracks 8, 9 and 10 still carry N, W and σ, only tracks 0, 1, 3, 4, 11, 12 and 14 are written, and every cell $x \ge 0$ is unchanged.

(c) *If τ is a working workspace of R rows on which track 3 carries r with $1 \le r < R$, then* shrink *runs from $(-1,\tau)$ within $1000(R+1)$ units to a working workspace of r rows that agrees with τ on the cells $x \ge 0$ and on every cell (q,k) with $q \le r$ and $k \ne 0$, and holds 0 in every cell of the rows $q > r$.*

Proof. (a) Let R_q ($q \le n$) say that the tape is a working workspace of $C+q$ rows on which tracks k, u and g carry $a+q$, q and n. After zero_u ($2u+7$ units) R_0 holds. From R_q, ginc_k (Lemma I.165(c)) and inc_u take at most $36(C+q)+36(a+q)+36q+200 \le 200(C+a+n+1)$ units and reach R_{q+1}; the origin marks up to C suffice for the repetition, whose cursor and guard stay in rows at most $n \le C$. By Lemma I.126(c), with r there equal to C, the repetition takes at most $(n+1)\cdot 400(C+a+n+1)$ units, and the total is at most $10\,000(C+a+n+1)^2$.

(b) $\mathsf{dup}_{0\to 3}$ ($48r+22$ units) copies the headers onto track 3, which then carries r; addrow ($36r+47$) makes the workspace have $r+1$ rows. Exp repeats N times, with track 14 as cursor and the guard 8, the addition of σ to track 12. Put $D = r+1+\sigma(N+1)+N+1$. The pass $q < N$ starts with $r+1+q\sigma$ rows and $q\sigma$ on track 12, so by (a) it costs at most $40\,000D^2+36D+66 \le 50\,000D^2$ units, and by Lemma I.126(c) the repetition leaves E on track 12 and $r+1+E$ rows within $(N+1)(50\,000D^2+200D)$ units; so Exp takes at most 10^6D^3. Wid adds W, E and N to the empty track 4 and four more marks, each mark with a new row (by (a) and Lemma I.165(c)): track 4 carries H and there are $r+1+E+H$ rows. With $D' = r+1+2E+W+N+5$, each of the three additions costs at most $10\,000(2D')^2$ by (a), and each ginc_4 at most $200D'$, so Wid takes at most $10^6D'^2$ units. Res adds 1000 rows for each of the H marks of track 4 and then 1020 rows, $1000(H+1)+20$ in all. Each addrow costs at most $36R+47$ units, so a pass of the repetition costs at most $50\,000(R+H+1)$, the repetition at most $(H+1)\cdot 50\,200(R+H+1)$ (Lemma I.126(c); there are at least H rows), and Res at most $10^9(R+H+1)^2$. The counters on tracks 8, 9 and 10 are only read.

(c) seek_3 ($18r+6$) and right^3 (4) reach the header $(r,0)$, which is set to 0; left^{16} reaches $(r+1,0)$. The headers of the rows $r+1,\dots,R-1$ hold 1 and that of row R holds 0, so the loop clears these rows with $\mathsf{put}(0^{16})$ (34 units a row with the test, Lemma I.12(c)), and the last put clears row R. The head is then at $(R+1,0)$; left reaches $(R+1,1)$. Along track 1 the rows $R+1, R, \dots, r+1$ now hold 0 and row $r \ge 1$ holds its origin mark 1, so $\mathsf{findR}^{\uparrow 16}$ stops at $(r,1)$

within $17(6(R+1-r)+5)$ units (Lemmas I.34(a) and I.8), and home_1 ($18r+5$) returns to the root. In all at most $36r+34R+102(R+1)+153 \le 1000(R+1)$ units. The headers now carry r, the origin marks reach r, and the rows beyond r are blank. □

I.12.4 The arithmetic area of a coordinate

The arithmetic of a coordinate is done in twelve-cell rows laid along track 7, whose value cells hold the binary stream between stages and are saved on the stack while a coordinate is computed.

Definition I.171 (The bank of a coordinate)**.** For a tape τ the *bank view* is the tape $\beta(x) = \tau(-9-16x)$, $x \in \mathbb{Z}$; for $x \ge 0$ this is the cell $(x,7)$, and for $x<0$ it is the positive cell $-9-16x$. The *bank of width H* is the block of twelve-cell rows at 12 of β (Definition I.20); it is *laid out* if it has H marked rows and is closed on the left, that is, $\beta(0)=0$ and $\beta(12+12k)=[k<H]$ for $k \le H$. Column c of the bank *reads* the integer z if the word $\beta(12+12k+c)$, $k<H$, has $\mathrm{sval}_H = z$ (Definition I.3(d)). The cell $\beta(10)$, column 10 of the row before row 0, is the *guard*.

The bank view and the stack view use the cells $\equiv 7$ and $\equiv 15$ modulo 16; they share no cell with each other or with any other track.

Lemma I.172 (Calling the bank)**.** *Let* $\mathsf{bcall}(P) = \mathsf{left}^{200}; P^{\downarrow 16}; \mathsf{home}_7$. *Let track 0 of τ carry the counter c, let τ have origin marks up to c, let β be its bank view, and let P run on β from $(12,\beta)$ in t units to (f,β') with $0 \le f \le c$. Then* $\mathsf{bcall}(P)$ *runs from $(-1,\tau)$ to $(-1,\tau')$ within $17t+18c+212$ units, where the bank view of τ' is β' and τ' agrees with τ on every cell that is not of the form $-9-16x$.*

Proof. left^{200} takes 201 units from -1 to $-201 = -9-16\cdot 12 = \mathrm{cell}(12,7)$. By Lemma I.9 with $o=-9$ and stride 16, $P^{\downarrow 16}$ runs within $17t$ units to $-9-16f = \mathrm{cell}(f,7)$, writing only cells $-9-16x$, and leaves the bank view β'. home_7 from row f takes $18f+11 \le 18c+11$ units (Lemma I.11(b)). □

The bank programs below run on β and are written for twelve-cell rows at h with $n \ge 1$ marked rows, closed on the left; they are used with $h=12$ and $n=H$. Here $\mathsf{bcp}_{s\to t}$ and bz_t are the copy and clear of Lemma I.138(a) (copy column s into column t in $(2s+2t+34)n+28$ units; set column t to 0 in $(2t+31)n+28$ units; both return to h), and the six-cell adder add of Lemma I.21 runs on the even cells as $\mathsf{add}^{\uparrow 2}$: its columns 1, 2, 3, 4 are the columns 2, 4, 6, 8 of the twelve-cell rows, so it adds columns 2 and 4 into column 8 with the carries in column 6 and the carry-in $h+6$.

Lemma I.173 (Bank routines)**.** *Let the twelve-cell rows at h have $n \geq 1$ marked rows and be closed on the left, let column 2 hold the word x and put $u = \mathrm{sval}_n(x)$. Define*

$$\begin{aligned}
\mathsf{badd} &= \mathsf{add}^{\uparrow 2};\mathsf{back};\mathsf{bcp}_{8\to 2}, \qquad \mathsf{bshl} = \mathsf{z}_{10};\mathsf{dbl};\mathsf{back},\\
\mathsf{bshr} &= \mathsf{fwd};\mathsf{left}^{10};\mathsf{branch}(S_0,S_1);\mathsf{loop}(D);\mathsf{right}^{12};\mathsf{bcp}_{8\to 2},\\
S_b &= \mathsf{right}^{8};\mathsf{write}\,b;\mathsf{left}^{10}, \qquad D = \mathsf{right}^{2};\mathsf{branch}(O_0,O_1),\\
O_b &= \mathsf{left}^{4};\mathsf{write}\,b;\mathsf{right}^{12};\mathsf{branch}(F_0,F_1),\\
F_b &= \mathsf{left}^{2};\mathsf{write}\,b;\mathsf{left}^{20},\\
\mathsf{bround} &= \mathsf{bz}_4;\mathsf{left}^{2};\mathsf{branch}(G_0,G_1);\mathsf{badd}, \qquad G_b = \mathsf{right}^{8};\mathsf{write}\,b;\mathsf{left}^{6}.
\end{aligned}$$

Each runs from h to h and keeps the presence marks.

(a) *If column 4 holds y and the cell $h+6$ holds c_0,* badd *leaves in column 2 the n lowest bits of $\mathrm{val}(x)+\mathrm{val}(y)+c_0$, in $128n+58$ units, writing only columns 2, 6 and 8.*

(b) bshl *leaves in column 2 the n lowest bits of $2\,\mathrm{val}(x)$, in $76n+51$ units, writing only columns 2 and 10; if $-2^{n-1} \leq 2u < 2^{n-1}$, column 2 then has $\mathrm{sval}_n = 2u$.*

(c) bshr *leaves in column 2 the word $x_1 \cdots x_{n-1}x_{n-1}$, whose sval_n is $\lfloor u/2 \rfloor$, and in the cell $h-2$ the bit $x_0 = u \bmod 2$, in $118n+76$ units, writing only columns 2, 8 and 10 (the cell $h-2$ is column 10 of row -1).*

(d) *If the cell $h-2$ holds g and $-2^{n-1} \leq u+g < 2^{n-1}$,* bround *leaves column 2 with $\mathrm{sval}_n = u+g$, in $167n+107$ units, writing only columns 2, 4, 6 and 8.*

Proof. (a) $\mathsf{add}^{\uparrow 2}$ takes at most $3(20n+1)$ units (Lemmas I.21 and I.8) and stops at the end row, back takes $14n+27$ (Lemma I.25(a)) and $\mathsf{bcp}_{8\to 2}$ takes $54n+28$. The sum is $128n+58$, and the value is Lemma I.21. (b) z_{10} (23 units) clears column 10 of row 0; by Lemma I.26 with $e=0$, dbl ($62n+1$) shifts column 2 by one place, and back ($14n+27$) returns. The word $0x_0 \cdots x_{n-2}$ has $\mathrm{sval}_n \equiv 2u$ modulo 2^n, so it is $2u$ in the stated range. (c) fwd ($14n+1$) walks to the end row, and left^{10} (11) to column 2 of row $n-1$, the top bit x_{n-1}; $S_{x_{n-1}}$ ($1+21$ with the test) writes it into column 10 of row $n-1$ and moves to the presence cell of row $n-1$. A pass of the loop at row k (presence 1) reads x_k in column 2, writes it into column 10 of row $k-1$, reads column 10 of row k, which holds x_{k+1} for $k < n-1$ and x_{n-1} for $k = n-1$, writes that bit into column 8 of row k and moves to the presence cell of row $k-1$: $1+3+1+5+1+13+1+3+1+21 = 50$ units. After the passes for $k = n-1, \ldots, 0$ the scanned cell is the closed left end, and right^{12} (13) returns to h: $64n+48$ units so far. Column 8 now holds $x_1 \cdots x_{n-1}x_{n-1}$ and the cell $h-2$ the bit x_0; the copy into column 2 adds $54n+28$. For the value, write $u = x_0 + 2v$ with $v = \sum_{1 \leq i < n-1} x_i 2^{i-1} - x_{n-1}2^{n-2}$; this v is the sval_n of the new word, and $u \equiv x_0$ modulo 2, so $v = \lfloor u/2 \rfloor$ (for $n=1$ the new word is x_0, and both sides are $-x_0$). (d) bz_4 ($39n+28$) clears column 4; left^2, the branch on g and G_g (21 units) copy g into the carry-in $h+6$ and return; badd ($128n+58$) adds. The value $\mathrm{val}(x)+g$ modulo 2^n has $\mathrm{sval}_n = u+g$ in the stated range, as in Corollary I.22(c). □

The last bank routine writes the signed word of the result in a form that can be read off along the column 6. It uses the stride-6 view of the bank, in which the twelve-cell rows become

two-cell rows whose presence cells are the presence cells of the bank and whose value cells are its column 6.

Lemma I.174 (Emitting the signed word)**.** *Put*

$$\begin{aligned}\mathsf{bemit} &= \mathsf{bcp}_{2\to 6};\mathsf{fwd};\mathsf{left}^6;\mathsf{branch}(P_0,P_1);\mathsf{left}^{18};\mathsf{sem}^{\uparrow 6},\\ P_b &= \mathsf{right}^6;\mathsf{back};\mathsf{left}^{18};\mathsf{write}\,b;\mathsf{right}^6;\mathsf{write}\,0;\mathsf{right}^6;\mathsf{write}\,0;\mathsf{right}^6,\\ \mathsf{sem} &= \mathsf{branch}(Q_0,Q_1),\qquad Q_b = \mathsf{right}^3;M_b;\mathsf{rewP};\mathsf{write}\,1;\mathsf{right};\mathsf{write}\,b;\mathsf{left},\end{aligned}$$

with $M_0 = \mathsf{scanP}$ *and* $M_1 = \mathsf{neg}$ *of Lemma I.24. Let the bank of width* $n \ge 1$ *be laid out on* β *(rows at* 12*), let column* 2 *read* z*, and let* z *fit* $n-1$*. Then* bemit *runs on* β *from* 12 *to* 0 *within* $428n+483$ *units, and afterwards the cells* $\beta(6+12k)$*,* $k \le n$*, hold the* $n+1$ *bits of* $\mathrm{sw}_{n-1}(z)$*.*

Proof. $\mathsf{bcp}_{2\to 6}$ ($50n+28$ units) copies the two's complement word of z into column 6. fwd ($14n+1$) and left^6 (7) reach column 6 of row $n-1$, its top bit $b = [z<0]$; the branch (1) and P_b ($14n+77$) return to the end row, walk back to 12, and write b into $\beta(-6)$ and 0 into $\beta(0)$ and $\beta(6)$, ending at 12. left^{18} (19) reaches $\beta(-6)$. Now consider the view $v(i) = \beta(6i)$. It holds b at -1 and 0 at 0 and 1, and since $\beta(12+12k) = [k<n]$ for $k \le n$ and $\beta(18+12k)$ is column 6 of row k, it holds at 2 the packed list of the word in column 6 (Definition I.122). On v, sem reads b at -1. If $b=0$, then $z \ge 0$ and the word is the n binary digits of z; Q_0 walks to 2 (4 units), over the list ($3n+1$), back to 0 (rewP, $4n+4$), and writes 1 at 0 and b at 1 (4 units). If $b=1$, the word has value $2^n+z>0$, and neg (within $30(n+1)$ units) replaces it by the word of value $2^n-(2^n+z) = |z|$, which has n digits because $|z|<2^n$; then Q_1 finishes in the same way. Either way v holds at 0 the packed list $\mathrm{sw}_{n-1}(z)$, so its value cells $v(1+2k) = \beta(6+12k)$, $k \le n$, hold the bits of $\mathrm{sw}_{n-1}(z)$, and the head is at $v(0) = \beta(0)$. On v, sem costs at most $34n+43$ units, so $\mathsf{sem}^{\uparrow 6}$ costs at most $7(34n+43)$ (Lemma I.8). The total is at most $316n+434 \le 428n+483$. □

Lemma I.175 (Laying out the bank)**.** *Put*

$$\begin{aligned}\mathsf{binit} &= \mathsf{clear}_7;\mathsf{zero}_5;\mathsf{inc}_5^{12};\mathsf{zero}_{11};\mathsf{rep}_{11,4}(\mathsf{bmark};\mathsf{inc}_5^{12};\mathsf{inc}_{11}),\\ \mathsf{bmark} &= \mathsf{seek}_5;\mathsf{left}^2;\mathsf{write}\,1;\mathsf{home}_7.\end{aligned}$$

Let τ *be a working workspace of* R *rows on which track* 4 *carries* H*, with* $12+12H \le R$*, and let* $\beta(x) = 0$ *for every* $x<0$*. Then* binit *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *within* $10^6(R+1)^2$ *units, where the bank of width* H *is laid out on* τ' *and every other cell of its bank view holds* 0*; tracks* 5*,* 11 *and* 4 *carry* $12+12H$*,* H *and* H*; only tracks* 5*,* 7 *and* 11 *are written; and the cells* $x \ge 0$ *are unchanged.*

Proof. clear_7 ($53R+22$ units, Lemma I.16) sets $(q,7)$ to 0 for $q \le R$; the rows beyond R are blank, and β vanishes on the negative indices, so now $\beta = 0$. zero_5 and inc_5^{12} put the counter 12 on track 5 ($17+3025$ units, Lemma I.14), and zero_{11} resets track 11. Let R_q say that track 5 carries $12+12q$, track 11 carries q, and $\beta(12+12k) = 1$ for $k<q$ while every other cell of β is 0. A pass from R_q, $q<H$: bmark goes to the hole $(12+12q,5)$, two cells left to $(12+12q,7) = \beta(12+12q)$, writes 1 and returns ($36(12+12q)+23$ units); inc_5^{12} and inc_{11} advance the two counters; at most $10\,000(R+1)$ units. By Lemma I.126(c) with the guard track 4, the H passes take at most $(H+1)\cdot 10\,200(R+1)$ units and end in R_H, in which the bank is laid out: $\beta(0)=0$, $\beta(12+12k)=1$ for $k<H$ and $\beta(12+12H)=0$. □

I.12.5 Horner's rule, the rounding and the write-back

The table entries are read bit by bit from the buffer, one signed word at a time, at the row that track 2 carries. Cells are copied between two cursors by short trips to the root.

Lemma I.176 (Reading and writing at a cursor)**.** *For tracks c and $v \geq 1$ put* $\mathsf{wrc}_{c,v}(b) = \mathsf{peek}_{c\to v}; \mathsf{write}\, b; \mathsf{home}_v$ *and* $\mathsf{rdc}_{c,v}(P_0, P_1) = \mathsf{peek}_{c\to v}; \mathsf{branch}(\mathsf{home}_v; P_0, \mathsf{home}_v; P_1)$*, and for a map $f : \{0,1\} \to \{0,1\}$ let* $\mathsf{cpb}^f_{c,v\to c',v'} = \mathsf{rdc}_{c,v}(\mathsf{wrc}_{c',v'}(f(0)), \mathsf{wrc}_{c',v'}(f(1)))$ *and* $\mathsf{lit}_k(p) = \mathsf{zero}_k; \mathsf{inc}^p_k$*. Let τ have origin marks up to q, and let track c carry q.*

(a) $\mathsf{wrc}_{c,v}(b)$ *runs from $(-1,\tau)$ to $(-1,\tau')$ in $36q + c + v + 9 + |c - v|$ units, τ' being τ with (q,v) set to b ($v \geq 2$). If $P_{\tau(q,v)}$ runs from $(-1,\tau)$ in t units to γ, then* $\mathsf{rdc}_{c,v}(P_0,P_1)$ *runs from $(-1,\tau)$ to γ in $36q + c + v + 9 + |c - v| + t$ units.*

(b) If also track c' carries q' and there are origin marks up to q', then $\mathsf{cpb}^f_{c,v\to c',v'}$ *sets (q', v') to $f(\tau(q,v))$ within $72\max(q,q') + 110$ units.*

(c) If $2 \leq k < 16$, $p \leq R$ and τ has origin marks up to R, $\mathsf{lit}_k(p)$ *makes track k carry p, writing only track k, within $100(p+1)(R+1)$ units.*

Proof. (a) $\mathsf{peek}_{c\to v}$ takes $18q + c + 4 + |c - v|$ units (Lemma I.126(a)), the write or the test one, and home_v from row q takes $18q + v + 4$. (b) is (a) twice, with all tracks below 16. (c) zero_k takes $2k + 7$ units and inc^p_k from 0 takes $18p^2 + (2k + 26)p + 1$ (Lemma I.14). □

Lemma I.177 (Loading a table entry)**.** *Put*

$$\mathsf{load} = \mathsf{dup}_{2\to 15}; \mathsf{rdc}_{2,13}(\mathsf{lb}(0), \mathsf{lb}(1)); \mathsf{dup}_{15\to 2},$$
$$\mathsf{lb}(b) = \mathsf{lit}_5(18); \mathsf{wrc}_{5,7}(b); \mathsf{inc}_2; \mathsf{lit}_5(16); \mathsf{lit}_{11}(0); \mathsf{rep}_{11,9}(\mathsf{lbit}(f_b)); \mathsf{lbit}(f_b); \mathsf{rep}_{11,4}(\mathsf{lbit}(e_b)),$$
$$\mathsf{lbit}(f) = \mathsf{cpb}^f_{2,13\to 5,7}; \mathsf{inc}_2; \mathsf{inc}^{12}_5; \mathsf{inc}_{11},$$

where $f_b(x) = x \oplus b$ and $e_b(x) = b$. Let τ be a working workspace of R rows on which tracks 2, 4 and 9 carry p, H and W, with $W + 1 \leq H$, $p + 1 + H \leq R$ and $16 + 12H \leq R$, and let the cells $(p + i, 13)$, $i < W + 2$, hold $\mathrm{sw}_W(z)$ for an integer z that fits W. Then load *runs from $(-1,\tau)$ to $(-1,\tau')$ within $20\,000(H+1)(R+1)$ units, where column 4 of the bank of τ' holds the H lowest binary digits of $|z|$, each complemented if $z < 0$, the cell $\beta(18)$ holds $[z < 0]$, track 2 carries p again, τ' is a working workspace of R rows, and τ' differs from τ only on tracks 2, 5, 11 and 15 and in the columns 4 and 6 of the twelve-cell rows at 12 of the bank view; no cell $x \geq 0$ is written.*

Proof. $\mathsf{dup}_{2\to 15}$ ($76R + 50$ units) saves track 2 on track 15. The test reads the sign bit $b = \tau(p, 13) = [z < 0]$ (Lemma I.176(a)). In $\mathsf{lb}(b)$, the first two parts write b into $(18, 7) = \beta(18)$, the carry-in of bank row 0; inc_2 moves the read cursor to the first digit $p + 1$; and the two literals point track 5 at $(16, 7) = \beta(16)$, column 4 of bank row 0, and reset track 11: at most $5000(R + 1)$ units. Let L_i ($i \leq H$) say that tracks 2, 5 and 11 carry $p + 1 + i$, $16 + 12i$ and i, and that column 4 of the bank rows $k < i$ holds the bits $\beta(16 + 12k) = \phi_k$, where ϕ_k is the digit k of $|z|$ (which is 0 for $k > W$) complemented if $b = 1$. From L_i, $\mathsf{lbit}(f)$ copies f of the cell $(p + 1 + i, 13)$ into $(16 + 12i, 7)$ and advances the three counters by 1, 12 and 1: at most $3000(R + 1)$ units (Lemma I.176(b) and Lemma I.14). With $f = f_b$ and $i \leq W$ the copied bit

is the digit i of $|z|$ xor b, which is ϕ_i; with $f = e_b$ and $W < i < H$ it is b, which is ϕ_i because the digit is 0. So $\mathsf{rep}_{11,9}(\mathsf{lbit}(f_b))$ (guard 9, Lemma I.126(c)) leads from L_0 to L_W, one more $\mathsf{lbit}(f_b)$ to L_{W+1}, and $\mathsf{rep}_{11,4}(\mathsf{lbit}(e_b))$ (guard 4, Lemma I.163(a) from $s = W+1$) to L_H, within $(H+2)\cdot 3200(R+1)$ units in all. Finally $\mathsf{dup}_{15\to 2}$ $(76R+50)$ restores track 2, which carried p. The total is at most $20\,000(H+1)(R+1)$. □

Lemma I.178 (Adding a table entry, and the Horner loop)**.** *Put*

$$\begin{aligned}\mathsf{addc} &= \mathsf{load};\mathsf{bcall}(\mathsf{badd}), \qquad \mathsf{lsh} = \mathsf{zero}_{11};\mathsf{rep}_{11,10}(\mathsf{bcall}(\mathsf{bshl});\mathsf{inc}_{11}),\\ \mathsf{str} &= \mathsf{zero}_{11};\mathsf{rep}_{11,6}(\mathsf{inc}_2;\mathsf{inc}_{11}),\\ \mathsf{Horner} &= \mathsf{zero}_{14};\mathsf{addc};\mathsf{rep}_{14,8}(\mathsf{lsh};\mathsf{str};\mathsf{addc};\mathsf{inc}_{14}).\end{aligned}$$

Let τ be a working workspace of R rows with $12 + 1000(H+1) \le R$, on which the bank of width H is laid out.

(a) Under the hypotheses of Lemma I.177, if column 2 reads x and $-2^{H-1} \le x+z < 2^{H-1}$, then addc *runs within $50\,000(H+1)(R+1)$ units to a working workspace of R rows on which column 2 reads $x+z$, the bank is still laid out and track 2 carries p; only tracks 2, 5, 7, 11 and 15 are written, no positive cell off the bank view, and no bank cell $\beta(x)$ with $x < -R$.*

(b) If track 10 carries $\sigma \le R$, column 2 reads x and $-2^{H-1} \le 2^q x < 2^{H-1}$ for $q \le \sigma$, then lsh *runs within $5000(\sigma+1)(R+H+1)$ units to a working workspace of R rows on which column 2 reads $2^\sigma x$ and the bank is still laid out; only tracks 7 and 11 are written, no positive cell off the bank view, and no bank cell $\beta(x)$ with $x < -R$.*

(c) If track 6 carries L and track 2 carries p with $p + L \le R$, str *runs within $1000(L+1)(R+1)$ units to a tape on which track 2 carries $p+L$; only tracks 2 and 11 are written, and no cell $x \ge 0$.*

(d) Let $z_0, \dots, z_N$ fit W, put $E = \sigma N$, $H = W + E + N + 4$ and $T_k = \sum_{l\le k} 2^{\sigma(k-l)} z_l$, let column 2 hold 0, and let tracks 2, 4, 6, 8, 9 and 10 carry $j(W+2)$, H, $d(W+2)$, N, W and σ, where $j < d$, $(kd+j+1)(W+2)+H \le R$ for $k \le N$ and $\sigma \le R$. Let the cells $((kd+j)(W+2)+i, 13)$, $i < W+2$, hold $\mathrm{sw}_W(z_k)$ for $k \le N$. Then Horner *runs from $(-1,\tau)$ within*

$$\Gamma_{\mathrm{H}} = 200\,000(N+1)\big(\sigma + d(W+2) + H + 1\big)(R+H+1)$$

units to a working workspace of R rows on which column 2 reads $T = T_N$ and the bank is still laid out; only tracks 2, 5, 7, 11, 14 and 15 are written, no positive cell off the bank view, and no bank cell $\beta(x)$ with $x < -R$.

Proof. (a) After load, column 4 holds y with $\mathrm{val}(y) = |z|$ if $z \ge 0$ and $2^H - 1 - |z|$ if $z < 0$, and the carry-in $\beta(18)$ holds $[z < 0]$. By Lemmas I.173(a) and I.172, bcall(badd) makes column 2 hold the H lowest bits of $\mathrm{val}(x) + |z|$ or of $\mathrm{val}(x) + 2^H - |z|$, a word whose value is congruent to $x+z$ modulo 2^H; in the stated range its sval_H is $x+z$. The call costs at most $17(128H+58)+18R+212$ units, so addc costs at most $50\,000(H+1)(R+1)$. The load writes no cell $x \ge 0$, and badd runs at most $128H + 58 \le 1000(H+1)$ units from 12; a unit moves the head by at most one cell, so it writes only cells $\beta(x)$ with $|x-12| \le 1000(H+1)$, which lie

between $-R$ and R. So the working workspace is kept and no bank cell below $-R$ is written. The same holds for every bank program of (b).

(b) Let R_q ($q \le \sigma$) say that column 2 reads $2^q x$ and track 11 carries q. A pass calls bshl (at most $17(76H+51)+18R+212$ units, Lemma I.173(b)) and increments track 11, reaching R_{q+1} within $4000(R+H+1)$ units. Lemma I.126(c) with the guard track 10 gives the bound.

(c) σ is replaced by the L marks of track 6: each pass increments tracks 2 and 11 ($36(p+q)+48+36q+66$ units), and Lemma I.126(c) gives at most $(L+1)\cdot 1000(R+1)$.

(d) zero_{14} resets track 14. Let H_k ($k \le N$) say that column 2 reads T_k, tracks 2 and 14 carry $(kd+j)(W+2)$ and k, the bank is laid out, and the other conditions of the lemma hold. Since $T_0 = 0 + z_0$ and $|T_0| < 2^{H-2}$ (Lemma I.158(d)), (a) with $p = j(W+2)$ leads to H_0. A pass from H_k, $k < N$: by (b), lsh makes column 2 read $2^\sigma T_k$, the range holding because $\sigma k + q \le E$ for $q \le \sigma$ (Lemma I.158(d)); by (c), str moves track 2 to $((k+1)d+j)(W+2)$; by (a), addc adds z_{k+1}, and $2^\sigma T_k + z_{k+1} = T_{k+1}$ is in range; inc_{14} advances track 14. Each pass reaches H_{k+1} within $100\,000(\sigma + d(W+2) + H + 1)(R+H+1)$ units, and Lemma I.126(c) with the guard track 8 gives the bound Γ_{H}. The written cells are those of (a)–(c). □

Lemma I.179 (The rounding)**.** *Put*

$$\mathsf{Round} = \mathsf{zero}_{14}; \mathsf{bcall}(\mathsf{left}^2; \mathsf{write}\,0; \mathsf{right}^2); \mathsf{rep}_{14,12}(\mathsf{bcall}(\mathsf{bshr}); \mathsf{inc}_{14}); \mathsf{bcall}(\mathsf{bround}); \mathsf{bcall}(\mathsf{bemit}).$$

Let τ be a working workspace of R rows with $12 + 1000(H+1) \le R$, on which the bank of width H is laid out, tracks 4 and 12 carry H and $E \le R$, and column 2 reads an integer T with $|T| < 2^{H-2}$. Put $V = \lfloor (2T + 2^E)/(2 \cdot 2^E) \rfloor$. Then Round *runs from $(-1,\tau)$ to $(-1,\tau')$ within*

$$\Gamma_{\mathrm{R}} = 20\,000(E+1)(R+H+1)$$

units to a working workspace of R rows, where the cells $\beta(6+12k)$, $k \le H$, of the bank view of τ' hold the bits of $\mathrm{sw}_{H-1}(V)$; only tracks 7 and 14 are written, no positive cell off the bank view, and no bank cell $\beta(x)$ with $x < -R$.

Proof. zero_{14} (35 units) and the first call (within $17 \cdot 7 + 18R + 212$ units) reset track 14 and the guard $\beta(10)$. Let S_k ($k \le E$) say that column 2 reads $q_k = \lfloor T/2^k \rfloor$, track 14 carries k, the guard holds 0 if $k = 0$ and $q_{k-1} \bmod 2$ if $k \ge 1$, and the bank is laid out. By Lemmas I.173(c) and I.158(c), a pass of the repetition, $\mathsf{bcall}(\mathsf{bshr})$ (at most $17(118H+76)+18R+212$ units) and inc_{14}, leads from S_k to S_{k+1} within $4000(R+H+1)$ units, and Lemma I.126(c) with the guard track 12 bounds the E passes by $(E+1)\cdot 4200(R+H+1)$. In S_E column 2 reads q_E and the guard holds g, with $g = q_{E-1} \bmod 2$ if $E \ge 1$ and $g = 0$ if $E = 0$. By Lemma I.158(c),(d), $q_E + g = V$ and $-2^{H-1} \le V < 2^{H-1}$, so $\mathsf{bcall}(\mathsf{bround})$ makes column 2 read V (Lemma I.173(d), within $17(167H+107)+18R+212$ units). Since V fits $H-1$, $\mathsf{bcall}(\mathsf{bemit})$ writes $\mathrm{sw}_{H-1}(V)$ into the cells $\beta(6+12k)$ (Lemma I.174, within $17(428H+483)+18R+212$ units). Each bank program called here runs at most $428H + 483 \le 1000(H+1)$ units from 12 on the bank view, so, as in the proof of Lemma I.178(a), it writes only cells $\beta(x)$ with $-R \le x \le R$. The sum of the bounds is at most Γ_{R}. □

Lemma I.180 (Writing the word back). *Put* $\mathsf{wb} = \mathsf{cpb}^{\mathrm{id}}_{5,7\to 2,13};\mathsf{inc}_2;\mathsf{inc}^{12}_5;\mathsf{inc}_{11}$ *and* $\mathsf{Wback} = \mathsf{lit}_5(6);\mathsf{zero}_{11};\mathsf{wp}(\mathsf{wb})$. *Let τ be a working workspace of R rows on which tracks 2 and 9 carry a and W, with $W+1\le H$, $a+W+2\le R$ and $6+12(W+2)\le R$, and let the cells $\beta(6+12k)$, $k\le H$, hold $\mathrm{sw}_{H-1}(V)$. Then* Wback *runs from $(-1,\tau)$ to $(-1,\tau')$ within $\Gamma_{\mathrm{W}}=10\,000(W+3)(R+1)$ units, where the cells $(a+k,13)$, $k<W+2$, hold the bits of $\mathrm{sw}_W(V)$, every other cell of track 13 is unchanged, track 2 carries $a+W+2$, only tracks 2, 5, 11 and 13 are written, and the bank view and the cells $x\ge 0$ are unchanged.*

Proof. The first $W+2$ bits of $\mathrm{sw}_{H-1}(V)$ and of $\mathrm{sw}_W(V)$ agree: both are $[V<0]$ followed by the lowest binary digits of $|V|$, and $W+1\le H$. $\mathsf{lit}_5(6)$ points track 5 at $(6,7)=\beta(6)$ and zero_{11} resets track 11. Let Q_k ($k\le W+2$) say that tracks 2, 5 and 11 carry $a+k$, $6+12k$ and k and that the cells $(a+i,13)$, $i<k$, hold the first k bits. A run of wb from Q_k copies $\beta(6+12k)$ into $(a+k,13)$ and advances the counters, within $3000(R+1)$ units (Lemma I.176(b)). By Lemma I.163(b) the $W+2$ runs take at most $(W+3)\cdot 3200(R+1)$ units, and with the first two parts at most Γ_{W}. □

I.12.6 Preparing and restoring the workspace

For the rest of the section fix $j<d$, a tape τ in the state C_j, and put

$$a=j(W+2),\qquad E=\sigma N,\qquad H=W+E+N+4,\qquad R=r+1+E+H+1000(H+1)+20,$$

and $\theta_k=\theta^r_k(\tau)$ for the snapshots of τ. Since the buffer word has $\ell=(N+1)d(W+2)\le r$ bits, $a+W+2\le d(W+2)\le r$; also $r\ge 2$, $12+1000(H+1)\le R$, and $R\ge r+H+1$. The *saved word* is

$$\Omega = 1^a\,0\,\theta_3\theta_2\theta_4\theta_5\theta_7\theta_{12}\theta_{14}\theta_{15}\,0^R,$$

of length $|\Omega|=a+1+8(r+1)+R$: the address, a separator, the eight borrowed tracks and R entries of padding. For $\epsilon=+$ and $-$ put $\mathsf{pad}^\epsilon=\mathsf{dup}_{0\to 14};\mathsf{zero}_{11};\mathsf{rep}_{11,14}(\mathsf{m}^\epsilon;\mathsf{inc}_{11})$ with $\mathsf{m}^+=\mathsf{spush}(0)$ and $\mathsf{m}^-=\mathsf{spop}$; on a working workspace of R rows it pushes, or pops, R entries 0 within $10\,000(R+|w|+1)^2$ units, w being the stack before (Lemmas I.126 and I.167; track 14 carries R after the copy of the headers).

Lemma I.181 (Preparation). *Put* $\mathsf{Prep} = \mathsf{sav};\mathsf{bkp};\mathsf{Par};\mathsf{pad}^+;\mathsf{binit};\mathsf{zero}_2;\mathsf{cpre}$ *with* $\mathsf{bkp}=\mathsf{save}_3;\mathsf{save}_2;\mathsf{save}_4;\mathsf{save}_5;\mathsf{save}_7;\mathsf{save}_{12};\mathsf{save}_{14};\mathsf{save}_{15};\mathsf{skip}$. *Then* Prep *runs from $(-1,\tau)$ to $(-1,\tau_1)$ within*

$$\begin{aligned}\Gamma_{\mathrm{P}} &= 5000(r+a+1)^2+88\,001(r+a+1+8(r+1)+1)^2+\Gamma_{\mathrm{par}}\\ &\quad+10\,000(R+a+1+8(r+1)+1)^2+10^6(R+1)^2+11+2000(R+a+1)^2\end{aligned}$$

units (Γ_{par} of Lemma I.170(b)), where

(i) τ_1 is a working workspace of R rows on which tracks 3, 12, 4, 8, 9, 10 and 2 carry r, E, H, N, W, σ and a;

(ii) the bank of width H is laid out on τ_1, and every other cell of its bank view holds 0;

(iii) τ_1 holds the stack Ω;

(iv) τ_1 *agrees with* τ *on tracks* 6, 8, 9, 10 *and* 13, *and every cell* $x \geq 0$ *that is not of the form* $15 + 16i$ *holds* 0.

Proof. τ is a workspace of r rows with origin marks up to r, so it is a working workspace of r rows, its positive half is blank and it holds the empty stack. Track 11 carries $a \leq r$. By Lemma I.169(a), sav leaves the stack 1^a0 and track 11 at 0; it wrote only track 11 among the rows, which is not saved, so by Lemma I.168(a) bkp pushes $\theta_3\theta_2\theta_4\theta_5\theta_7\theta_{12}\theta_{14}\theta_{15}$, the snapshots of τ itself. The counters on tracks 8, 9 and 10 are at most $r + 1$ (Lemma I.4), so Lemma I.170(b) applies to Par: R rows, and r, E, H on tracks 3, 12, 4. pad^{+} pushes 0^R. Every positive cell $-9 - 16x$ is still blank, so Lemma I.175 lays out the bank and clears the rest of the bank view. zero_2 (11 units) and, by Lemma I.169(b), cpre put a on track 2. The bounds of the seven parts are the seven terms of Γ_{P}, with $|w| = 0$, $a + 1$, $a + 1 + 8(r + 1)$ for the three uses of the stack lemmas. The tracks written are 0, 1, 2, 3, 4, 5, 7, 11, 12 and 14, and no positive cell outside the stack and the bank. □

Lemma I.182 (Restoration)**.** *Put*

$$\begin{aligned}
\mathsf{Restore} &= \mathsf{clear}_7; \mathsf{cpos}; \mathsf{pad}^{-}; \mathsf{zero}_{11}; \mathsf{rtail}; \mathsf{shrink}; \mathsf{rest}_3; \mathsf{spop}; \mathsf{fin},\\
\mathsf{rtail} &= \mathsf{skip}; \mathsf{rest}_{15}; \mathsf{rest}_{14}; \mathsf{rest}_{12}; \mathsf{rest}_7; \mathsf{rest}_5; \mathsf{rest}_4; \mathsf{rest}_2,\\
\mathsf{cpos} &= \mathsf{right}^8; \mathsf{write}\,0; \mathsf{right}^{16}; \mathsf{write}\,0; \mathsf{right}^{24};\\
&\qquad \mathsf{loop}(\mathsf{left}^8; \mathsf{write}\,0; \mathsf{right}^{16}; \mathsf{write}\,0; \mathsf{right}^{24}); \mathsf{left}^{32}; \mathsf{loop}(\mathsf{left}^{32}); \mathsf{left}^{16}.
\end{aligned}$$

Let τ_4 *be a working workspace of* R *rows on which tracks* 3 *and* 9 *carry* r *and* W, *which holds the stack* Ω, *whose positive cells not of the forms* $15 + 16i$ *and* $-9 - 16x$ *hold* 0, *and whose bank view vanishes below* $-R$. *Then* $\mathsf{Restore}$ *runs from* $(-1, \tau_4)$ *to* $(-1, \tau_5)$ *within*

$$\Gamma_{\mathrm{X}} = 10^8(R + a + W + r + 1)^2$$

units, where τ_5 *is a workspace of* r *rows with origin marks up to* r, *track* 11 *carries* $a + W + 2$, $\tau_5(q, k) = \tau(q, k)$ *for* $q \leq r$ *and* $k \in \{2, 3, 4, 5, 7, 12, 14, 15\}$, *and* $\tau_5(q, k) = \tau_4(q, k)$ *for* $q \leq r$ *and every other track* $k \neq 0, 11$.

Proof. clear_7 ($53R + 22$ units) clears track 7 in the rows $q \leq R$. cpos goes to the cells $7 = \beta(-1)$ and $23 = \beta(-2)$ and clears them, and reaches $\varsigma(2) = 47$. While the presence cell $\varsigma(2 + 2k) = 47 + 32k$ of the entry k holds 1, a pass clears the bank cells $39 + 32k = \beta(-3 - 2k)$ and $55 + 32k = \beta(-4 - 2k)$ and moves to the next presence cell (54 units with its test). After the $L = |\Omega|$ passes it returns over the presence cells to $\varsigma(0) = 15$ and to the root: $88L + 105$ units in all, and $\beta(x) = 0$ now for $-2L - 2 \leq x \leq -1$, hence for all $x < 0$, since $L \geq R$. No stack cell is written. pad^{-} pops the padding, zero_{11} resets track 11, and by Lemma I.168(b) rtail restores tracks 15, 14, 12, 7, 5, 4 and 2 in the rows $q \leq r$ from their snapshots, track 3 carrying r throughout. By Lemma I.170(c), shrink returns to a working workspace of r rows, blank beyond row r; then rest_3 (Lemma I.168(b) with $R = r$) restores track 3, spop removes the separator, and by Lemma I.169(c), fin leaves $a + W + 2$ on track 11 and empties the stack view on the cells $x \geq 0$. These last three write only rows $q \leq r$ and stack cells. Now every positive cell holds 0: the stack cells by fin, the bank cells by cpos and the others by hypothesis; the root still holds 1; so τ_5 is a workspace of r rows with origin marks up to r. Tracks other than 0,

11 and the borrowed ones were written only in rows beyond r (by shrink). The bounds of the nine parts, with $L + R + 1 \le 10(R + a + W + r + 1)$ and $R + a + 9r + 10 \le 10(R + a + W + r + 1)$, add up to at most $10^6 + 2.1 \cdot 10^7 + 2 \cdot 10^5$ times $(R + a + W + r + 1)^2$, which is less than Γ_{X}. □

I.12.7 Proof of Theorem I.160

Proof of Theorem I.160. Keep the notation of Section I.12.6, and let $z_{k,j}$ be the entry j of the row k of the table. By Lemma I.181, Prep runs from $(-1, \tau)$ within Γ_{P} units to $(-1, \tau_1)$.

Horner. On τ_1 the bank is laid out with column 2 equal to 0, and tracks 2, 4, 6, 8, 9, 10 carry $a = j(W + 2)$, H, $d(W + 2)$, N, W, σ: track 6 is the presence track of the stored vector, kept from τ. By (iv) of Definition I.159 and Lemma I.181(iv), the cells $((kd + j)(W + 2) + i, 13)$, $i < W + 2$, hold $\mathrm{sw}_W(z_{k,j})$ for $k \le N$: only the words $0, \dots, j - 1$ of the first row have been replaced, and $kd + j \ge j$. Also $(kd + j + 1)(W + 2) + H \le \ell + H \le R$ and $\sigma \le r + 1 \le R$. So Lemma I.178(d) runs Horner within Γ_{H} units to τ_2, on which column 2 reads $T = \sum_l 2^{\sigma(N-l)} z_{l,j}$.

Rounding. $|T| < 2^{H-2}$ by Lemma I.158(d), and tracks 4 and 12 still carry H and $E \le R$. By Lemma I.179, Round runs within Γ_{R} units to τ_3, on which the cells $\beta(6 + 12k)$, $k \le H$, hold $\mathrm{sw}_{H-1}(V_j)$, where by Lemma I.158(a)

$$V_j = \left\lfloor \frac{2T + 2^E}{2 \cdot 2^E} \right\rfloor = \mathrm{near}\Big(\sum_{l \le N} 2^{-\sigma l} z_{l,j} \Big).$$

Write-back. Horner and Round wrote no stack cell and no row cell outside tracks 2, 5, 7, 11, 14 and 15. zero_2 (11 units) and cpre (Lemma I.169(b), within $2000(R + a + 1)^2$ units, the stack being $\Omega = 1^a 0 \cdots$) put a on track 2 again. By Lemma I.180, Wback runs within Γ_{W} units to τ_4, on which the cells $(a + k, 13)$, $k < W + 2$, hold $\mathrm{sw}_W(V_j)$ and the rest of track 13 is as on τ.

Restoration. τ_4 satisfies the hypotheses of Lemma I.182: it is a working workspace of R rows (tracks 0 and 1 were not written after Prep), tracks 3 and 9 carry r and W, the stack is Ω, the positive cells outside the stack and the bank were never written, and no bank cell $\beta(x)$ with $x < -R$ was written after Prep, so these still hold 0. So Restore runs within Γ_{X} units to $\tau_5 = \tau'$.

The state C_{j+1}. τ' is a workspace of r rows with origin marks up to r, and track 11 carries $a + W + 2 = (j + 1)(W + 2)$. The borrowed tracks 2, 3, 4, 5, 7, 12, 14, 15 agree with τ in the rows $q \le r$, and beyond row r both tapes are blank. The tracks 6, 8, 9 and 10 were never written, so they agree with τ too; with tracks 3, 4, 5, 2, 14 and 15 this proves that the protected tracks are kept, and with tracks 6, 7, 12 that (ii) and (iii) of Definition I.159 hold. Track 13 is that of τ_4: the word j of the first row now holds $\mathrm{sw}_W(V_j)$, which is the word j of $\mathrm{sw}_W(V)$, and every other cell is as on τ. So τ' is in the state C_{j+1}.

The count. The units add up to

$$\Gamma = \Gamma_{\mathrm{P}} + \Gamma_{\mathrm{H}} + \Gamma_{\mathrm{R}} + 11 + 2000(R + a + 1)^2 + \Gamma_{\mathrm{W}} + \Gamma_{\mathrm{X}}.$$

Put $Y = d + \sigma + N + W + r + 1$ and $U = 20\,000 Y^2$. Since $\sigma, N, W, r, d < Y$,

$$E \le Y^2, \qquad H \le 7Y^2, \qquad R \le r + 1 + E + 1001H + 1020 \le 10^4 Y^2,$$

$a \le r$, $W + 2 \le 2Y$ and $\sigma(N+1) \le Y^2$. Hence every factor in the terms of Γ — such as $R + a + W + r + 1$, $R + H + 1$, $\sigma + d(W+2) + H + 1$, $r + 1 + \sigma(N+1) + N + 1$ and $N + 1$ — is at most U, and each term is a constant times a product of at most three such factors. The constants of the terms add up to less than $1.2 \cdot 10^9$, and the linear terms of Γ_{par} and the two terms 11 are less than $100U$. So

$$\Gamma \le 2 \cdot 10^9 U^3 = 2 \cdot 10^9 \cdot 8 \cdot 10^{12}\, Y^6 < 10^{31}\, Y^6. \qquad \square$$

The exponent 6 is that of U^3: every term of the count is a constant times at most three factors, and each factor is at most quadratic in Y, because the exponent $E = \sigma N$ of the rounding, the width H of the arithmetic and the row count R of a coordinate are.

I.13 The step loop and the selected word

After the first vector the machine repeats one Taylor step S times and then looks for the answer. Where is it? After S steps the binary stream holds $\mathrm{sw}_W(Z_S)$, the d signed words of the last vector, and the request asks for coordinate i. The machine reads i from the next-to-last frame of the saved request, walks to bit $i(W+2)$ of the stream, copies the $W+2$ bits of word i to the front of the stream and ends it there. For the oscillator of Section I.11, with $d = 2$ and $i = 1$, the stream $\mathrm{sw}_W(Z_{S,0})\,\mathrm{sw}_W(Z_{S,1})$ becomes $\mathrm{sw}_W(Z_{S,1})$. This section proves the loop rule for the steps, constructs the selection and the emptying of the buffer, and composes the whole trajectory: the first vector, the S steps and the selection, with the exponent $762700(g+20)$.

I.13.1 The step contract and the loop

The notation is that of Section I.10.1. For an integer vector Z of length d write Z^+ for the vector that Lemma 15.35, with $w = N$, obtains from $Z_k = Z$: the rows $r_0 = Z$ and $r_{l+1} = \mathrm{near}\big(2^N \mathrm{next}(f, l)\big)$ with $f_j = r_j / 2^N$ for $l < N$, and then $Z^+ = \mathrm{near}\big(2^N S_N(f)\big)$. So $Z_{k+1} = Z_k^+$.

Definition I.183 (The step contract)**.** A program P *meets the step contract with exponent* g if for every problem with a coefficient field and every level n_0 there is a constant K, depending only on the problem and n_0, with the following property. Let $i < d$, m, r and $c < S$, let Z be an integer vector of length d with $\|Z/2^N\| \le M$, and let τ hold the stored vector Z on r rows, with the counter c on track 2 and a retained word of length S from row 0 on track 14. Then P runs from $(-1, \tau)$ to $(-1, \tau')$ in some number t of units, where

(a) τ' holds the stored vector Z^+ on the same r rows;

(b) $\tau'(q, 2) = \tau(q, 2)$ and $\tau'(q, 14) = \tau(q, 14)$ for every $q \le S$;

(c) $t \le K(X + r + 1)^g$.

The rows do not change, so the bound counts the units alone (Definition I.7). The stored step of Section I.12, the coefficient table followed by the Taylor sum, meets this contract (Theorem I.162).

Theorem I.184 (The step loop)**.** *Let P meet the step contract with exponent g, and let K_{s} be its constant for the problem and n_0. Let r, $i < d$ and m, and let τ hold the stored vector Z_0 on r rows, with the counter 0 on track 2 and a retained word of length S from row 0 on track 14. Then $\mathsf{repeat}_2(P)$ of Lemma I.18 runs from $(-1,\tau)$ to $(-1,\tau')$ in some number t of units, where τ' holds the stored vector Z_S on the same r rows and*

$$t + r + 1 \le \big(S(36S + K_{\mathrm{s}} + 58) + 18S + 40\big)(X + r + 1)^{g+1}.$$

Proof. Apply Lemma I.18 with $c = 2$, $r_0 = 0$, $n = S$, $b = K_{\mathrm{s}}(X + r + 1)^g$ and R_k, for $k \le S$, the property of holding the stored vector Z_k on r rows. Every tape with R_k has origin marks up to r, and $r \ge \rho_{\mathrm{traj}} \ge S$, so it has origin marks up to S. Let $k < S$ and let σ be a tape with R_k on which track 2 carries k and track 14 the retained word. Since $n \ge n_0$ and $k \le S$, Lemma 15.35 and Theorem 15.20 give $\|Z_k/2^N\| = \|y_k^{(n)}\| \le M$. So the step contract applies to σ with $c = k$: P runs from $(-1,\sigma)$ within b units to some $(-1,\sigma_1)$ that holds the stored vector $Z_k^+ = Z_{k+1}$ on r rows and agrees with σ on the cells $(q,2)$ and $(q,14)$, $q \le S$. The tape σ_2 obtained from σ_1 by setting $(k,2)$ to 1 and $(k+1,2)$ to 0 still has R_{k+1}: Definition I.101 does not mention track 2, and the two cells lie in rows $k+1 \le S \le r$, so the workspace and the origin marks are kept. This is the hypothesis of Lemma I.18, which gives a run of $\mathsf{repeat}_2(P)$ to a tape with R_S. Every tape with some R_k is a workspace of r rows and $S \le r$, so Lemma I.19 with $Y = X + r + 1 \ge r + 1$ gives the bound. □

So the loop adds 1 to the exponent of the step and puts the number S of steps into the constant only, however large the precision.

I.13.2 The selected word and the empty buffer

The selection is

$$\begin{aligned}
\mathsf{Select} &= \mathsf{Read};\mathsf{Slice},\\
\mathsf{Read} &= \mathsf{cur}_2;\mathsf{dup}_{5\to11};\mathsf{dup}_{8\to12};\mathsf{dup}_{7\to13};\mathsf{dup}_{9\to14};\mathsf{skip};\mathsf{clear}_{8,9};\mathsf{dup}_{2\to5};\mathsf{nat};\\
&\qquad \mathsf{dup}_{8\to2};\mathsf{dup}_{13\to7};\mathsf{dup}_{11\to5};\mathsf{dup}_{12\to8};\mathsf{dup}_{2\to13};\mathsf{dup}_{14\to9};\mathsf{skip},\\
\mathsf{Slice} &= \mathsf{Locate};\mathsf{Cut},
\end{aligned}$$

with cur_2 of Section I.10.2, dup of Lemma I.126, nat of Lemma I.128, and Locate and Cut of Lemma I.186. Read finds the frame of i, saves the counters m, N, W and the values of the stored vector on tracks 11 to 14, decodes i in unary, and copies everything back, with i on track 13. Slice moves a cursor on track 2 to row $i(W+2)$ and copies the $W+2$ bits of word i to the rows $0,\dots,W+1$ of the binary stream. The empty buffer is the program $\mathsf{empty} = \mathsf{clear}_{11,12}$ of Lemma I.125(a).

A word of the stream has $W+2$ bits, and the register W on track 9 counts all but two of them; the program $\mathsf{wp}(P) = \mathsf{rep}_{11,9}(P);P;P$ of Lemma I.163(b) runs P once per bit. Moving a cursor and copying bits use

$$\begin{aligned}
\mathsf{sk} &= \mathsf{inc}_2;\mathsf{inc}_{11}, \qquad \mathsf{Locate} = \mathsf{zero}_2;\mathsf{zero}_{12};\mathsf{rep}_{12,13}\big(\mathsf{zero}_{11};\mathsf{wp}(\mathsf{sk});\mathsf{inc}_{12}\big),\\
\mathsf{out}_b &= \mathsf{seek}_{11};\mathsf{shift}_{11\to6};\mathsf{write}\,1;\mathsf{left};\mathsf{write}\,b;\mathsf{home}_7,\\
\mathsf{xbit} &= \mathsf{peek}_{2\to7};\mathsf{branch}\big(\mathsf{home}_7;\mathsf{out}_0;\mathsf{sk},\ \mathsf{home}_7;\mathsf{out}_1;\mathsf{sk}\big),\\
\mathsf{Cut} &= \mathsf{zero}_{11};\mathsf{wp}(\mathsf{xbit});\mathsf{seal}_6, \qquad \mathsf{seal}_6 = \mathsf{seek}_{11};\mathsf{shift}_{11\to6};\mathsf{write}\,0;\mathsf{home}_6.
\end{aligned}$$

Lemma I.185 (Reading the coordinate). *Let τ hold the stored vector Z on r rows, for an integer vector Z of length d. Then* Read *runs from $(-1,\tau)$ to $(-1,\tau_1)$ within $20000(r+1)^2$ units, where track 13 of τ_1 carries i, tracks 5, 8 and 9 carry m, N and W, $\tau_1(q,7)=\tau(q,7)$ for every $q\le r$, and τ_1 is a workspace of r rows with origin marks up to r.*

Proof. The last two frames of the request are those of i and m, so by Section I.10.2 cur_2 leaves on track 2 the row s of the frame of i, within $106(r+1)$ units, and changes only tracks 2 and 14. The next four copies (Lemma I.126(b), at most $102r+76$ units each) put the cells of rows $j\le r$ of tracks 5, 8, 7 and 9 onto tracks 11, 12, 13 and 14. $\mathsf{clear}_{8,9}$ ($112r+51$ units) blanks tracks 8 and 9, and $\mathsf{dup}_{2\to5}$ makes track 5 carry s. The frame of i is followed by that of m, so $s+\mathrm{bl}(i)+1<|w_u|\le r+1$, and $i+1\le r$ by the reserve. So Lemma I.128 applies: nat runs within $10000(r+1)^2$ units, leaves the counter i on track 8, changes only tracks 5 to 10, and keeps every cell $x\ge -1$ and every row beyond r. Tracks 11 to 14 have not been written since the backup. The last six copies put the counter i on track 2, the old track 7 back on track 7, m on track 5, N on track 8, i on track 13 and W on track 9. Copies write only rows $j\le r$ of tracks other than 0 and 1, so the workspace and the origin marks are kept. The total is at most $106(r+1)+10(102r+76)+112r+53+10000(r+1)^2\le 20000(r+1)^2$. □

Lemma I.186 (Cutting out a word). *Let τ be a workspace of r rows with origin marks up to r on which track 13 carries i and track 9 carries W, with $(i+1)(W+2)\le r$, and let $b_j=\tau(i(W+2)+j,7)$ for $j<W+2$.*

(a) Locate *runs from $(-1,\tau)$ to $(-1,\tau')$ within $4000(i+1)(W+3)(r+1)$ units; track 2 of τ' carries $i(W+2)$, and only tracks 2, 11 and 12 change.*

(b) Slice = Locate; Cut *runs from $(-1,\tau)$ to $(-1,\tau'')$ within $7000(i+1)(W+3)(r+1)$ units; the binary stream of τ'' holds $b_0\cdots b_{W+1}$, τ'' is a workspace of r rows with origin marks up to r, and only tracks 2, 6, 7, 11 and 12 change.*

Proof. (a) zero_2 and zero_{12} take 42 units. For $q\le i$ let R_q say that track 2 carries $q(W+2)$, track 12 carries q, and tracks 9 and 13 are as in τ. From R_q, $q<i$, the body sets the counter of track 11 to 0 (29 units); by Lemma I.163(b), with R'_j saying that tracks 2 and 11 carry $q(W+2)+j$ and j, wp(sk) advances both $W+2$ times, each run of sk taking at most $100(r+1)$ units, so within $300(W+3)(r+1)$ units; and inc_{12} ($36q+68$) reaches R_{q+1}. So the body takes at most $400(W+3)(r+1)$ units, and Lemma I.126(c) with $c=12$, $g=13$ and $n=i$ bounds the loop by $(i+1)(400(W+3)(r+1)+200(r+1))$.

(b) After Locate, zero_{11} (29 units) sets track 11 to 0. For $j\le W+2$ let C_j say that tracks 2 and 11 carry $i(W+2)+j$ and j, that $(q,6)=1$ and $(q,7)=b_q$ for $q<j$, and that the cells $(i(W+2)+q,7)$, $j\le q<W+2$, still hold b_q. From C_j, xbit reads $(i(W+2)+j,7)=b_j$, returns, writes 1 and b_j into $(j,6)$ and $(j,7)$, and advances both counters: at most $500(r+1)$ units. Since $j\le i(W+2)+j$ and every later read is of a row above j, no unread cell is overwritten, also when $i=0$; so C_{j+1} holds. By Lemma I.163(b), wp(xbit) reaches C_{W+2} within $700(W+3)(r+1)$ units, and seal_6 ($36(W+2)+31$) writes the terminator $(W+2,6)=0$. Now the stream on tracks 6 and 7 from row 0 is $b_0\cdots b_{W+1}$. All writes are in rows $j\le(i+1)(W+2)\le r$ of tracks 2, 6, 7, 11 and 12. With (a) the total is at most $7000(i+1)(W+3)(r+1)$. □

Theorem I.187 (The selected word). *Let $r, i < d$ and m, let Z be an integer vector of length d whose entry Z_i fits W, and let τ hold the stored vector Z on r rows.*

(a) Select *runs from $(-1, \tau)$ to $(-1, \tau')$ in some number t of units, where the binary stream of τ' holds $\mathrm{sw}_W(Z_i)$, tracks 5, 8 and 9 carry the counters m, N and W, τ' is a workspace of the same r rows with origin marks up to r, and*

$$t + r + 1 \le 100000(r+1)^3 \le 100000(X + r + 1)^3.$$

(b) Select; empty *runs from $(-1, \tau)$ to $(-1, \tau'')$ in some number t of units, where τ'' has all the properties of τ' in (a), its output buffer holds the empty word with capacity r, and*

$$t + r + 1 \le 18\,800\,000\,(X + r + 1)^3.$$

The exponent of the stage is 3.

Proof. (a) By Lemma I.185, Read runs within $20000(r+1)^2$ units to a tape τ_1 with i on track 13, m, N, W on tracks 5, 8, 9, the cells $(q, 7)$, $q \le r$, of τ, and the same workspace and origin marks. By Definition I.101(c) the bits $b_0, \dots, b_{W+1}$ of $\mathrm{sw}_W(Z_i)$ are the cells $(i(W+2)+j, 7)$ of τ, and $(i+1)(W+2) \le d(W+2) < r$ by the reserve. So Lemma I.186 applies to τ_1: Slice runs within $7000(i+1)(W+3)(r+1)$ units to a tape τ' whose binary stream holds $b_0 \cdots b_{W+1} = \mathrm{sw}_W(Z_i)$, which keeps the workspace and the origin marks and changes only tracks 2, 6, 7, 11 and 12, so that tracks 5, 8 and 9 still carry m, N and W. Since $i + 1 \le r + 1$ and $W + 3 \le 3(r+1)$ (by the reserve, $W < r$),

$$t + r + 1 \le 20000(r+1)^2 + 21000(r+1)^3 + (r+1) \le 100000(r+1)^3,$$

and $r + 1 \le X + r + 1$.

(b) By Lemma I.125(a), empty takes $124r + 63 \le 187(r+1)$ units on the workspace of r rows, empties the output buffer with capacity r and changes only tracks 11 and 12, so the properties of (a) survive. Since $r + 1 \le 100000(X + r + 1)^3$, the total is at most $100000(X + r + 1)^3 + 187 \cdot 100000(X + r + 1)^3 = 18\,800\,000\,(X + r + 1)^3$. □

I.13.3 The whole trajectory

Let Step = Build; Sum be the stored step of Section I.12, with Build of Theorem I.121, and let $g = 118$ be the exponent of one entry of the coefficient table (Theorem I.119). By Theorem I.162, Step meets the step contract with exponent $g_{\mathrm{s}} = g + 18$. The trajectory stage is

$$\mathsf{Traj} = \mathsf{Init}; \mathsf{repeat}_2(\mathsf{Step}); \mathsf{Select}; \mathsf{empty}.$$

Theorem I.188 (The trajectory). *There is a constant K_{t}, depending only on the problem and n_0, with the following property. Let r, $i < d$ and m, and let τ be a scheduled request with r rows (Definition I.85). Then* Traj *runs from $(-1,\tau)$ to $(-1,\tau')$ in some number t of units, where for some r' the binary stream of τ' holds $\mathrm{sw}_W\big((Z_S)_i\big)$, tracks 5, 8 and 9 carry the counters m, N and W, the output buffer holds the empty word with capacity r', τ' is a workspace of r' rows, and*

$$t + r' + 1 \le K_{\mathrm{t}}(X + r + 1)^{762700(g+20)}.$$

With $g = 118$ the exponent is $762700 \cdot 138 = 105\,252\,600$.

Proof. Put $Y = X + r + 1 \ge 1$. By Theorem I.102, Init runs in t_1 units to a tape τ_1 that holds the stored vector Z_0 on r_1 rows, with the counter 0 on track 2 and the retained word of length S on track 14, and $t_1 + r_1 + 1 \le K_{\mathrm{i}} Y^{190674} \le K_{\mathrm{i}} Y^{190675}$. By Theorem I.184 with $P =$ Step and its constant K_{s}, $\mathsf{repeat}_2(\mathsf{Step})$ runs from τ_1 in t_2 units to a tape τ_2 that holds the stored vector Z_S on the same r_1 rows, and

$$t_2 + r_1 + 1 \le K_{\mathrm{l}}(X + r_1 + 1)^{g_{\mathrm{s}}+1} \le K_{\mathrm{l}}(Y + r_1 + 1)^{g_{\mathrm{s}}+1}, \qquad K_{\mathrm{l}} = S(36S + K_{\mathrm{s}} + 58) + 18S + 40.$$

Lemma 15.36(a) with Y for its N, $e = 190675$ and $g = g_{\mathrm{s}} + 1$ gives $t_1 + t_2 + r_1 + 1 \le LY^D$ with $L = K_{\mathrm{i}} + K_{\mathrm{l}}(K_{\mathrm{i}} + 1)^{g_{\mathrm{s}}+1}$ and $D = 190675(g_{\mathrm{s}} + 2)$. Every entry of Z_S fits W (Proposition I.32(a)), so Theorem I.187(b) applies to τ_2: Select; empty runs in t_3 units to a tape τ' with the stated properties on $r' = r_1$ rows, and $t_3 + r' + 1 \le K_{\mathrm{p}}(X + r_1 + 1)^3 \le K_{\mathrm{p}}(Y + r_1 + 1)^3$ with $K_{\mathrm{p}} = 18\,800\,000$. Lemma 15.36(a) again, with $e = D$ and $g = 3$, gives

$$t_1 + t_2 + t_3 + r' + 1 \le K_{\mathrm{t}} Y^{4D}, \qquad K_{\mathrm{t}} = L + K_{\mathrm{p}}(L + 1)^3.$$

Finally $4D = 4 \cdot 190675\,(g + 20) = 762700(g + 20)$, since $g_{\mathrm{s}} + 2 = g + 20$. □

The trajectory stage hands to the rounding stage of Section I.14 the stored integer $(Z_S)_i$ at precision N, the precision m and the width W; by Lemma 15.35 the rounding of $2^m (Z_S)_i / 2^N$ is the answer a_m.

I.14 Rounding and emitting the answer

When the step loop and the selection have run, the binary stream holds the signed word of one integer $z = (Z_S)_i$ at the working precision $w = N$, and the answer is $a_m = \mathrm{near}(2^m z / 2^w)$ (Lemma 15.35). Take $m = 1$, $w = 3$ and $z = -6$. Then $2^m z / 2^w = -3/2$, and $\mathrm{near}(-3/2) = \lfloor -1 \rfloor = -1$: a half is rounded upward, to -1 and not to -2. The machine never forms $2^m z$. It counts $w - m = 2$ on its unary registers and shifts the magnitude 6, with digits $0, 1, 1$ from the least significant, two places to the right. The digit that remains gives 1. The last digit shifted out, the *guard*, is 1; the OR of the digits shifted out before it, the *sticky* bit, is 0. For a nonnegative number a guard 1 always raises the magnitude by one. For a negative number it does so only when the sticky bit is 1 as well, because only then is the dropped part more than one half. Here the number is negative and the sticky bit is 0, so the magnitude stays 1 and the answer is -1. With $z = -7$ the guard and the sticky bit are both 1, the magnitude becomes 2, and the answer is $-2 = \mathrm{near}(-7/4)$.

This section writes that procedure as one program, proves that it leaves the signed word of $\mathrm{near}(2^m z / 2^w)$ in the binary stream, and proves its bound with exponent 7 (Theorem I.198). The arithmetic on magnitudes comes first, then the routines, then the stage.

I.14.1 Rounding a magnitude

For natural numbers n and k and a bit e put

$$\mu_e(n,k) = \Big\lfloor \frac{n}{2^k} \Big\rfloor + \begin{cases} [\,2^k \le 2(n \bmod 2^k)\,] & \text{if } e = 0, \\ [\,2^k < 2(n \bmod 2^k)\,] & \text{if } e = 1, \end{cases}$$

and write $(-1)^e n$ for the integer with magnitude n that is negative exactly when $e = 1$ and $n > 0$.

Lemma I.189 (Rounding on magnitudes). *Let $m \le w$, $k = w - m$, e a bit, $n \in \mathbb{N}$ and $z = (-1)^e n$. Then* $\mathrm{near}(2^m z / 2^w) = (-1)^e \mu_e(n,k)$.

Proof. By definition $\mathrm{near}(2^m z/2^w) = \lfloor (2^{m+1}z + 2^w)/2^{w+1} \rfloor = \lfloor (2z + 2^k)/2^{k+1} \rfloor$. Write $n = 2^k q + \rho$ with $0 \le \rho < 2^k$. If $e = 0$, then $(2n + 2^k)/2^{k+1} = q + (2\rho + 2^k)/2^{k+1}$, and the second term lies in $[1/2, 3/2)$; its floor is $[2\rho \ge 2^k]$. If $e = 1$, then $(-2n + 2^k)/2^{k+1} = -q + (2^k - 2\rho)/2^{k+1}$, and the second term lies in $(-1/2, 1/2]$; its floor is 0 when $2\rho \le 2^k$ and -1 when $2\rho > 2^k$. In both cases the value is $(-1)^e \mu_e(n,k)$, also when the magnitude is 0. □

The machine reaches $\mu_e(n,k)$ by k single shifts. For a word $x = x_0 x_1 \cdots x_{\ell-1}$ with $\ell \ge 1$ and bits g and s put

$$\theta(x, g, s) = \big(x_1 \cdots x_{\ell-1} 0,\ x_0,\ s \vee g \big)\ :$$

the word loses its lowest digit and gains a 0 on top, the guard becomes the digit that was lost, and the sticky bit absorbs the old guard. Write $(x^{(k)}, g_k, s_k) = \theta^k(x, 0, 0)$.

Lemma I.190 (Guard and sticky bit). *Let x be a word of length $\ell \ge 1$ and $n = \mathrm{val}(x)$. For every k, $|x^{(k)}| = \ell$ and, for each bit e,*

$$\mathrm{val}(x^{(k)}) + [\, g_k \wedge (\neg e \vee s_k) \,] = \mu_e(n,k).$$

Proof. The length is kept by every step. For $k = 0$ the guard is 0 and $\mu_e(n,0) = n$. For $k \ge 1$ we show by induction that $n = 2^k \mathrm{val}(x^{(k)}) + 2^{k-1} g_k + \rho_k$ with $0 \le \rho_k < 2^{k-1}$ and $s_k = [\rho_k > 0]$. For $k = 1$, $g_1 = x_0$, $s_1 = 0$, $\rho_1 = 0$ and $n = 2\,\mathrm{val}(x_1 \cdots x_{\ell-1}0) + x_0$. For the step write $x^{(k)} = bu$; then $\mathrm{val}(x^{(k)}) = 2\,\mathrm{val}(u0) + b$, $x^{(k+1)} = u0$, $g_{k+1} = b$, $s_{k+1} = s_k \vee g_k$, and with $\rho_{k+1} = 2^{k-1} g_k + \rho_k < 2^k$,

$$n = 2^{k+1}\,\mathrm{val}(x^{(k+1)}) + 2^k g_{k+1} + \rho_{k+1}, \qquad s_{k+1} = [\rho_k > 0] \vee g_k = [\rho_{k+1} > 0].$$

Hence $\lfloor n/2^k \rfloor = \mathrm{val}(x^{(k)})$ and $n \bmod 2^k = 2^{k-1} g_k + \rho_k$. Since $2\rho_k < 2^k$, the condition $2^k \le 2(n \bmod 2^k)$ holds exactly when $g_k = 1$, and $2^k < 2(n \bmod 2^k)$ exactly when $g_k = 1$ and $\rho_k > 0$, that is, when $g_k \wedge s_k$. So the bracket in $\mu_e(n,k)$ is g_k for $e = 0$ and $g_k \wedge s_k$ for $e = 1$, which is $[g_k \wedge (\neg e \vee s_k)]$ in both cases. □

I.14.2 The routines

Throughout this subsection the magnitude of the stored word is read from row 1: if the binary stream holds $\mathrm{sw}_W(z)$, then the word x of the $W + 1$ binary digits of $|z|$ lies on tracks 6 and 7 from row 1, and the cell $(0, 7)$ holds $[z < 0]$. Three cells of row 0 serve as flags: $(0, 10)$ for the

guard and later for the sign, $(0,3)$ for the sticky bit, and $(0,6)$, the presence cell of the sign, which is set to 0 while the magnitude is shifted. For a track k and a bit b let

$$\mathsf{set}_k(b) = \mathsf{left}^{k+1}; \mathsf{write}\, b; \mathsf{right}^{k+1};$$

it sets $(0,k)$ to b and returns to the root in $2k+5$ units (Lemma I.5). The decrement retr_k of Lemma I.66(b) moves the hole of a counter one row back.

Lemma I.191 (Consuming the precision)**.** *Let*

$$\mathsf{diff} = \mathsf{left}^6; \mathsf{loop}(\mathsf{home}_5; \mathsf{retr}_8; \mathsf{retr}_5; \mathsf{left}^6); \mathsf{home}_5.$$

Let τ be a workspace of r rows whose output buffer holds some word with capacity r, and on which track 5 carries m and track 8 carries $w \geq m$. Then diff *runs from $(-1,\tau)$ to $(-1,\tau')$ in $36mw + 93m + 17 \leq 150(m+w+1)^2$ units, where track 5 of τ' carries 0, track 8 carries $w-m$, and τ' differs from τ only in cells of tracks 5 and 8 in rows $j < w$.*

Proof. By Lemma I.4, $w \leq r+1$. left^6 takes 7 units to $-7 = \mathrm{cell}(0,5)$. For $j \leq m$ let I_j be the configuration at $\mathrm{cell}(0,5)$ whose tape is τ with track 5 carrying $m-j$ and track 8 carrying $w-j$, the cells between the old and the new holes set to 0. For $j < m$ the scanned cell $(0,5)$ holds 1, since $m-j \geq 1$. The pass returns to the root (9 units, Lemma I.11(b)), moves the hole of track 8 from row $w-j$ to row $w-j-1$ ($36(w-j-1)+59$) and that of track 5 from row $m-j$ to row $m-j-1$ ($36(m-j-1)+53$), by Lemma I.66(b), whose origin marks are there because $w-j-1 \leq r$; and left^6 returns to $(0,5)$ (7). With its test the pass takes $36(w+m-2j)+57$ units and ends in I_{j+1}. At I_m the cell $(0,5)$ is the hole of track 5, so it holds 0. By Lemma I.6 the loop ends in I_m, and its units are

$$\sum_{j<m} \big(36(w+m-2j)+57\big) + 1 = 36mw + 93m + 1.$$

home_5 from row 0 adds 9. Each of $36mw$, $93m$ and 17 is at most its coefficient times $(m+w+1)^2$. □

Lemma I.192 (Dropping digits)**.** *Let*

$$\begin{aligned}
\mathsf{flag} &= \mathsf{left}^{11}; \mathsf{branch}\big(\mathsf{right}^{11}; \mathsf{cap},\ \mathsf{right}^7; \mathsf{write}\,1; \mathsf{right}^4; \mathsf{cap}\big),\\
\mathsf{cap} &= \mathsf{left}^{24}; \mathsf{branch}(G_0, G_1), \qquad G_b = \mathsf{right}^{13}; \mathsf{write}\, b; \mathsf{right}^{11},\\
S_b &= \mathsf{right}^{16}; \mathsf{write}\, b; \mathsf{left}^{31},\\
\mathsf{shr} &= \mathsf{left}^{16}; \mathsf{loop}\big(\mathsf{left}; \mathsf{branch}(S_0, S_1)\big); \mathsf{right}^{15}; \mathsf{write}\,0; \mathsf{left}^{15},\\
\mathsf{drop}_1 &= \mathsf{flag}; \mathsf{left}^{23}; \mathsf{shr}; \mathsf{right}^{16}; \mathsf{scanR}; \mathsf{right}^7,\\
\mathsf{drop} &= \mathsf{left}^9; \mathsf{loop}(\mathsf{home}_8; \mathsf{drop}_1; \mathsf{retr}_8; \mathsf{left}^9); \mathsf{home}_8.
\end{aligned}$$

Let a word x of length $\ell \geq 1$ lie on tracks 6 and 7 from row 1, let $\tau(0,6) = 0$, $\tau(0,10) = g$ and $\tau(0,3) = s$.

(a) drop_1 *runs from $(-1,\tau)$ to $(-1,\tau')$ within $71\ell + 128 \leq 200(\ell+1)$ units, where, with $(x', g', s') = \theta(x,g,s)$, the word x' lies on tracks 6 and 7 from row 1, $\tau'(0,10) = g'$, $\tau'(0,3) = s'$, $\tau'(0,6) = 0$, and τ' differs from τ only in the cells $(0,3)$, $(0,10)$ and $(j,7)$, $1 \leq j \leq \ell$.*

(b) Let moreover τ be a workspace of r rows whose output buffer holds some word with capacity r, let $\ell \le r$, and let track 8 carry k. Then drop *runs from $(-1,\tau)$ to $(-1,\tau')$ within $500k(r+1)+23$ units, where, with $(x_k, g'_k, s'_k) = \theta^k(x,g,s)$, the word x_k lies on tracks 6 and 7 from row 1, $\tau'(0,10) = g'_k$, $\tau'(0,3) = s'_k$, $\tau'(0,6) = 0$, track 8 carries 0, and τ' differs from τ only on tracks 3, 7, 8 and 10, in rows $j \le r$.*

Proof. (a) left^{11} (12 units) reaches $(0,10)$, which holds g, and the branch tests it (1). If $g=0$, right^{11} (12) returns to the root; if $g=1$, right^{7} (8) reaches $(0,3)$, the write sets it to 1 and right^{4} (5) returns. Either way $(0,3)$ now holds $s \vee g$. Then cap walks to $(1,7) = -25$ (25), tests x_0 (1), returns to $(0,10)$ (14), writes x_0 there (1) and returns to the root (12): 53 units. So flag takes 78 or 80 units. left^{23} (24) reaches $(1,6)$. In shr, left^{16} (17) reaches $(2,6)$; for $1 \le j \le \ell$ let I_j be the configuration at $(j+1,6)$ whose tape has x_i in $(i,7)$ for $1 \le i < j$, the other cells as before. From I_j with $j < \ell$ the presence bit $(j+1,6)$ is 1; the pass reads x_j in $(j+1,7)$, writes it into $(j,7)$ and walks to $(j+2,6)$: $1+1+1+17+1+32 = 53$ units, ending in I_{j+1}. At I_ℓ the cell $(\ell+1,6)$ is the end of the word, and the loop stops (1). right^{15} (16) reaches $(\ell,7)$, which is set to 0, and left^{15} (16) returns: shr takes $53(\ell-1)+51$ units and leaves $x_1 \cdots x_{\ell-1}0$ on tracks 6 and 7 from row 1. right^{16} (17) reaches $(\ell,6)$, and scanR passes the presence marks of the rows $\ell, \dots, 1$ and stops at $(0,6) = 0$ ($18\ell+1$, Lemma I.10); right^{7} (8) returns to the root. In all $71\ell+126$ or $71\ell+128$ units.

(b) left^{9} (10) reaches $(0,8)$. By Lemma I.4, $k \le r+1$. For $j \le k$ let J_j be the configuration at $(0,8)$ whose tape holds $\theta^j(x,g,s)$ as in (a) and carries $k-j$ on track 8. From J_j with $j<k$ the scanned cell holds 1; the pass returns to the root (12), runs drop_1 (at most $200(\ell+1)$ units, by (a), which writes no cell of track 8), moves the hole of track 8 from row $k-j$ to row $k-j-1$ ($36(k-j-1)+59$, Lemma I.66(b)) and returns to $(0,8)$ (10). With its test it takes at most $1+12+200(\ell+1)+36r+59+10 \le 500(r+1)$ units, since $\ell \le r$, and ends in J_{j+1}. At J_k the cell $(0,8)$ holds 0. By Lemma I.6 the loop takes at most $500k(r+1)+1$ units, and home_8 from row 0 adds 12. □

Lemma I.193 (Choosing and adding the carry)**.** *Let*

$$\begin{aligned}
\mathsf{cflag}_0 &= \mathsf{skip}, \qquad C_b = \mathsf{left}^7;\mathsf{write}\,b;\mathsf{right}^{11},\\
\mathsf{cflag}_1 &= \mathsf{left}^{11};\mathsf{branch}\big(\mathsf{right}^{11},\ \mathsf{right}^7;\mathsf{branch}(C_0,C_1)\big),\\
\mathsf{incm} &= \mathsf{left}^{11};\mathsf{branch}\big(\mathsf{right}^{11},\ \mathsf{left}^{13};\mathsf{carry}^{\downarrow 16};\mathsf{home}_7\big).
\end{aligned}$$

(a) For a bit e, cflag_e *runs from $(-1,\tau)$ within 50 units to $(-1,\tau')$, where τ' is τ with $(0,10)$ set to $g \wedge (\neg e \vee s)$, $g = \tau(0,10)$ and $s = \tau(0,3)$.*

(b) Let a word x of length ℓ lie on tracks 6 and 7 from row 1, let $c = \tau(0,10)$, let τ have origin marks up to ℓ, and let $\mathrm{val}(x) + c < 2^\ell$. Then incm *runs from $(-1,\tau)$ to $(-1,\tau')$ within $100(\ell+1)$ units, where a word x' of length ℓ with $\mathrm{val}(x') = \mathrm{val}(x)+c$ lies on tracks 6 and 7 from row 1, and τ' differs from τ only in the cells $(j,7)$, $1 \le j \le \ell$.*

Proof. (a) For $e=0$ the skip takes one unit and $g \wedge (\neg 0 \vee s) = g$. For $e=1$, left^{11} (12) reaches $(0,10)$. If $g=0$, right^{11} returns (25 units in all). If $g=1$, then right^{7} (8) reaches $(0,3)$, the

branch reads s, and C_s walks back to $(0,10)$ (8), writes s and returns (12): 43 units. The new guard is $s = g \wedge s$.

(b) left^{11} (12) reaches $(0,10)$. If $c = 0$, right^{11} returns: 25 units. If $c = 1$, then $\mathrm{val}(x) + 1 < 2^\ell$, so x has a 0; write $x = 1^q 0 u$ with $q < \ell$. left^{13} (14) reaches $(1,7) = -25$. Track 7 from row 1 is the descending tape with origin cell$(1,7)$ and stride 16, on which carry runs in $3q+2$ units and turns 1^q0 into 0^q1 (Lemma I.23(a)); by Lemma I.9, $\mathsf{carry}^{\downarrow 16}$ does so on the track within $17(3q+2)$ units, ends at $(1+q,7)$ and writes no other cell. home_7 from row $1+q \le \ell$ takes $18(1+q)+11$. In all at most $69q + 90 \le 100(\ell+1)$ units, and $\mathrm{val}(0^q1u) = \mathrm{val}(1^q0u) + 1$. □

The three routines combine into the arithmetic part of the stage. It reads the sign of z once, in the cell $(0,7)$, and branches into two copies of the same program that differ only in the carry rule.

Lemma I.194 (Rounding the stored magnitude)**.** *Let*

$$\mathsf{rnd}_e = \mathsf{set}_6(0); \mathsf{set}_{10}(0); \mathsf{set}_3(0); \mathsf{drop}; \mathsf{cflag}_e; \mathsf{incm}; \mathsf{set}_{10}(e),$$
$$\mathsf{DropCarry} = \mathsf{diff}; \mathsf{left}^8; \mathsf{branch}(\mathsf{right}^8; \mathsf{rnd}_0,\ \mathsf{right}^8; \mathsf{rnd}_1).$$

Let $m \le w$, W and r be natural numbers and z an integer such that z and $\mathrm{near}(2^m z/2^w)$ fit W, and let τ be a workspace of r rows on which the binary stream holds $\mathrm{sw}_W(z)$, tracks 5, 8 and 9 carry m, w and W, and the output buffer holds the empty word with capacity r. Put $e = [z < 0]$ and $n = |z|$. Then $\mathsf{DropCarry}$ *runs from $(-1,\tau)$ to $(-1,\tau_1)$ in t_1 units, where a word x' of length $W+1$ with $\mathrm{val}(x') = \mu_e(n, w-m)$ lies on tracks 6 and 7 from row 1, $\tau_1(0,10) = e$, track 5 carries 0, track 9 carries W, the output buffer holds the empty word with capacity r, τ_1 is a workspace of r rows, and*

$$t_1 + r + 1 \le 2000(m + w + W + r + 1)^2.$$

Proof. The stream $\mathrm{sw}_W(z)$ has $W+2$ bits; its last presence mark is in row $W+1$, and the rows beyond r are blank, so $W+1 \le r$; also $w \le r+1$ (Lemma I.4). Put $k = w - m$ and let x be the $W+1$ digits of n. By Lemma I.191, diff takes $36mw + 93m + 17$ units and leaves 0 on track 5 and k on track 8. left^8 (9) reaches $(0,7)$, which holds e; the branch (1) and right^8 (9) lead to rnd_e at the root. The three writes (53 units) clear $(0,6)$, $(0,10)$ and $(0,3)$: now x lies on tracks 6 and 7 from row 1 with guard 0 and sticky bit 0. By Lemma I.192(b), with $\ell = W+1 \le r$, drop takes at most $500k(r+1)+23$ units and leaves $x^{(k)}$, g_k and s_k. By Lemma I.193(a), cflag_e (at most 50) sets $(0,10)$ to $c = g_k \wedge (\neg e \vee s_k)$. By Lemma I.190, $\mathrm{val}(x^{(k)}) + c = \mu_e(n,k)$, and by Lemma I.189, $\mu_e(n,k) = |\mathrm{near}(2^m z/2^w)| < 2^{W+1}$. So Lemma I.193(b) applies: incm (at most $100(W+2)$) leaves a word x' of length $W+1$ with value $\mu_e(n,k)$. The last write (25) puts e into $(0,10)$.

The cells written are $(0,3)$, $(0,6)$, $(0,10)$, cells of track 7 in rows $1,\dots,W+1$, of track 8 in rows $j < w$ and of track 5 in rows $j < m$, all in rows $j \le r$. Tracks 0, 1, 9, 11, 12 and 13 are not written, so τ_1 is a workspace of r rows, track 9 still carries W, and the output buffer still holds the empty word with capacity r. In all

$$t_1 \le 36mw + 93m + 187 + 500k(r+1) + 100(W+2),$$

and with $Y = m + w + W + r + 1$, $k \le w$ and $Y \ge 1$, $t_1 + r + 1 \le (36 + 93 + 500 + 101 + 388)Y^2 \le 2000Y^2$. □

Before the answer can be framed, the workspace must have room for the frame in the output buffer: the frame of a word of $W+2$ bits has $2(W+2)+1$ bits. The machine does not compute this length. It counts its own rows, which are more than $W+1$, and doubles them.

Lemma I.195 (Room for the frame)**.** *Let* $\mathsf{Room} = \mathsf{grow};\mathsf{hc}_{13};\mathsf{zero}_2;\mathsf{alloc};\mathsf{clear}_{12}$*, with* hc_{13} *the header count of Lemma I.91(a), which copies the row headers of track* 0 *into track* 12*, and* alloc *the growth routine of Lemma I.67. Let* τ *be a workspace of* r *rows on which the output buffer holds the empty word with capacity* r*, tracks* 5 *and* 9 *carry* 0 *and* W*, and a word* x *of length* $W+1$ *lies on tracks* 6 *and* 7 *from row* 1*. Put* $r' = 2r+3$*. Then* Room *runs from* $(-1,\tau)$ *to* $(-1,\tau')$ *in* t *units, where* τ' *is a workspace of* r' *rows, its output buffer holds the empty word with capacity* r'*,* x *still lies on tracks* 6 *and* 7 *from row* 1*,* $\tau'(0,10) = \tau(0,10)$*, tracks* 5 *and* 9 *still carry* 0 *and* W*,* $2(W+2)+1 \le r'$*, and*

$$t + r' + 1 \le 12000(r+2)^2.$$

Proof. As in Lemma I.194, $W+1 \le r$, which gives $2(W+2)+1 \le r'$. grow ($72r+99$, Lemma I.17) gives a workspace of $r+1$ rows with origin marks up to $r+1$. hc_{13} (within $300(r+2)$ units, Lemma I.91(a)) puts the value $r+1$ on track 12 and changes only tracks 12 and 13, and zero_2 (11) puts the hole of track 2 in row 0. Lemma I.67 with $R = c = r+1$ then gives, within $2000(2r+4)^2 = 8000(r+2)^2$ units, a workspace of $R+1+c = r'$ rows with origin marks up to r'; it writes only track 2, the headers and the new rows. clear_{12} ($63r'+33$) blanks track 12 in every row.

No routine writes track 11 in row 0, so track 11 still carries 0; track 12 is blank in rows $j \le r'$; so the buffer holds the empty word with capacity r'. The new rows carry the pattern β of Lemma I.17, which is 0 on tracks 6, 7, 9 and 10; the rows $j \le r$ are written only on tracks 0, 2, 12 and 13. So the word x, whose end mark lies in row $W+2 \le r+1$, the cell $(0,10)$, and the counters 0 and $W \le r$ on tracks 5 and 9 are kept. The count is $t + r' + 1 \le 8000(r+2)^2 + 500r + 936 \le 12000(r+2)^2$. □

The last routine writes the sign. It must not write the sign 1 in front of a zero magnitude: the answer word of 0 has the sign bit 0. The OR of the digits decides, and the program computes it with the following scan.

Lemma I.196 (The OR of a word)**.** *Let*

$$\mathsf{or} = \mathsf{loop}(\mathsf{left};\mathsf{branch}(\mathsf{left}^3;\mathsf{branch}(O_0,O_1),\ \mathsf{left}^3;O_1)), \qquad O_b = \mathsf{left}^{16};\mathsf{write}\,b;\mathsf{right}^4.$$

Let a word x *of length* ℓ *lie on tracks* 6 *and* 7 *from row* q*, and let* $a = \tau(q,10)$*. Then* or *runs from* $(\mathrm{cell}(q,6),\tau)$ *to* $(\mathrm{cell}(q+\ell,6),\tau')$ *in at most* $31\ell+1$ *units, where* τ' *is* τ *with* $(q+j+1,10)$ *set to* $a \vee x_0 \vee \cdots \vee x_j$ *for every* $j < \ell$*.*

Proof. Let I_j be the configuration at $(q+j,6)$ in which $(q+i+1,10)$ holds $a_{i+1} = a \vee x_0 \vee \cdots \vee x_i$ for $i < j$; put $a_0 = a$, so $(q+j,10)$ holds a_j. From I_j, $j < \ell$, the presence bit is 1; the pass reads x_j in $(q+j,7)$ and moves to $(q+j,10)$ ($1+1+1+4$ units). If $x_j = 0$ it reads a_j (1) and runs O_{a_j}; if $x_j = 1$ it runs O_1. O_b writes b into $(q+j+1,10)$ and moves to $(q+j+1,6)$ (23). In both cases the bit written is $a_j \vee x_j = a_{j+1}$, and the pass takes 31 or 30 units. At I_ℓ the presence bit is 0 (1 unit). □

Lemma I.197 (Writing the sign). *Let* $\mathsf{sign}(b) = \mathsf{write}\,1;\mathsf{left};\mathsf{write}\,b;\mathsf{right}$ *and*

$$\begin{aligned}\mathsf{Emit} &= \mathsf{left}^{27};\mathsf{write}\,0;\mathsf{right}^{4};\mathsf{or};\mathsf{left}^{4};\mathsf{branch}(E_{\mathrm{z}},E_{\mathrm{n}}),\\ E_{\mathrm{z}} &= \mathsf{home}_{10};\mathsf{left}^{7};\mathsf{sign}(0);\mathsf{right}^{7},\\ E_{\mathrm{n}} &= \mathsf{home}_{10};\mathsf{left}^{11};\mathsf{branch}\big(\mathsf{right}^{4};\mathsf{sign}(0);\mathsf{right}^{7},\ \mathsf{right}^{4};\mathsf{sign}(1);\mathsf{right}^{7}\big).\end{aligned}$$

Let a word x of length $W+1$ lie on tracks 6 and 7 from row 1, let $\tau(0,10)=e$, let τ have origin marks up to $W+2$, and put $y=(-1)^{e}\,\mathrm{val}(x)$. Then Emit *runs from $(-1,\tau)$ to $(-1,\tau')$ within $200(W+2)$ units, where the binary stream of τ' holds $\mathrm{sw}_W(y)$, and τ' differs from τ only in the cells $(0,6)$, $(0,7)$ and $(j,10)$, $1\le j\le W+2$.*

Proof. left^{27} (28) reaches $(1,10)=-28$, the write sets it to 0 (1), and right^{4} (5) reaches $(1,6)$. By Lemma I.196 with $q=1$ and $a=0$, or takes at most $31(W+1)+1$ units, ends at $(W+2,6)$, and leaves $o=[\mathrm{val}(x)>0]$ in $(W+2,10)$; the cell $(0,10)$ is not written. left^{4} (5) reaches $(W+2,10)$ and the branch reads o (1). If $o=0$, E_{z} returns to the root ($18(W+2)+14$), reaches $(0,6)=-8$ (8), writes 1 there and 0 into $(0,7)$ (4) and returns (8). If $o=1$, E_{n} returns to the root, reaches $(0,10)$ (12), reads e (1), moves to $(0,6)$ (5), writes 1 there and e into $(0,7)$ (4) and returns (8). In all at most $49(W+1)+103\le 200(W+2)$ units. Now $(0,6)=1$, $(0,7)=e\wedge o=[y<0]$, and x follows from row 1. Since $|y|=\mathrm{val}(x)<2^{W+1}$ and x has $W+1$ digits, x is the word of the $W+1$ lowest digits of $|y|$, so the binary stream holds $[y<0]\,x=\mathrm{sw}_W(y)$. □

I.14.3 The stage

Theorem I.198 (Round and emit). *Let* $\mathsf{RoundEmit}=(\mathsf{DropCarry};\mathsf{Room});\mathsf{Emit}$ *and $K_{\mathrm{e}}=2000+12000\cdot 2001^{2}+400=48\,048\,014\,400$. Let $m\le w$, W and r be natural numbers and z an integer such that z and $\mathrm{near}(2^{m}z/2^{w})$ fit W. Let τ be a workspace of r rows on which the binary stream holds $\mathrm{sw}_W(z)$, tracks 5, 8 and 9 carry the counters m, w and W, and the output buffer holds the empty word with capacity r. Then* RoundEmit *runs from $(-1,\tau)$ to $(-1,\tau')$ in some number t of units, and there is r' such that:*

(a) the binary stream of τ' holds $\mathrm{sw}_W\big(\mathrm{near}(2^{m}z/2^{w})\big)$;

(b) track 5 of τ' carries 0, the output buffer holds the empty word with capacity r', and τ' is a workspace of r' rows;

(c) $2(W+2)+1\le r'$;

(d) $t+r'+1\le K_{\mathrm{e}}(m+w+W+r+1)^{7}$.

The stage reads tracks 5, 6, 7, 8 and 9, uses the cells $(0,3)$ and $(0,10)$ and tracks 10, 12 and 13 as scratch, and adds rows with track 2 as their counter. The saved request and the step count are not needed any more, and the contract says nothing about them. The exponent is $7=2\cdot(2+1)+1$: the arithmetic part has exponent 2, the growth of the workspace is quadratic in the rows and so turns it into $2(2+1)$, and the final scan adds one more.

Proof. Put $Y=m+w+W+r+1$, $e=[z<0]$ and $n=|z|$. By Lemma I.194, DropCarry runs to a tape τ_1, a workspace of r rows, in t_1 units with $t_1+r+1\le 2000Y^{2}$; on τ_1 a word

x' of length $W+1$ and value $\mu_e(n, w-m)$ lies on tracks 6 and 7 from row 1, $(0,10)$ holds e, tracks 5 and 9 carry 0 and W, and the output buffer holds the empty word with capacity r. By Lemma I.195, Room runs to a tape τ_2, a workspace of $r' = 2r+3$ rows with the empty buffer of capacity r', in t_2 units with $t_2 + r' + 1 \le 12000(r+2)^2$, and keeps x', the cell $(0,10)$ and the counter 0 on track 5. By Lemma I.197, whose origin marks up to $W+2 \le r'$ are those of the buffer, Emit runs in $t_3 \le 200(W+2)$ units to τ', whose binary stream holds $\mathrm{sw}_W(y)$ with $y = (-1)^e \mu_e(n, w-m)$; by Lemma I.189, $y = \mathrm{near}(2^m z/2^w)$. Emit writes only row 0 and track 10 in rows $j \le W+2$, so (b) still holds, and (c) is part of Lemma I.195.

For (d): since $Y \ge 1$, $r+2 \le t_1 + r + 1 + 1 \le 2000Y^2 + Y^3 \le 2001Y^3$, so $t_2 + r' + 1 \le 12000 \cdot 2001^2 Y^6$; also $t_1 \le 2000Y^6$ and $t_3 \le 200(W+2) \le 400Y \le 400Y^7$. Hence

$$t + r' + 1 = t_1 + t_2 + t_3 + r' + 1 \le (2000 + 12000 \cdot 2001^2)Y^6 + 400Y^7 \le K_{\mathrm{e}} Y^7. \qquad \square$$

I.15 Framing the answer and erasing the workspace

At the end of the arithmetic the answer is a signed word in the scratch area, and the input cells are blank. Definition 15.31 asks for more: the machine must halt with the frame of that word written from cell 0 and 0 in every other cell of the tape. Take $W = 1$ and $a_m = -1$. The signed word is $\mathrm{sw}_1(-1) = 110$: the sign 1, then the two digits $1, 0$ of 1. Its frame is 1110 110. The last stage copies the three bits of the stream into the output buffer twice, first as three marks and then as themselves, with a 0 between the two passes; writes the seven bits of the buffer into the cells $0, \dots, 6$; and erases every row of the workspace and the root. For a word u we write $\iota(u)$ for the tape that holds u from cell 0 and 0 in every other cell; the stage ends with the head on cell 0 and the tape $\iota(1110110)$.

The erasure is where the layout of Section I.1 pays off. By Lemma I.4 every cell that holds 1 on a workspace of r rows is the root or lies in a row $j \le r$, and the rows $j < r$ are exactly those whose header on track 0 holds 1. So the machine can find every written cell without knowing r: it walks down the headers, clears each row, clears the sentinel row, and walks back to the root.

I.15.1 The frame in the buffer

The output buffer receives bits through the routine $\mathsf{put}_{11}(b)$ of Lemma I.124. Track 5 serves as the read counter of the stream. For bits h and b put

$$T_b = \mathsf{home}_7; \mathsf{put}_{11}(b); \mathsf{seek}_5; \mathsf{next}; \mathsf{left}, \qquad \mathsf{tx}(h) = \mathsf{left}; \mathsf{branch}(T_{h\vee 0}, T_{h\vee 1}).$$

Lemma I.199 (Copying the stream into the buffer)**.** *Let the binary stream of τ hold a word v of length n, let track 5 carry 0, and let the output buffer hold a word w with capacity R, where $|w| + n \le R$. Let h be a bit and let v^h be 1^n if $h = 1$ and v if $h = 0$. Then $\mathsf{loop}(\mathsf{tx}(h))$ runs from $(\mathrm{cell}(0,6), \tau)$ to $(\mathrm{cell}(n,6), \tau')$ in exactly $36n^2 + (36|w| + 82)n + 1$ units, where the output buffer of τ' holds wv^h with capacity R, track 5 carries n, and τ' differs from τ only on tracks 5, 11, 12 and 13, in rows $j \le R$.*

Proof. For $k \le n$ let I_k be the configuration at $(k,6)$ whose tape is τ with track 5 carrying k and the buffer holding w followed by the first k bits of v^h. From I_k, $k < n$, the presence bit

$(k, 6)$ is 1. The pass moves to $(k, 7)$ (1), reads v_k (1) and runs T_b with $b = h \vee v_k$, the kth bit of v^h: home_7 from row k ($18k + 11$), $\mathsf{put}_{11}(b)$ at buffer length $|w| + k$ ($36(|w| + k) + 75$; the origin marks up to $|w| + k + 1 \le R$ are those of the buffer), seek_5 to the hole $(k, 5)$ ($18k + 8$), next (20), which advances the counter, and left (1) to $(k + 1, 6)$. With its test the pass takes $72k + 36|w| + 118$ units and ends in I_{k+1}. At I_n the presence bit is 0. By Lemma I.6 the loop takes $\sum_{k<n}(72k + 36|w| + 118) + 1 = 36n^2 + (36|w| + 82)n + 1$ units. □

Lemma I.200 (Framing the stream)**.** *Let*

$$\begin{aligned}\mathsf{Frame} = {} & \mathsf{pres}_5; \mathsf{loop}(\mathsf{tx}(1)); \mathsf{home}_6; \mathsf{put}_{11}(0); \mathsf{reset}_5; \\ & \mathsf{pres}_5; \mathsf{loop}(\mathsf{tx}(0)); \mathsf{home}_6; \mathsf{reset}_5.\end{aligned}$$

Let the binary stream of τ hold a word v of length n, let track 5 carry 0, and let the output buffer hold w with capacity R, where $|w| + 2n + 1 \le R$. Then Frame *runs from $(-1, \tau)$ to $(-1, \tau')$ in exactly*

$$F(|w|, n) = 108n^2 + 72|w|n + 344n + 36|w| + 189 \le 700(|w| + n + 1)^2$$

units, where the output buffer of τ' holds $w1^n0v$, the word w followed by the frame of v, with capacity R, track 5 carries 0, and τ' differs from τ only on tracks 5, 11, 12 and 13, in rows $j \le R$.

Proof. pres_5 (10 units, Lemma I.11) reaches $(0, 6)$. By Lemma I.199 with $h = 1$ the first loop takes $36n^2 + (36|w| + 82)n + 1$ units, leaves $w1^n$ in the buffer and n on track 5, and stops at $(n, 6)$. home_6 ($18n + 10$) returns to the root, $\mathsf{put}_{11}(0)$ ($36(|w| + n) + 75$) appends the separator, and reset_5 ($36n + 36$, Lemma I.14(c)) puts the hole of track 5 back in row 0. pres_5 (10) and the second loop, with $h = 0$ and the buffer word of length $|w| + n + 1$, take $10 + 36n^2 + (36(|w| + n + 1) + 82)n + 1$ units and append v; the hypothesis of Lemma I.199 holds because $|w| + n + 1 + n \le R$. home_6 ($18n + 10$) and reset_5 ($36n + 36$) end at the root with track 5 carrying 0. The sum is $F(|w|, n)$, and each of its five coefficients is at most 700 times the corresponding coefficient of $(|w| + n + 1)^2$. □

I.15.2 Writing the output

The buffer is turned into the output by a single raw marker in the input cells, in the sense of Definition I.33, and the routines raw and unraw of Lemma I.34, which walk from the root to the marker and back. The machine has no addresses, so it cannot write the bit of row j into cell j directly. Instead it first pushes the marker from cell 0 to cell $n - 1$, one cell per row of the buffer; then it walks the buffer backwards, and at each row replaces the marker by the

row's bit and puts a new marker one cell to the left. Let

$$\begin{aligned}
\mathsf{oprep} &= [\mathsf{reset}_{11}, \mathsf{right}, \mathsf{write}\,1, \mathsf{left}, \mathsf{pres}_{11}], \qquad \mathsf{onil} = [\mathsf{home}_{12}, \mathsf{raw}, \mathsf{write}\,0, \mathsf{left}],\\
\mathsf{osp} &= [\mathsf{home}_{12}, \mathsf{raw}, \mathsf{write}\,0, \mathsf{right}, \mathsf{write}\,1, \mathsf{unraw}, \mathsf{inc}_{11}, \mathsf{pres}_{11}, \mathsf{left}^{16}],\\
\mathsf{ospread} &= [\mathsf{left}^{16}, \mathsf{loop}(\mathsf{osp}), \mathsf{home}_{12}],\\
U_b &= [\mathsf{home}_{13}, \mathsf{raw}, \mathsf{write}\,b, \mathsf{left}, \mathsf{write}\,1, \mathsf{unraw}, \mathsf{seek}_{11}, \mathsf{right}^{10}],\\
\mathsf{oul} &= [\mathsf{left}^{12}, \mathsf{branch}(U_0, U_1), \mathsf{left}^{10}, \mathsf{write}\,1, \mathsf{right}^{16}, \mathsf{write}\,0, \mathsf{right}^{10}],\\
L_b &= [\mathsf{home}_{13}, \mathsf{raw}, \mathsf{write}\,b, \mathsf{left}], \qquad \mathsf{olast} = [\mathsf{left}^{12}, \mathsf{branch}(L_0, L_1)],\\
\mathsf{ounload} &= [\mathsf{seek}_{11}, \mathsf{right}^{10}, \mathsf{loop}(\mathsf{oul}), \mathsf{olast}],\\
\mathsf{Out} &= \big[\mathsf{oprep}, \mathsf{branch}\big(\mathsf{onil}, [\mathsf{ospread}, \mathsf{ounload}]\big)\big].
\end{aligned}$$

Lemma I.201 (Writing the buffer to the input cells)**.** *Let u be a word of length n and let τ be a tape with $\tau(-1) = 1$ and $\tau(x) = 0$ for every $x \geq 0$, with origin marks up to n, on which track 11 carries n, $\tau(j, 12) = [j < n]$ for $j \leq n$, and $\tau(j, 13) = u_j$ for $j < n$. Then* Out *runs from $(-1, \tau)$ to $(-1, \tau')$ in exactly $O(n)$ units, where $O(0) = 108$ and $O(n) = 66n^2 + 209n - 34$ for $n \geq 1$, so that $O(n) \leq 500(n+1)^2$. In τ' the cell x holds u_x for $0 \leq x < n$ and 0 for $x \geq n$, track 11 carries 0, and every cell $x < 0$ other than the cells $(j, 11)$, $j \leq n$, holds what it held in τ.*

Proof. oprep resets track 11 ($36n + 60$, Lemma I.14(c)), writes a raw marker at cell 0 (3) and moves to $(0, 12)$ (16); with the list, $36n + 80$ units. The branch reads $(0, 12) = [n > 0]$ (1). If $n = 0$, onil returns to the root (16), finds the marker (7, Lemma I.34(b)), erases it and steps back to the root (3, with the list): in all $36 \cdot 0 + 80 + 1 + 26 + 1 = 108$ units.

Let $n \geq 1$. In ospread, left^{16} (17) reaches $(1, 12)$. For $k \leq n - 1$ let A_k be the configuration at $(k + 1, 12)$ whose tape has the raw marker at k, the counter k on track 11, and otherwise agrees with τ off track 11. From A_k, $k < n - 1$, the cell $(k + 1, 12)$ holds 1; the pass returns to the root ($18(k + 1) + 16$), finds the marker ($6k + 7$), moves it to $k + 1$ (3), returns ($6(k + 1) + 7$), advances track 11 ($36k + 66$) and moves to $(k + 2, 12)$ ($18(k + 1) + 16 + 17$): with the list and the test, $84k + 176$ units, ending in A_{k+1}. At A_{n-1} the cell $(n, 12)$ holds 0, and home_{12} from row n costs $18n + 16$. So ospread takes $18n + 34 + \big(42(n-1)^2 + 134(n-1) + 1\big)$ units.

In ounload, seek_{11} ($18(n - 1) + 14$) and right^{10} (11) reach $(n - 1, 1)$. For $k \leq n - 1$ let B_k be the configuration at $(k, 1)$ whose tape has the raw marker at k, the cells x with $k < x < n$ holding u_x, the counter k on track 11, and otherwise agrees with τ off track 11. From B_{k+1} the origin mark $(k + 1, 1)$ is 1. The pass reads u_{k+1} in $(k + 1, 13)$ (13, and the branch 1); $U_{u_{k+1}}$ returns to the root ($18(k + 1) + 17$), finds the marker at $k + 1$ ($6(k + 1) + 7$), writes u_{k+1} there and a new marker at k (3), returns ($6k + 7$) and goes back to $(k + 1, 1)$ ($18(k + 1) + 14 + 11$, and the list 1); the rest of oul moves the hole of track 11 from row $k + 1$ to row k and reaches $(k, 1)$ (42 units). With the test the pass takes $48k + 159$ units and ends in B_k. At B_0 the origin mark $(0, 1)$ is 0, and olast reads u_0, finds the marker at 0 and replaces it by u_0 (42 units). So ounload takes $18(n - 1) + 68 + \big(24(n-1)^2 + 135(n-1) + 1\big)$ units. With oprep, the branch and the two lists the total is $O(n)$. No cell $x \geq n$ is written, and among the cells $x < 0$ only track 11 changes. □

Lemma I.202 (Erasing the workspace)**.** *Let*

$$\mathsf{Erase} = [\mathsf{left}, \mathsf{loop}(\mathsf{put}(0^{16})), \mathsf{put}(0^{16}), \mathsf{findR}, \mathsf{write}\,0],$$

with findR *the mirror of* findL *(Lemma I.34(a)). Let $\tau(j,0) = 1$ for $j < r$, $\tau(r,0) = 0$, $\tau(-1) = 1$, and let every cell of every row $j > r$ hold 0. Then* Erase *runs from $(-1,\tau)$ to $(-1,\tau')$ in $130r+144$ units, where $\tau'(x) = 0$ for every $x < 0$ and $\tau'(x) = \tau(x)$ for every $x \geq 0$.*

Proof. left (1) reaches the header $(0,0)$. For $j \leq r$ let I_j be the configuration at $(j,0)$ in which the rows before j hold 0. From I_j, $j < r$, the header holds 1; $\mathsf{put}(0^{16})$ (33 units, Lemma I.12(c)) writes 0 in the sixteen cells of row j and stops at $(j+1,0)$, so the pass takes 34 units and ends in I_{j+1}. At the sentinel header the loop stops (1), and $\mathsf{put}(0^{16})$ (33) clears row r and stops at $(r+1,0) = -18-16r$. Now every cell from there up to -2 holds 0 and the root holds 1, so findR passes $16r+17$ zeros to the root in $6(16r+17)+5$ units, and the write clears the root. Every negative cell is now 0: the rows $j \leq r$ were cleared and the rows $j > r$ were blank. With the list the count is $1 + (34r+1) + 33 + (96r+107) + 1 + 1 = 130r+144$. □

Lemma I.203 (Finalizing)**.** *Let* $\mathsf{Finalize} = \mathsf{Out}; \mathsf{Erase}; \mathsf{right}$*. Let τ be a workspace of r rows whose output buffer holds a word u with capacity r. Then* Finalize *runs from $(-1,\tau)$ to $(0,\iota(u))$ in exactly $O(|u|) + 130r + 145$ units.*

Proof. The buffer gives the hypotheses of Lemma I.201 with $n = |u|$: the counter n on track 11, the presence cells $(j,12) = [j < n]$ for $j \leq n \leq r$, the bits on track 13 and the origin marks; the workspace gives $\tau(-1) = 1$ and the blank input cells. After Out the input cells hold u followed by 0s, and only track 11 in rows $j \leq n \leq r$ has changed among the negative cells, so the headers, the sentinel, the blank rows beyond r and the root are as in τ. Lemma I.202 clears every negative cell and keeps the input cells, and right moves the head to cell 0: the tape is $\iota(u)$, after $O(n) + (130r+144) + 1$ units. □

I.15.3 The stage

Theorem I.204 (Frame and erase)**.** *Let* $\mathsf{FrameErase} = \mathsf{Frame}; \mathsf{Finalize}$*. Let τ be a workspace of r rows on which the binary stream holds a word v, track 5 carries 0, and the output buffer holds a word w with capacity r, where $|w| + 2|v| + 1 \leq r$. Then* FrameErase *runs from $(-1,\tau)$ to $(0,\iota(w\,1^{|v|}0v))$ in exactly*

$$D(w,v,r) = F(|w|,|v|) + O(|w| + 2|v| + 1) + 130r + 145$$

units. If w is empty, $D(w,v,r) + 1 \leq 2000(r+1)^2$.

Proof. By Lemma I.200 with $R = r$, Frame takes $F(|w|,|v|)$ units, and afterwards the buffer holds $u = w\,1^{|v|}0v$ with capacity r. It writes only tracks 5, 11, 12 and 13 in rows $j \leq r$, so the tape is still a workspace of r rows, and $|u| = |w| + 2|v| + 1 \leq r$. Lemma I.203 finishes. If w is empty, then $|v| + 1 \leq r + 1$ and $2|v| + 2 \leq r + 1$, so $F(0,|v|) \leq 700(r+1)^2$ and $O(2|v|+1) \leq 500(r+1)^2$, and $1200(r+1)^2 + 130r + 146 \leq 2000(r+1)^2$. □

The stage is quadratic in the rows, so a bound of the form of Definition I.7 for everything before it doubles its exponent.

Lemma I.205 (Paying for the frame). *Let $Y \geq 1$, and let t, r, K and g be natural numbers with $t + r + 1 \leq KY^g$. If v is a word with $2|v| + 1 \leq r$ and ε is the empty word, then*

$$t + D(\varepsilon, v, r) + 1 \leq 2001(K+1)^2 Y^{2g}.$$

Proof. By Theorem I.204, $D(\varepsilon, v, r) + 1 \leq 2000(r+1)^2 \leq 2000K^2Y^{2g}$, since $r + 1 \leq KY^g$. Also $t \leq KY^g \leq (K+1)^2Y^{2g}$. Add. □

I.16 The whole count

The stages are now all in place. This section puts them together into the one program P of Theorem 15.33, computes its exponent λ from the exponents of the stages, writes down its constant K, and proves the theorem. The program is

$$\begin{aligned} \mathsf{P} &= \mathsf{Parse}; (\mathsf{Decode}; \mathsf{Solve}), \\ \mathsf{Solve} &= \big(\mathsf{Schedule}; (\mathsf{Traj}; \mathsf{RoundEmit})\big); \mathsf{FrameErase}, \\ \mathsf{Traj} &= \mathsf{Init}; \big(\mathsf{repeat}_2(\mathsf{Step}); (\mathsf{Select}; \mathsf{empty})\big), \qquad \mathsf{Step} = \mathsf{Build}; \mathsf{Sum}, \end{aligned}$$

with the stage programs of Sections I.7 to I.15, the program $\mathsf{empty} = \mathsf{clear}_{11,12}$ of Lemma I.125, and the loop repeat_2 of Lemma I.18, which runs the step once for each of the S marks of the step count on track 14. Table I.5 lists every stage with the result that proves its contract and the exponent of its bound. Throughout, a problem with a coefficient field of dimension d is fixed, with initial point y_0, radius $M \geq 1$ and natural end time T, satisfying the region certificate at level n_0; $X = m + n_0 + \kappa + 1$, $W = W_m$, and $g = 118$ is the exponent of one entry of the coefficient table (Theorem I.119).

The exponent is assembled in four steps. The trajectory and the rounding compose to g_{tr}; the schedule in front of them gives g_{f} by Lemma 15.36(c); the frame doubles it; and the reading of the request, with exponent 11 in X alone, multiplies by 11 after one more step of Lemma 15.36(a):

$$\lambda = 11\Big(2(g_q+1)\big(8(762700(g+20)+2)+1\big)+1\Big) = 11\big(2 \cdot 842\,020\,817\,(g_q+1)+1\big),$$

with $g = 118$ and

$$g_q + 1 = 111\,736\,803\,796\,728\,983\,743\,307\,618\,367\,111\,577\,196\,298\,253.$$

As a numeral,

$$\lambda = 2\,069\,863\,726\,081\,589\,698\,020\,631\,180\,195\,588\,915\,541\,683\,736\,068\,119\,433.$$

It is a fixed number: nothing in it depends on the problem, the coordinate or the precision.

Stage	Result	Exponent of the bound
Parse	Theorem I.42	3, in X
Decode	Theorem I.58	8, in X
Parse; Decode	Corollary I.59	$g_d + 3 = 11$, in X

one coefficient, one row	Theorems I.119, I.120	$g = 118$
Build	Theorem I.121	$g + 2 = 120$
Sum	Theorem I.161	8
Step	Theorem I.162	$g + 18 = 136$
repeat_2(Step)	Theorem I.184	$g + 19 = 137$
Select; empty	Theorem I.187	3
Traj	Theorem I.188	$g_{\mathrm{t}} = 762700(g + 20) = 105\,252\,600$
RoundEmit	Theorem I.198	7, in $m + w + W + r + 1$
Traj; RoundEmit	Lemma I.206	$g_{\mathrm{tr}} = 8(g_{\mathrm{t}} + 2) = 842\,020\,816$
Schedule; (Traj; RoundEmit)	Lemma I.207	$g_{\mathrm{f}} = (g_q + 1)(g_{\mathrm{tr}} + 1)$
FrameErase	Theorem I.204	2, in the rows
Solve	Lemma I.208	$g_{\mathrm{sol}} = 2g_{\mathrm{f}}$
P	Theorem I.209	$\lambda = (g_d + 3)(g_{\mathrm{sol}} + 1)$, in $m + 1$

Table I.5. The stages of the program P in the order in which they run, the result that proves the contract of each, and the exponent of its bound. Unless stated otherwise the bound is $K(X + r + 1)^g$ of Definition I.7, with r the rows in use when the stage starts.

Lemma I.206 (The arithmetic after the schedule)**.** *Let K_{t} be the constant of Theorem I.188 for the problem, $g_{\mathrm{t}} = 105\,252\,600$ its exponent, and $c_W = 4(q_P + l_P + c_P) + 4$ the constant of Proposition I.32(e). Put $A_{\mathrm{tr}} = K_{\mathrm{t}} + c_W + 3$, $K_{\mathrm{tr}} = K_{\mathrm{t}} + K_{\mathrm{e}} A_{\mathrm{tr}}^7$ and $g_{\mathrm{tr}} = 8(g_{\mathrm{t}} + 2)$. Let $i < d$, m and r be given, and let τ be a scheduled request of the request for coordinate i at precision m with r rows (Definition I.85). Then* Traj; RoundEmit *runs from $(-1, \tau)$ to $(-1, \tau')$ in t units, and there is r' such that the binary stream of τ' holds $\mathrm{sw}_W(a_m)$, track 5 carries 0, the output buffer holds the empty word with capacity r', τ' is a workspace of r' rows, $2(W + 2) + 1 \le r'$, and*

$$t + r' + 1 \le K_{\mathrm{tr}}(X + r + 1)^{g_{\mathrm{tr}}}.$$

Proof. Put $Y = X + r + 1$, $n = \max(m, n_0)$ and $w = N(n)$. By Theorem I.188, Traj runs from $(-1, \tau)$ to $(-1, \tau_1)$ in t_1 units, where the binary stream of τ_1 holds $\mathrm{sw}_W(z)$ with $z = (Z_S)_i$, the integer vector of Lemma 15.35 after S steps at level n; tracks 5, 8 and 9 carry m, w and W; the output buffer holds the empty word with capacity r_1; τ_1 is a workspace of r_1 rows; and $t_1 + r_1 + 1 \le K_{\mathrm{t}} Y^{g_{\mathrm{t}}}$. The integer z fits W by Proposition I.32(a), since the region certificate keeps the stored vectors in the ball. By Lemma 15.35, $a_m = \mathrm{near}(2^m z / 2^w)$, and a_m fits W by Lemma H.5. Also $m \le w$, because $w = n + \kappa$. So Theorem I.198 applies to τ_1: RoundEmit runs to a tape τ' with all the stated properties in t_2 units, with $t_2 + r' + 1 \le K_{\mathrm{e}}(m + w + W + r_1 + 1)^7$.

Now $m \le X \le Y$, $w \le X \le Y$, $W \le c_W X^2 \le c_W Y^2$ by Proposition I.32(e), and $r_1 + 1 \le K_{\mathrm{t}} Y^{g_{\mathrm{t}}}$. Each of these powers of Y is at most $Y^{g_{\mathrm{t}}+2}$, so $m + w + W + r_1 + 1 \le A_{\mathrm{tr}} Y^{g_{\mathrm{t}}+2}$ and $t_2 + r' + 1 \le K_{\mathrm{e}} A_{\mathrm{tr}}^7 Y^{7(g_{\mathrm{t}}+2)}$. With $t_1 \le K_{\mathrm{t}} Y^{g_{\mathrm{t}}}$ and $Y \ge 1$, both bounds are at most their constants times $Y^{8(g_{\mathrm{t}}+2)}$; add them. □

Lemma I.207 (After the decoded request)**.** *Let K_q be the constant of Theorem I.88 for the problem and g_q its exponent, and put $K_{\mathrm{f}} = K_q + K_{\mathrm{tr}}(K_q+1)^{g_{\mathrm{tr}}}$ and $g_{\mathrm{f}} = (g_q+1)(g_{\mathrm{tr}}+1)$. Let τ be a decoded request of the request for coordinate i at precision m with r rows (Definition I.56). Then* Schedule; (Traj; RoundEmit) *runs from $(-1,\tau)$ to $(-1,\tau')$ in t units, where τ' has the properties of Lemma I.206 for some r', and*

$$t + r' + 1 \le K_{\mathrm{f}}(X + r + 1)^{g_{\mathrm{f}}}.$$

Proof. By Theorem I.88, Schedule runs from $(-1,\tau)$ to a scheduled request with r_1 rows in t_1 units, with $t_1 + r_1 + 1 \le K_q(X+r+1)^{g_q}$. By Lemma I.206 the rest runs from there in t_2 units, with $t_2 + r' + 1 \le K_{\mathrm{tr}}(X + r_1 + 1)^{g_{\mathrm{tr}}}$. Lemma 15.36(c), with $K_1 = K_q$, $g_1 = g_q$, $K_2 = K_{\mathrm{tr}}$ and $g_2 = g_{\mathrm{tr}}$, gives the bound. □

Lemma I.208 (Solving from the decoded request)**.** *Put $K_{\mathrm{sol}} = 2001(K_{\mathrm{f}}+1)^2$ and $g_{\mathrm{sol}} = 2g_{\mathrm{f}}$, and let τ be as in Lemma I.207. Then* Solve *runs from $(-1,\tau)$ to $(0,\iota(\hat a_m))$ in t units, where $\hat a_m$ is the answer word of a_m at width W (Definition 15.32), and*

$$t + 1 \le K_{\mathrm{sol}}(X + r + 1)^{g_{\mathrm{sol}}}.$$

Proof. By Lemma I.207, the first part of Solve runs in t_1 units to a tape τ', with $t_1 + r' + 1 \le K_{\mathrm{f}} Y^{g_{\mathrm{f}}}$, $Y = X + r + 1$. On τ' the binary stream holds $v = \mathrm{sw}_W(a_m)$, track 5 carries 0, the output buffer holds the empty word with capacity r', and $2|v| + 1 = 2(W+2) + 1 \le r'$. By Theorem I.204 with w empty, FrameErase runs from $(-1,\tau')$ to $(0,\iota(1^{|v|}0v))$ in $D(\varepsilon, v, r')$ units, and $1^{|v|}0v$ is the frame of v, which is $\hat a_m$. Lemma I.205 with $K = K_{\mathrm{f}}$ and $g = g_{\mathrm{f}}$ gives $t_1 + D(\varepsilon, v, r') + 1 \le 2001(K_{\mathrm{f}}+1)^2 Y^{2g_{\mathrm{f}}}$. □

Theorem I.209 (The whole program and its count)**.** *Let*

$$\lambda = 11\big(2(g_q+1)(8(762700\cdot 138 + 2) + 1) + 1\big),$$

the numeral displayed above. Let a problem have a coefficient field, with rational initial point y_0, radius $M \ge 1$ and natural end time T, and let it satisfy the region certificate at level n_0. Put $c = n_0 + \kappa + 1$, let $A = 100000(c_{\mathrm{req}}+2)^3 + K_d c_{\mathrm{num}}^8$ be the constant of Corollary I.59, and

$$K = \big(A + K_{\mathrm{sol}}(A+1)^{g_{\mathrm{sol}}}\big)c^{\lambda},$$

with K_{sol} and g_{sol} as in Lemma I.208. Then for every coordinate $i < d$ and every precision m:

(a) P *has a counted execution in some $t \le K(m+1)^{\lambda}$ units from the head on cell 0 and the input tape of the request for coordinate i at precision m (Definition 15.32) to the head on cell 0 and the tape on which the answer word of a_m is written from cell 0, with 0 in every other cell;*

(b) $|a_m| < 2^{W_m+1}$, and the machine $H = \mathrm{machine}(\mathsf{P})$ runs from that request to the answer word of a_m within $K(m+1)^{\lambda}$ steps.

The same holds for every polynomial field whose quadratized problem satisfies the region certificate at level n_0: with the constants of the quadratized problem, H runs from the request of the quadratized problem for the variable w_{e_i} at precision m to the answer word of the answer at precision m of the polynomial solution x_i within $K(m+1)^{\lambda}$ steps, and that answer is less than 2^{W_m+1} in absolute value.

The program P, and hence H, and the number λ are fixed before the problem is given; only K depends on it. That is the order of quantifiers of Theorem 15.33.

Proof. (a) Let u be the request. By Corollary I.59, $\mathsf{Parse};\mathsf{Decode}$ runs from the head on cell 0 of the input tape of u to $(-1,\tau_D)$, a decoded request with r_D rows, in t_P+t_D units with $t_P+t_D+r_D+1\le AX^{11}$. By Lemma I.208, Solve runs from $(-1,\tau_D)$ to $(0,\iota(\hat{a}_m))$ in t_S units with $t_S+1\le K_{\mathrm{sol}}(X+r_D+1)^{g_{\mathrm{sol}}}$. The counted executions compose in sequence. Lemma 15.36(a), with $N=X\ge 1$, $e=11$, $s=t_P+t_D$, $r=r_D$, $t=t_S$, $r'=0$, $K=K_{\mathrm{sol}}$ and $g=g_{\mathrm{sol}}$, gives

$$t_P+t_D+t_S+1\le \big(A+K_{\mathrm{sol}}(A+1)^{g_{\mathrm{sol}}}\big)X^{11(g_{\mathrm{sol}}+1)},$$

and $11(g_{\mathrm{sol}}+1)=\lambda$. Since $X=m+c$ with $c\ge 1$, Lemma 15.36(b) gives $X^{\lambda}\le c^{\lambda}(m+1)^{\lambda}$, so $t\le K(m+1)^{\lambda}$.

(b) $|a_m|<2^{W_m+1}$ is Lemma H.5. The final tape of (a) is the answer word written from cell 0 with 0 everywhere else, so by Lemma 15.34(b) the machine machine(P) runs from u to the answer word within t steps.

For a polynomial field, the polynomial solution x_i is by Definition 15.27 the certified real of Theorem 15.22 for the variable w_{e_i} of the quadratized problem, which has a coefficient field and satisfies the region certificate at level n_0. Parts (a) and (b), applied to the quadratized problem and the coordinate of w_{e_i}, give the claim with the same H and λ. □

Appendix J

Proofs for the calculus of δ's objects

This appendix carries the verifications deferred in Chapter 16: the equivalence tools behind the compiler, the remaining compiler cases, the derivation of every true equational sentence in the full calculus, the programs that track the maps used, the readings of the sentences in the model of named objects, the computability of addresses, the names of the cover series, and the tent function. Notation is that of the chapter. Arguments about the model of named objects are carried out in ordinary classical mathematics, as there.

J.1 Equivalence and reindexing

Recall that $A \equiv B$ means that the calculus derives $A \vdash B$ and $B \vdash A$. The same constructions work in the computable calculus.

Lemma J.1 (Equivalence is a congruence)**.** *The relation $\equiv$ is reflexive, symmetric and transitive. If $A \equiv A'$ and $B \equiv B'$, then $A \wedge B \equiv A' \wedge B'$, $A \vee B \equiv A' \vee B'$, $A \to B \equiv A' \to B'$ and $f^*A \equiv f^*A'$ for every map f; and for formulas in a context $G \times X$, $A \equiv A'$ gives $\forall_X A \equiv \forall_X A'$ and $\exists_X A \equiv \exists_X A'$. Moreover $f^*\top \equiv \top$, $f^*\bot \equiv \bot$ and $g^*f^*A \equiv (f \circ g)^*A$.*

Proof. Reflexivity is construction (2), and transitivity is cut. For conjunction, eliminate each conjunct of $A \wedge B$, cut with $A \vdash A'$ and $B \vdash B'$, and introduce. For disjunction, apply (11) to $A \vee B$, with branches that project A from $(A \vee B) \wedge A$, cut with $A \vdash A'$ and introduce $A' \vee B'$. For implication, from $(A \to B) \wedge A'$ derive A by cutting $A' \vdash A$, apply (13) to obtain B, cut with $B \vdash B'$, and close with (12). Reindexing is construction (18) applied to both derivations.

For the universal quantifier we use the *generic instance*. Let $\pi = \pi_1 : G \times X \to G$ and let $v = \mathrm{map}(\pi_2)$ be the newest variable. The composite of $\mathrm{gr}(v) : G \times X \to (G \times X) \times X$ and $\pi \times \mathrm{id} : (G \times X) \times X \to G \times X$ sends (g, x) to $((g, x), x)$ and then to (g, x): it is the identity. By rules 12–15, $\mathrm{gr}(v)^*(\pi \times \mathrm{id})^*A \equiv A$. Now $\pi^*\forall_X A \equiv \forall_X(\pi \times \mathrm{id})^*A$ by rules 26 and 27; universal elimination at v and the generic instance give $\pi^*\forall_X A \vdash A$, a cut with $A \vdash A'$ gives $\pi^*\forall_X A \vdash A'$, and (14) gives $\forall_X A \vdash \forall_X A'$. For the existential quantifier, $A \vdash A'$ and the generic instance give $A \vdash \mathrm{gr}(v)^*(\pi \times \mathrm{id})^*A'$, so existential introduction at v gives $A \vdash \exists_X(\pi \times \mathrm{id})^*A'$, and this formula is $\equiv \pi^*\exists_X A'$ by rules 28 and 29. Hence $\pi^*\exists_X A \wedge A \vdash \pi^*\exists_X A'$, and (17), applied to $\exists_X A \vdash \exists_X A$, gives $\exists_X A \vdash \exists_X A'$. The statements about $\top$ and $\bot$ are the derivations given after Table 16.2, and the last statement is rules 14 and 15. □

The coherence lemma (Lemma 16.12) uses these facts at every connective and quantifier. Its atomic cases rest on the substitution lemma for number terms, which says, for the three operations: evaluating t with s substituted at position k, at a valuation ρ, equals evaluating t at ρ with the value of s inserted at k; evaluating t lifted by d at cutoff c at ρ equals evaluating t at ρ with the d positions from c deleted; and a renaming of set positions does not touch number

terms. Each is proved by induction on t, the case of a variable being the definition of the operation (Definition 5.2).

J.2 The remaining cases of the compiler

We complete the proof of Theorem 16.11. In each case the induction hypothesis gives the translated premises.

Falsehood, conjunction and disjunction introductions, conjunction eliminations and implication elimination translate to the constructions of the same name, with the same premises: the translation commutes with these connectives and leaves the context unchanged.

Disjunction elimination. The HAS premises are $\Gamma \vdash A \vee B$, $A, \Gamma \vdash C$ and $B, \Gamma \vdash C$. Cut the translated second and third premises with the swaps $\Gamma^\circ \wedge A^\circ \vdash A^\circ \wedge \Gamma^\circ$ and $\Gamma^\circ \wedge B^\circ \vdash B^\circ \wedge \Gamma^\circ$, and apply (11).

Existential introduction at a term t. The premise is $\Gamma^\circ \vdash A(t)^\circ$, which is $\equiv$ to

$$\Gamma^\circ \vdash \mathrm{gr}(\ulcorner t \urcorner)^* \mathrm{push}_{\mathbb{N}}^* A^\circ$$

by (16.1). Construction (16) at $\ulcorner t \urcorner$ gives $\Gamma^\circ \vdash \exists_{\mathbb{N}} \mathrm{push}_{\mathbb{N}}^* A^\circ$.

Existential elimination. The premises are $\Gamma \vdash \exists x\, A$ and $A, \Gamma\!\uparrow \vdash C\!\uparrow$. Reindex the second translated premise along $\mathrm{push}_{\mathbb{N}}$ and push the reindexing inside the conjunction:

$$\mathrm{push}_{\mathbb{N}}^* A^\circ \wedge \mathrm{push}_{\mathbb{N}}^* (\Gamma\!\uparrow)^\circ \vdash \mathrm{push}_{\mathbb{N}}^* (C\!\uparrow)^\circ.$$

The lifting instance of the coherence lemma replaces $\mathrm{push}_{\mathbb{N}}^*(\Gamma\!\uparrow)^\circ$ by $\pi_1^* \Gamma^\circ$ and $\mathrm{push}_{\mathbb{N}}^*(C\!\uparrow)^\circ$ by $\pi_1^* C^\circ$; a swap gives $\pi_1^* \Gamma^\circ \wedge \mathrm{push}_{\mathbb{N}}^* A^\circ \vdash \pi_1^* C^\circ$, and (17) with the first premise gives $\Gamma^\circ \vdash C^\circ$.

The set quantifiers. The four rules are the four number-quantifier cases with $\mathrm{push}_{\mathbb{S}}$ in place of $\mathrm{push}_{\mathbb{N}}$, the shift of set positions in place of lifting, and the instance of a set variable in place of (16.1). For universal introduction, the premise $\Gamma^+ \vdash A$ is reindexed along $\mathrm{push}_{\mathbb{S}}$ and $\mathrm{push}_{\mathbb{S}}^*(\Gamma^+)^\circ \equiv \pi_1^* \Gamma^\circ$; for universal elimination at X_j, construction (15) at the term $\ulcorner X_j \urcorner$ gives $\Gamma^\circ \vdash \mathrm{gr}(\ulcorner X_j \urcorner)^* \mathrm{push}_{\mathbb{S}}^* A^\circ \equiv A(X_j)^\circ$; existential introduction and elimination follow the number cases.

Reflexivity is construction (19) at $\ulcorner t \urcorner$.

Together with the cases in the text, every one of the twenty-eight rules of HAS (twenty logical and equality rules, the six arithmetic axioms, induction and comprehension) has been treated.

J.3 The full calculus derives every true equational sentence

We prove Proposition 16.15, reasoning in a classical metatheory. Throughout, G is a context, P a formula in context G, 1 the term $S(0)$, and "equational" means equational over constant carriers. For a term $t : G \vdash X$ and $g \in G_1$ we write $t(g)$ for the later value $[\![t]\!]_1(g)$, and for numbers v we use the numeral v, the term of the constant map with value v. The indicator χ_A of a formula A is the map of Proposition 16.15, and we write χ_A also for its term $\mathrm{map}(\chi_A)$.

(E) Equal later values. A map $f : G \to X$ into a constant carrier is determined by its later component: $f_0(g) = h_X(f_0(g)) = f_1(h(g))$ for every $g \in G_0$. Conversely every function $G_1 \to X_1$, composed with the passage at the earlier stage, is a map of carriers. So if X is constant and $t, u : G \vdash X$ have the same later values, then $[\![t]\!] = [\![u]\!]$, and Remark 16.7 derives $P \vdash t = u$. In the same way a derived equation may have its sides replaced by terms with the same maps: from $P \vdash t = u$, rule 13 and rule 18 at the identity give $P \vdash \mathrm{map}([\![t]\!] \circ \mathrm{id}) = \mathrm{map}([\![u]\!] \circ \mathrm{id})$, which is literally the judgment $P \vdash \mathrm{map}([\![t']\!] \circ \mathrm{id}) = \mathrm{map}([\![u']\!] \circ \mathrm{id})$ when $[\![t']\!] = [\![t]\!]$ and $[\![u']\!] = [\![u]\!]$, and rule 19 and rule 12 return to $P \vdash t' = u'$. In particular two formulas $\chi_B = 1$ whose indicators are the same map are the same formula; for a map $f : D \to G$ the indicator of f^*B is $\chi_B \circ f$, and rules 18 and 19 make $f^*(\chi_B = 1)$ and $\chi_{f^*B} = 1$ interderivable.

(S) Substitution through a map. Let $a, b : G \vdash X$, let Y be constant and let $\varphi, \psi : G \times X \to Y$ be maps; write $\varphi(a)$ for the term $\mathrm{map}(\varphi \circ \mathrm{gr}(a))$. Let B be the equation $\mathrm{map}(\varphi) = \mathrm{map}(\psi)$ in context $G \times X$. From $P \vdash a = b$ and $P \vdash \varphi(a) = \psi(a)$, rule 19 at $\mathrm{gr}(a)$ gives $P \vdash \mathrm{gr}(a)^*B$, construction (20) gives $P \vdash \mathrm{gr}(b)^*B$, and rule 18 gives $P \vdash \varphi(b) = \psi(b)$. When $\varphi(a)$ and $\psi(a)$ have the same later values, the second premise holds by (E); so a derived equation $a = b$ gives $P \vdash s = s'$ for all terms s, s' of Y whose later values are those of $\varphi(b)$ and $\psi(b)$. With $Y = X$ constant, $\varphi(g, z) = z$ and $\psi(g, z) = a(g)$, this gives symmetry: $P \vdash a = b$ yields $P \vdash b = a$.

(Z) Refutation. If $P \vdash s = s'$ is derivable for terms $s, s' : G \vdash \mathbb{N}$ with $s(g) = 0$ and $s'(g) = 1$ at every $g \in G_1$, then symmetry and (E) give $P \vdash S(0) = 0$, rule 1 and construction (13) give $P \vdash \bot$, and (4) gives $P \vdash Q$ for every Q.

(D) Case split. Let $D(x)$ be $x = 0 \vee \exists_{\mathbb{N}} y(x = S(y))$ in context $G \times \mathbb{N}$, with x the newest variable. By rules 12–29 and the composition rules, $\mathrm{gr}(0)^*D$ is equivalent to $0 = 0 \vee \exists_{\mathbb{N}} y(0 = S(y))$, whose left side is (19), and succ^*D to $S(x) = 0 \vee \exists_{\mathbb{N}} y(S(x) = S(y))$, whose right side follows by existential introduction at x and (19). So $\mathrm{Ind}(D)$ is derivable, and rule 7 gives $P \vdash \forall_{\mathbb{N}} D$. Let $t : G \vdash \mathbb{N}$ take only the values 0 and 1. Universal elimination at t gives $P \vdash t = 0 \vee \exists_{\mathbb{N}} y(t = S(y))$. In the second case, under existential elimination, apply (S) to the equation $t = S(y)$ with $\varphi(g, z) = t(g)$ and $\psi(g, z) = e(z)$, where $e(0) = 0$ and $e(z) = 1$ for $z \geq 1$: the two sides agree at t, because t takes only the values 0 and 1, and at $S(y)$ they are t and a term with the value 1. So $P \vdash t = 0 \vee t = 1$.

(T) Transfer. Let $C_1, \ldots, C_m$ and A be formulas in context G and $v_1, \ldots, v_m \in \{0, 1\}$, and suppose that every $g \in G_1$ with $\chi_{C_i}(g) = v_i$ for every i satisfies $g \Vdash_1 A$. Then from $P \vdash \chi_{C_i} = v_i$ for $i = 1, \ldots, m$ the calculus derives $P \vdash \chi_A = 1$. Let $F(g, z_1, \ldots, z_m)$ be 1 when $z_i = v_i$ for every i, and $\chi_A(g)$ otherwise. The equation $\chi_A = F(g, \chi_{C_1}, \ldots, \chi_{C_m})$ holds at every later object, by the hypothesis, so it is derivable by (E). Substituting the equations $\chi_{C_i} = v_i$ one at a time by (S) turns its right side into $F(g, v_1, \ldots, v_m)$, which has the value 1.

The induction. For every equational formula A in every context G, the calculus derives $\chi_A = 1 \vdash A$ and $A \vdash \chi_A = 1$. The proof is by induction on A, for all contexts at once.

$\top$ and $\bot$. $\chi_\top$ has the value 1 and $\chi_\bot$ the value 0 at every later object. So $\chi_\top = 1$ is derivable by (E), and $\top$ by (3); $\chi_\bot = 1$ gives $\bot$ by (Z), and (4) gives the converse.

An equation $t = u$, with X constant. From $\chi_{t=u} = 1$, apply (S) with $\varphi(g, z) = t(g)$ and $\psi(g, z) = u(g)$ when $z = 1$ and $t(g)$ otherwise: the two sides agree at $\chi_{t=u}$, and at 1 they are t and u. From $t = u$, apply (S) with $\varphi(g, z) = 1$ when $z = t(g)$ and 0 otherwise, and $\psi(g, z) = 1$: the two sides agree at t, and at u the left side has the values of $\chi_{t=u}$.

Conjunction. From $\chi_{A\wedge B} = 1$, transfer gives $\chi_A = 1$ and $\chi_B = 1$, the induction hypotheses give A and B, and (6) gives $A \wedge B$. From $A \wedge B$, constructions (7–8) and the induction hypotheses give $\chi_A = 1$ and $\chi_B = 1$, and transfer with $m = 2$ gives $\chi_{A\wedge B} = 1$.

Disjunction. From $\chi_{A\vee B} = 1$, the case split (D) gives $\chi_A = 0 \vee \chi_A = 1$, and (11) treats the cases. If $\chi_A = 1$, the induction hypothesis gives A and (9) gives $A \vee B$. If $\chi_A = 0$, transfer from $\chi_{A\vee B} = 1$ and $\chi_A = 0$ gives $\chi_B = 1$, so B, and (10) gives $A \vee B$. From $A \vee B$, apply (11): in each branch the induction hypothesis and transfer give $\chi_{A\vee B} = 1$.

Implication. By (12), it is enough to derive $\chi_{A\to B} = 1 \wedge A \vdash B$. The induction hypothesis gives $\chi_A = 1$; at a later object an implication is read pointwise, so transfer from $\chi_{A\to B} = 1$ and $\chi_A = 1$ gives $\chi_B = 1$, and the induction hypothesis gives B. Conversely, from $A \to B$ split on χ_A by (D) and (11). If $\chi_A = 0$, transfer gives $\chi_{A\to B} = 1$. If $\chi_A = 1$, the induction hypothesis gives A, construction (13) gives B, the induction hypothesis gives $\chi_B = 1$, and transfer gives $\chi_{A\to B} = 1$.

The universal quantifier, with X constant. The judgment $\chi_{\forall_X A} = 1 \vdash \forall_X A$ follows by construction (14) from

$$\pi^*(\chi_{\forall_X A} = 1) \vdash A \qquad \text{in context } G \times X.$$

By (E) the hypothesis is $\chi_{\pi^*\forall_X A} = 1$; at every later (g, x) where it holds, $g \Vdash_1 \forall_X A$ and so $(g, x) \Vdash_1 A$; transfer gives $\chi_A = 1$, and the induction hypothesis gives A. For the converse, if X_1 is empty, $\chi_{\forall_X A}$ has the value 1 everywhere and (E) suffices. Otherwise let $c_1(g)$ be an $x \in X_1$ with $(g, x) \nVdash_1 A$ when one exists, and a fixed element of X_1 when none does; by (E) this is a map $c : G \to X$, a counterexample chosen in the metatheory. Construction (15) at $\mathrm{map}(c)$ gives $\forall_X A \vdash \mathrm{gr}(c)^* A$, and the induction hypothesis reindexed along $\mathrm{gr}(c)$ by (18), with (E), gives $\chi_{\mathrm{gr}(c)^* A} = 1$. If A holds at $(g, c_1(g))$, it holds at every (g, x), since otherwise $c_1(g)$ would be a counterexample; so transfer gives $\chi_{\forall_X A} = 1$.

The existential quantifier, with X constant. If X_1 is empty, $\chi_{\exists_X A}$ has the value 0 everywhere, and (Z) gives $\chi_{\exists_X A} = 1 \vdash \exists_X A$. Otherwise let $w_1(g)$ be an $x \in X_1$ with $(g, x) \Vdash_1 A$ when one exists, and a fixed element otherwise; by (E) this is a map $w : G \to X$. Where $\chi_{\exists_X A}(g) = 1$, A holds at $(g, w_1(g))$, so transfer gives $\chi_{\mathrm{gr}(w)^* A} = 1$; with (E) and the induction hypothesis reindexed along $\mathrm{gr}(w)$ this gives $\mathrm{gr}(w)^* A$, and (16) at $\mathrm{map}(w)$ gives $\exists_X A$. For the converse, by (17) it is enough to derive $\pi^*\exists_X A \wedge A \vdash \pi^*(\chi_{\exists_X A} = 1)$ in context $G \times X$. The induction hypothesis gives $\chi_A = 1$. At every later (g, x) with $\chi_A(g, x) = 1$, $g \Vdash_1 \exists_X A$; so transfer gives $\chi_{\pi^*\exists_X A} = 1$, which is $\pi^*(\chi_{\exists_X A} = 1)$ by (E).

Reindexing $f^* A$, for $f : D \to G$. By (E), $f^*(\chi_A = 1)$ and $\chi_{f^* A} = 1$ are interderivable, and construction (18) applied to the two induction hypotheses gives $f^*(\chi_A = 1) \vdash f^* A$ and $f^* A \vdash f^*(\chi_A = 1)$.

Conclusion. If $g \Vdash_1 A$ for every $g \in G_1$, then χ_A and 1 have the same later values, (E) gives $P \vdash \chi_A = 1$, and a cut with $\chi_A = 1 \vdash A$ gives $P \vdash A$. No step uses a base rule other than rules 1, 7 and 12–29 and the constructions; the truth of A enters only through the indicator and the maps chosen in the metatheory.

J.4 Programs that track the maps

All programs below are built from given programs by the operations of Definition 10.5, so they exist by Proposition 10.6; from a program for a function of two arguments a program for the function of the second argument is computed from the first [19, Chapter XII].

Structural maps. The identity is tracked by the program that returns its input, a composite by the composite program, the projections by the two unpairing functions, and a pairing $\langle f, g\rangle$ by the program that pairs the outputs of the trackers of f and g. Evaluation $\mathrm{ev} : Y^X \times X \to Y$ is tracked by the universal program that sends e to $\{(e)_0\}((e)_1)$: if $(e)_0$ names f and $(e)_1$ names x, the run halts with a name of $f(x)$, by the definition of a name of a function. If c tracks $k : Z \times X \to Y$, the curried map λk is tracked by the program that sends a name a of z to a program that, on input b, runs c on the number of the pair (a, b); for every name b of every x that program halts with a name of $k_1(z, x)$, so its output names the function $x \mapsto k_1(z, x)$. A map into Ω is tracked by the program that returns 0, because 0 names every truth value; the same program, read as a program on every input, names every later object of Ω^X.

Numbers and finite data. Successor, sum and product on $\mathbb{N}$ are tracked by their programs, since a name of a number is the number. A constant map with a named value is tracked by a program that ignores its input and returns the name. Coding and decoding of strings, bits and ratio records are computable.

The line. The quotient map $\mathscr{R} \to \mathscr{L}$ is tracked by the identity program, since a name of s names its class. The point $\eta(q)$ of a ratio record is named by the program that returns the code of q on every input. Negation, sum, product, maximum and minimum of points are computed stage by stage from the stages of given regular sequences by the formulas of Proposition 12.19: the sum at stage n reads both sequences at $2n + 1$, and the product reads a stage computed from the first stages of both sequences. So one program for each operation computes, from programs for s and t, a program for the result; this tracks the operation on $\mathscr{L}$, because its value on classes does not depend on the representatives. Multiplication by a fixed ratio is a product with a named point. For a fixed N, the reciprocal $n \mapsto 1/s_{4(N+1)^2(n+1)-1}$ of Lemma F.11 is computed from a program for s; the stage N is part of the program, not computed from s.

The translation of HAS. A name of an environment is a pair of a program for the number valuation ρ and a name of the set valuation. Evaluating a number term at ρ composes the program for ρ with the finitely many arithmetic operations of the term, so the term maps $\ulcorner t \urcorner$ are tracked; $\ulcorner X_j \urcorner$ is tracked by reading the j-th entry of the set valuation through the universal program. The map $\mathrm{push}_{\mathbb{N}}$ is tracked by the program that sends a name of $((\rho, \sigma), n)$ to a name of $(n \cdot \rho, \sigma)$, where $n \cdot \rho$ is computed by a program that returns n on input 0 and, on input $k + 1$, runs the program for ρ on input k; the map $\mathrm{push}_{\mathbb{S}}$ is the same for set valuations; successor, projections and graphs of tracked terms are tracked as above.

The maps of the compactness sentences. Section 16.10 writes every relation as an equation, so each map that the equations of Definition 16.30 apply must be tracked; otherwise its term would not belong to the computable calculus. Each map below is tracked by the program described.

- *Strings.* The length $|w|$, the digit w_i (with the value 0 for $i \geq |w|$), the concatenation wt and the extension wb by one digit are computable functions of codes, and a name of a

string or of a bit is its code; so each is tracked by its own program. The empty string and the bit 1 are constants with named values. These maps let a string variable stand for the initial segment $\bar{p}(n)$, which turns $D(\bar{p}(n)) = 1$ into an equation.

- *Applications.* The terms $p(i)$, $D(w)$ and $f(x)$ apply a sequence, a decidable set or a function on the line to its argument; they are instances of evaluation, tracked by the universal program.

- *The line.* The maximum, the sum and the negation are the operations of the previous paragraphs. The map $k \mapsto \eta(1/(k+1))$ is tracked by the program that computes from k a program returning the code of $1/(k+1)$ on every input, and the points 0 and 1 are named in the same way. With these maps the order of the line becomes the equation $\max(a, b) = b$, and strict order and closeness become existential and conjunctive combinations of such equations.

- *Covers.* The endpoints $a_c(k)$ and $b_c(k)$ are tracked by the program that runs the given name of c on k, decodes the two ratios of the k-th interval and returns programs for their constant sequences. They write membership in an interval as two strict inequalities.

- *Nets.* The number $\ell_K(n)$ and the point $y_K(n, i)$ are tracked by the program that runs the given name of K on n, obtains the list of programs of the entries of the n-th net, and returns its length, or its i-th entry, or a program for the constant sequence 0 when $i \geq \ell_K(n)$. The map $r(n) = 2^n - 1$ on numbers is computable. With them membership in a presented set becomes a condition on its nets, as in Definition 16.30.

- *Packages.* A name of a presented uniform map or of a map package lists programs for its parts. The set K_M is tracked by the program that returns the component naming the set, and the value $f_M(x)$ by the program that runs the component naming the function on the given name of x. They let one variable M range over maps together with their sets.

J.5 Reading the sentences in the model

The separations evaluate closed sentences at the point of **1** in the model of named objects. The evaluation unfolds Definition 16.20. Three observations shorten it: every number, string and bit is named, so a quantifier over $\mathbb{N}$, W or B ranges over all of them; a quantifier over Seq, P or D ranges over the computable objects, by Proposition 16.21(a); and an equation is read at the later stage as the equality of the values of its two sides.

Proof of Lemma 16.31. The quantifiers over $\mathbb{N}$ and W in Definition 16.30 range over all numbers and all strings.

Numbers. Some k has $n + k = N$ exactly when $n \leq N$, and some k has $i + (k+1) = n$ exactly when $i < n$.

Hits. If $D(\bar{p}(n)) = 1$, the string $\bar{p}(n)$ is a witness for $\mathrm{Hit}(D, p, n)$. Conversely a witness w has length n and the digits $p(0), \dots, p(n-1)$, so $w = \bar{p}(n)$ and $D(\bar{p}(n)) = 1$. The same argument, with every string t in the last conjunct, gives CHit.

The order of the line. By Proposition 12.19(5), $\max(a,b)$ is the least upper bound of a and b. If $a \le b$, then b is an upper bound, so $\max(a,b) \le b \le \max(a,b)$ and $\max(a,b) = b$ by item 2; conversely $\max(a,b) = b$ gives $a \le b$. If $0 < y$, Lemma 12.52, item 1, gives a ratio q with $0 < \eta(q) < y$; since $q > 0$ is a ratio, $1/(k+1) \le q$ for some k, and $\eta(1/(k+1)) \le \eta(q) \le y$. Conversely, if $\eta(1/(k+1)) \le y$, then cotransitivity of $<$ (Proposition 12.19(1)) applied to $0 < \eta(1/(k+1))$ gives $0 < y$ or $y < \eta(1/(k+1))$, and the second contradicts $\eta(1/(k+1)) \le y$. Since $a < b$ means $b - a > 0$, the strict order follows. Closeness within $1/(j+1)$ is by definition the conjunction of the two inequalities, the k-th interval of c consists of the points strictly between its ends (Definition 13.5), and $[0,1]$ consists of the points x with $0 \le x \le 1$.

Membership. If $x \in K$, the n-th net has an entry within $2^{-n} = 1/(r(n)+1)$ of x (Definition 13.22), at an index below $\ell_K(n)$. Conversely, suppose every net has such an entry. For every k the entry of the k-th net names a member of K within $2^{-k} \le 1/(k+1)$ of x, so $x \in K$ by Proposition 13.23. No quantifier over points occurs in the formula, so the restriction of the model to named points does not enter. □

Lemma J.2 (The sentences in the model)**.** *At the point of* **1** *in the model of named objects:*

(a) LPO *holds exactly when every computable binary sequence vanishes or has an entry* 1*;*

(b) $\mathsf{WLPO}_{\mathsf{seq}}$ *holds exactly when for every computable binary A there is a computable binary f with $f(i) = 0$ exactly when $A\langle i,n\rangle = 0$ for every n;*

(c) $\mathsf{FAN}^{=}_{\Delta}$ *holds exactly when every computable decidable set of strings that every computable sequence meets has one bound N such that every computable sequence meets it at a length $n \le N$, and* $\mathsf{FAN}^{=}_{c}$ *likewise with c-sets;*

(d) $\mathsf{WKL}^{=}$ *holds exactly when every computable decidable tree with a member of every length has a computable path;*

(e) $\mathsf{HB}^{=}$ *holds exactly when for every named presented set K and every named cover, if every named point of K lies in an interval of the cover, then some N has every named point of K in one of the first N intervals; and* $\mathsf{HB}^{=}_{[0,1]}$ *holds exactly when the same is true of* $[0,1]$ *and every named cover;*

(f) $\mathsf{PLB}^{=}$ *and* $\mathsf{PINF}^{=}$ *hold exactly when the statements of Chapter 13 hold for every named presented uniform map, with every quantifier over points restricted to the named points, and* $\mathsf{PLB}^{=}_{[0,1]}$ *and* $\mathsf{PINF}^{=}_{[0,1]}$ *likewise for every named function on the line that is uniformly continuous on the named points of* $[0,1]$*;* $\mathsf{HC}^{=}$ *holds exactly when every named map package that is pointwise continuous on the named points of its set is uniformly continuous on them, both notions read with the named points only, and* $\mathsf{HC}^{=}_{[0,1]}$ *likewise for every named function on the line and the named points of* $[0,1]$.

Proof. Each item unfolds the clauses of Definition 16.20 and uses the three observations. In (a), $\mathrm{Bin}(\alpha)$ reads as "every value of α is 0 or 1", and the disjunction is read classically. In (b), the inner universal quantifiers range over all numbers, and the pairing term $\langle i,n\rangle$ is read as its value. In (c) to (f) the abbreviations of Definition 16.30 read as the relations they abbreviate, by Lemma 16.31. In (c) and (d), the quantifiers over strings and bits range over all of them, so

Tree(T) and Inf(T) read as in Definition 12.71, and the quantifiers over sequences range over the computable ones. In (e) and (f), the quantifiers over points range over the named points, and the quantifiers over packages, covers and maps over the named ones. □

J.6 Addresses and the dead cover

We use the geometry and the facts (a)–(c) of the proof of Theorem 13.6: the number $\kappa(s)$, the Cantor point $c(s)$, the Cantor interval $J(s)$, the cells $C(s)$, and $u_n = 1/(8 \cdot 4^n)$.

(C3) Addresses of computable sequences are computable. In fact (c), the digit given to a string s of length n reads one stage of the regular sequence, a stage computed from n, and compares it with the ratio $(32\kappa(s) + 16)/2^{2n+5}$, computed from the digits already chosen. So the address is defined by a primitive recursion on the depth from finitely many stages of the sequence, and a program for the sequence gives a program for its address. The recursion is defined for every regular sequence, and the inductive step of fact (c), that $x \in C(s)$ gives $x \in C(sd)$ for the chosen digit d, holds for every point x; so $x \in C(\bar{a}_r(n))$ for every n whenever x lies in $C(\emptyset) = (-1, 2)$.

Names. The Cantor point $c(t)$ is a ratio, so it is named. The dead cover of T_K is named: from k a program decodes w_k, decides $w_k \in T_K$ by Lemma 16.29(a), and returns the ends of $(0, 0)$ or of $C(w_k)$, which are computed from $\kappa(w_k)$ and $|w_k|$ by the recursion that defines the cells. The presentation of $[0, 1]$ in Chapter 13 has, at every precision, a finite list of dyadic ratios; a program computes from n the list of the programs of their constant sequences, so the presented set $[0, 1]$ is named.

J.7 The cover series as a named map

Let c be a cover named by a program, and use the notation of Lemma 13.26. The functions θ_i are built from translation by the ratios a_i and b_i, negation, max, min and the constant 1, and the weights ω_i are ratios. By the programs of Section J.4, one program computes from i, from the program of the cover and from a name of x a name of $\omega_i\theta_i(x)$, and so, by finite summation, a name of the partial sum $\sum_{i<n} \omega_i\theta_i(x)$ from n and a name of x. The diagonal of Theorem 12.25 reads the stage $2n + 1$ of the $(2n + 1)$-th of these names, so one program computes a name of $f_c(x)$ from a name of x. This program is the transformer of the presented uniform map, and it names f_c as a function on the line. A modulus is computed by a program: $f_c(x)$ is within $1/(n + 1)$ of the partial sum at n, by Theorem 12.25; the partial sums at n of two points within $1/(j + 1)$ are within $1/(j + 1)$, because each θ_i moves by at most the move of its argument (Lemma 12.52, item 5) and the weights ω_i add up to less than 1; so at $n = 4k + 3$, points within $1/(2k + 2)$ have values within $1/(4k + 4) + 1/(2k + 2) + 1/(4k + 4) = 1/(k + 1)$, and $\mu(k) = 2k + 1$ is a modulus. Pairing these programs with a program naming the presented set gives a name of the presented uniform map.

J.8 The tent function

We use the facts (d) and (e) of the proof of Theorem 13.13, which hold for every decidable binary tree, in particular for T_K: overlaps of different strings are disjoint and contain no Cantor

point; and if $u \notin T_K$, every tent of a member of T_K of length at least $|u|$ vanishes on $C(u)$.

(T1) Values at the special points. Every tent vanishes at every Cantor point, so every head does, and $\tau(c(s)) = 0$. For $s \in T_K$ the point $g(s)$ lies in $O(s)$ and in no other overlap, so $H_N(g(s)) = \tau_s(g(s)) = 1$ for every $N > |s|$, and $\tau(g(s)) = 1$.

(T2) Heads stop changing on a dead cell. If $u \notin T_K$, fact (e) gives $H_M = H_{|u|}$ on $C(u)$ for every $M \geq |u|$, so $\tau = H_{|u|}$ on $C(u)$.

(T3) The tent function is named. Let a program compute a regular sequence r naming a point x. The program for τ computes the address digits of r by (C3) and searches for the first depth n with $\bar{a}_r(n) \notin T_K$. The address is computable, so by Lemma 16.29(d) the search ends. If x lies in $(-1, 2)$, then $x \in C(\bar{a}_r(n))$ by (C3), and (T2) gives $\tau(x) = H_n(x)$. Otherwise every overlap, which lies in $[0, 1]$, misses x, so every tent vanishes at x, every head is 0 there, and again $\tau(x) = H_n(x)$. The program does not decide which case holds; the two cases are distinguished only in this proof. It then computes a name of $H_n(x)$: the members of T_K of length below n are listed by Lemma 16.29(a), and each tent is built from the tracked operations of Section J.4 and the ratios $g(s)$ and $8 \cdot 4^{|s|}$. Since $\tau(x)$ depends only on x, the program tracks τ on all named points.

(T4) Continuity at named points of $[0, 1]$. Let $x \in [0, 1]$ be named, and let u be an initial segment of its address outside T_K, as in the proof of Theorem 16.34; then $x \in C(u)$. The cell is open with ratio ends, so some j_0 puts every point within $1/(j_0 + 1)$ of x inside $C(u)$, by Lemma 12.52, item 3. On $C(u)$, $\tau = H_{|u|}$ by (T2), a sum of fewer than $2^{|u|}$ tents of strings shorter than $|u|$, each of which changes by at most $8 \cdot 4^{|u|}$ times the change of its argument. Given k, choose $j \geq j_0$ with $2^{|u|} \cdot 8 \cdot 4^{|u|}/(j + 1) \leq 1/(k + 1)$. Every named $y \in [0, 1]$ within $1/(j + 1)$ of x has $\tau(y)$ within $1/(k + 1)$ of $\tau(x)$.

(T5) No uniform modulus. For every j, Lemma 16.29(c) gives $s \in T_K$ of length $n = j + 1$. The ratios $c(s)$ and $g(s)$ lie in $[0, 1]$, at distance $4u_n = 2^{-(2n+1)} \leq 1/(j + 1)$, and by (T1) $\tau(c(s)) = 0$ and $\tau(g(s)) = 1$.

Appendix K

The comparison with Peano arithmetic: routine cases

This appendix proves the results of Section 20.3 whose proofs there were deferred. The conventions of that section apply: every derivation is posit-free, $\Delta \vdash \varphi$ is a posit-free derivation of φ from the hypotheses Δ, and a statement with free variables holds for every substitution of terms. Unless stated otherwise, every derivation constructed here inducts on formulas with quantifiers, so its ledger records the induction entry.

The elementary facts of arithmetic are used freely: $0+t = t$ and $S(t)+u = S(t+u)$; associativity and commutativity of addition; cancellation $a + c = b + c \to a = b$ and its left form; $0 \cdot t = 0$ and $S(t) \cdot u = t \cdot u + u$; distributivity, commutativity and associativity of multiplication; and monotonicity, $a \le b \to a \cdot c \le b \cdot c$, which follows from distributivity. Each has a derivation by the rules of Chapter 5 whose inductions are on equations or on implications between equations, so these derivations have the empty ledger; Chapter 3 gives the same inductions for the constructed numbers.

K.1 Order and pairing

Proof of Lemma 20.2. Every number is zero or a successor: induct on x in $x = 0 \vee \exists y(x = S(y))$.

Order split, $a < b \vee b \le a$. Induct on a, keeping the statement universal in b. At $a = 0$: if $b = 0$ then $b \le 0$ with witness 0; if $b = S(t)$ then $0 < b$ with witness t. At $a + 1$: if $b = 0$ then $b \le a + 1$ with witness $a + 1$. Otherwise $b = t + 1$, and the induction hypothesis at a, t gives $t = a + (k + 1)$, so $b = (a + 1) + (k + 1)$ and $a + 1 < b$; or $a = t + l$, so $a + 1 = (t + 1) + l = b + l$ and $b \le a + 1$.

Disjointness. From $a + (k + 1) = b$ and $b + l = a$ follows $a + ((k + 1) + l) = a + 0$, so cancellation gives $(k + 1) + l = 0$, that is $S(k + l) = 0$, which separation refutes.

Totality. By the order split, take $z = b \cdot b + a$ when $a < b$ and $z = (a \cdot a + a) + b$ when $b \le a$; each branch of G holds by reflexivity.

Uniqueness. If both graphs use the same branch, both values equal the same term. A crossed case supplies $a < b$ and $b \le a$, which disjointness refutes.

Injectivity. Let s be the larger of a, b. If $a < b$ then $s = b$ and $s \cdot s \le \langle a, b\rangle < s \cdot s + s$; if $b \le a$ then $s = a$ and $s \cdot s + s \le \langle a, b\rangle \le s \cdot s + 2s < (s + 1) \cdot (s + 1)$. So every pair with larger coordinate s has its value in $[s^2, (s + 1)^2)$, and these intervals are disjoint for different s by monotonicity: if $s < s'$ then $s + 1 \le s'$ and $(s + 1)^2 \le s'^2$. Equal values therefore have the same s. Within one s the first branch lies below $s^2 + s$ and the second at or above it, so equal values use the same branch, and cancellation in $s^2 + a = s^2 + c$, or in $s^2 + s + b = s^2 + s + d$, identifies the remaining coordinate.

Decoding. First derive $G(a,b,z) \to \exists a', b'\, G(a',b',z+1)$ by four cases. If $a+1=b$, take $(b,0)$: the second branch gives $b\cdot b+b=z+1$. If $a+1<b$, take $(a+1,b)$: the first branch gives $b\cdot b+(a+1)$. If $b=a$, take $(0,a+1)$: the first branch gives $(a+1)\cdot(a+1)=a\cdot a+2a+1$, and $z=a\cdot a+a+a$. If $b<a$, take $(a,b+1)$: the second branch gives $a\cdot a+a+(b+1)$. The cases are exhaustive by the order split. Then induct on z in $\exists a,b\, G(a,b,z)$, starting from $G(0,0,0)$. □

K.2 The computation formula

Coding finite lists

Lemma K.1 (Remainders). *There are derivations of:* $\mathrm{Rem}(a,d,r) \to \mathrm{Rem}(a,d,t) \to r=t$; *and* $0<d \to \exists r\, \mathrm{Rem}(a,d,r)$. *Consequently* $\beta(A,B,i,w)$ *and* $\beta(A,B,i,v)$ *imply* $w=v$, *and every* A,B,i *have some* w *with* $\beta(A,B,i,w)$.

Proof. For uniqueness write $a=qd+r=pd+t$ with $r<d$ and $t<d$. If $q<p$, then $q+1\le p$ and $qd+r<(q+1)d\le pd\le pd+t$, a contradiction; $p<q$ is symmetric; so $q=p$ and cancellation gives $r=t$. For existence induct on a. At 0 use quotient 0 and remainder 0, with the predecessor of d as the slack witness. At $a+1$, open $a=qd+r$ and $r+(s+1)=d$: if $s=0$ then $a+1=(q+1)d+0$; if $s=t+1$ then $a+1=qd+(r+1)$ and $(r+1)+(t+1)=d$. The modulus $1+(i+1)B$ of β is positive. □

Lemma K.2 (Combining two residues). *If* M,d *are positive with* $uM=vd+1$, *and* $r<M$, $s<d$, *then some* z *has* $\mathrm{Rem}(z,M,r)$ *and* $\mathrm{Rem}(z,d,s)$.

Proof. Write $d=h+1$ and put $w=s+hr$ and $z=r+uMw$. Then $z=(uw)M+r$, and, using $uM=vd+1$ and $r+hr=dr$, $z=r+(vd+1)(s+hr)=(r+vw)d+s$. □

Three identities supply the coefficients that a coprimality theorem would otherwise provide. If $b=kt$, and $g=ab$, $h=(a+k)b$, $c=a^2t$, then

$$(1+h)(c+1+g)=(1+g)(g+c+h)+1, \tag{K.1}$$

which follows on expanding, using $h=g+kb$ and $g^2=ckb$. If $nu=mv+1$ and $m=a+1$, then $m(va+1)=n(ua)+1$. If $au=nv+1$ and $cp=nq+1$, then $(ac)(up)=n(nvq+v+q)+1$.

Lemma K.3 (Appending an entry). *For all* j,A,B,w *there are* y,b *such that* $\beta(A,B,i,r)\to\beta(y,b,i,r)$ *for every* $i<j$ *and every* r, *and* $\beta(y,b,j,w)$.

Proof. Some positive L is divisible by every number from 1 to $j+1$: induct, with $L(n+2)$ covering $n+2$. Put $b=L(A+w)$ and $m_i=1+(i+1)b$ for $i\le j$. Every old entry is at most A and $w\le b$, so all are below every m_i. For $i<l\le j$ the difference $l-i$ divides b; writing $b=kt$ with $k=l-i$, identity (K.1) with $a=i+1$ gives an equation $m_lu=m_iv+1$, and the second identity reverses it. Now process positions $0,\dots,j-1$ in order, by induction, keeping a positive M and $x<M$ such that every processed modulus divides M, x has the required residue at each processed position, and for every remaining $l\le j$ some μ,ν satisfy $M\mu=m_l\nu+1$. Start with $M=1$, $x=0$. At position q, take the old entry r there (Lemma K.1), combine x modulo

M with r modulo m_q by Lemma K.2, and reduce modulo $M' = Mm_q$. Reduction keeps both residues, by remainder uniqueness applied to the quotients, and every earlier divisor of M divides M'. The third identity gives the coefficients of M' against each remaining m_l. At the end, combine x modulo M with w modulo m_j; the result y keeps every earlier residue and has residue w at j. □

Proof of Theorem 20.3(4), finite choice. Assume $\forall i\, \exists r\, \varphi(i, r)$ and induct on j. At 0 take $A = B = 0$. At $j + 1$ the induction hypothesis gives A, B for every $i < j$, the premise gives r for $i = j$, and Lemma K.3 gives parameters that keep the earlier entries and add r at j. □

Rows and the exact graph

Write

$$\mathrm{Packed}(K, e, n, y, w) \;:=\; \exists p, q \big(G(n, y, p) \wedge G(e, p, q) \wedge G(K, q, w)\big),$$

so that $\mathrm{Row}(A, B, i; K, e, n, y)$ is $\exists w(\beta(A, B, i, w) \wedge \mathrm{Packed}(K, e, n, y, w))$. By remainder uniqueness and three uses of pairing injectivity, *a row determines its four coordinates*: two rows at the same position of the same table have equal coordinates.

Proof of Theorem 20.3(1). Say that c returns y on n with allowance K when a finite computation tree built by the evaluation clauses has c, n, y at its root, where every node with allowance $s + 1$ has input at most s, calls of a proper part keep the allowance of the node, and the two calls that repeat the program use s. Every computation of Definition 10.5 has such a tree: choose the allowance one more than the sum of the largest input and the number of nested repetitions. Given a tree, list its nodes with each parent before its children, the root first and then the lists of its children; each node's children stand later in the list, so every row satisfies its local condition with later rows. Finite-list coding stores the packed rows, and the root is row 0. Conversely, from an indexed table and a selected row whose program field is the code of an actual program c, build a tree by strong induction on the number of rows after the selected one: every dependency is later, so has fewer rows after it. The constructor of c eliminates every incompatible alternative, because the four basic codes are below 4, compound codes are $4u + b$ with $u \geq 1$ and $b < 4$, and $4u + b = 4v + c$ with $b, c < 4$ forces $b = c$ and $u = v$; pairing injectivity then identifies the part codes. Each alternative rebuilds the corresponding clause. □

Proof of Theorem 20.3(2), functionality. Prove the following *comparison*: if $\mathrm{Indexed}(N, A, B)$ and $\mathrm{Indexed}(M, C, D)$, $i < N$, $j < M$, and row i of the first table is (K, e, n, y) and row j of the second is (L, e, n, t), then $y = t$; the allowances need not agree. Induct strongly on the rank d with $i + d = N$, keeping everything else universal; strong induction is ordinary induction on u in $\forall d \leq u\, F(d)$. Indexedness and row uniqueness supply the local condition of each selected row. A dependency of the first row has a position p with $i < p < N$, and its rank is smaller. Constructor separation, as in the proof of part (1), leaves only matching alternatives.

- *Zero, successor*: both outputs are 0, or both $n + 1$.
- *Projections*: pairing injectivity on the two decompositions of n.

- *Pairing*: compare the dependencies for f on n and for g on n, by the induction hypothesis; pairing uniqueness gives $y = t$.
- *Composition*: compare the dependencies for g on n, giving equal intermediate values; then those for f.
- *Recursion start*: injectivity on $\langle a, 0\rangle$; compare the dependencies for f. A crossed case would give $0 = m + 1$.
- *Recursion step*: injectivity identifies a and m; compare the dependencies for the previous call, which have program e and input $\langle a, m\rangle$ although their allowances may differ, to get equal previous values; the step inputs are then equal; compare the dependencies for g.
- *Search stop*: both outputs are m. A crossed case compares the two test dependencies and equates 0 with a positive value.
- *Search continue*: injectivity identifies a, m; compare the two dependencies for the rest of the search.

Functionality follows by opening the two applications. Every case split eliminates a derived disjunction. □

Closure of the computation formula

For a table (N, A, B), say that (A', B') *raises it by* d when every row (K, e, n, y) of (A, B) at a position $i < N$ is the row $(K + d, e, n, y)$ of (A', B') at i.

Lemma K.4 (Table operations)**.** *There are derivations of the following.*

1. *Every table has a raise by every d, and a raise of an indexed table is indexed. Consequently, if $K \le L$ and some indexed table has a row (K, e, n, y), some indexed table has a row (L, e, n, y).*
2. *Two indexed tables with selected rows can be placed in one indexed table that contains both rows.*
3. *If (T, A, B) is indexed and every table (C, D) that lists the rows of (A, B) one position later satisfies $\mathrm{Local}_{T+1,C,D,0}(K, e, n, y)$, then some indexed table has the row (K, e, n, y).*

Proof. (1) At each position, remainder existence gives the entry, three decodings write it as $\langle K, \langle e, \langle n, y\rangle\rangle\rangle$, and pairing totality packs $(K + d, e, n, y)$; finite choice stores these. Every local condition transfers: the guard $K = k + 1$, $n \le k$ becomes $K + d = (k + d) + 1$, $n \le k + d$; each dependency keeps its position and moves its allowance by d. For the consequence, write $L = K + d$.

(2) Every position below $N + M$ is below N or equal to $N + j'$ with $j' < M$; finite choice stores the entries of the first table in place and those of the second shifted by N. Rows, local conditions and dependencies move with them, and the strict order of dependency positions is kept.

(3) Pairing totality packs the new row; finite choice stores it at position 0 and the old entries one place later. The hypothesis gives the local condition at 0; each old row keeps its local condition shifted by one. □

Proof of Theorem 20.3(3), closure. For a basic clause, the one-row table whose two parameters are the packed row z lists it, since $\beta(z, z, 0, z)$ holds with quotient 0 because $z < 1 + z$; its local condition holds with allowance $n + 1$ and the clause's alternative, using the supplied graph for a projection. For a compound clause, open the premise computations, with allowances K and L, and put $k := K + (L + n)$, so that $n, K, L \le k$. Raise each premise table that computes a proper part to allowance $k + 1$, and a premise that repeats the program (the previous step of a recursion or the rest of a search) to allowance k, by Lemma K.4(1). Place the two tables in one by part (2); a clause with one premise uses its table twice. Add the parent row $(k + 1, e, n, y)$ in front by part (3): the premise rows sit at positions after 0, so they are dependencies of the new row, the guard is $k + 1 = k + 1$ with $n \le k$, and the clause's alternative holds with the supplied code relation, graphs and test value. The identity law follows from the decoding of n, the two projection laws and the pair law. □

K.3 The record test

The checking programs are built from the eight constructors without the search constructor. Write one $:=$ succ $\circ$ zero, $\mathrm{const}_0 :=$ zero, $\mathrm{const}_{k+1} :=$ succ $\circ\, \mathrm{const}_k$, prev $:=$ pair(left, left $\circ$ right), and $f \oplus g$, $f \otimes g$, $f \ominus g$ for add, mul, $\dot{-}$ composed with pair(f, g). A recursion rec(f, g) receives $\langle a, m\rangle$ and recurses on m; at a successor its step receives $\langle a, \langle m, x\rangle\rangle$, with x the previous value.

Program	Constructor expression
ζ	rec(one, zero $\circ$ prev) $\circ$ pair(zero, id)
pred	rec(zero, right $\circ$ prev) $\circ$ pair(zero, id)
$\dot{-}$	rec(id, pred $\circ$ (right $\circ$ right))
add	rec(id, succ $\circ$ (right $\circ$ right))
mul	rec(zero, add $\circ$ pair(left, right $\circ$ right))
cond(t, f, g)	rec$(f, (g \circ \mathrm{left}) \circ \mathrm{prev}) \circ \mathrm{pair}(\mathrm{id}, t)$: the value of f where t returns 0, of g elsewhere
rem	rec(zero, cond(eq(inc, left), inc, zero)) $\circ$ pair(right, left), with inc $:=$ (right $\circ$ right) $\oplus$ one; on $\langle m, d\rangle$ it recurses on the dividend m
entry(A, B, I)	rem $\circ$ pair$(A, ((I \oplus \mathrm{one}) \otimes B) \oplus \mathrm{one})$
eq(f, g)	$\zeta \circ ((f \ominus g) \oplus (g \ominus f))$
le(f, g), lt(f, g)	$\zeta \circ (f \ominus g)$ and $\zeta \circ ((\mathrm{succ} \circ f) \ominus g)$
and, or	$f \otimes g$ and $f \oplus g$
bnd(t, b)	norm(agg(t) $\circ$ pair(id, b)), with agg$(t) :=$ rec(one, mul $\circ$ pair(right $\circ$ right, $t \circ$ prev)) and norm$(f) :=$ rec(zero, (one $\circ$ left) $\circ$ prev) $\circ$ pair(id, f)
Ver	and$\big($bnd(row, slot_5), and(lt(slot_2, slot_5), rowEq(slot_4, slot_3, slot_2; slot_1, e, n, slot_0))$\big)$
T, $\bigcup$	$\zeta \circ$ Ver; right $\circ$ (search(T) $\circ$ pair(id, zero))

The roman add, mul and pred are programs, not the terms of (20.2) or the predecessor of Chapter 9. Here $\mathrm{slot}_k := (\mathrm{right} \circ d_k) \circ \mathrm{right}$ reads the field of c at depth k from the right on the input $z = \langle\langle e, n\rangle, c\rangle$, while $\mathrm{e} := \mathrm{left} \circ \mathrm{left}$ and $\mathrm{n} := \mathrm{right} \circ \mathrm{left}$ read e and n; $\mathrm{rowEq}(A, B, I; K, E, M, Y)$ is $\mathrm{eq}(\mathrm{entry}(A, B, I), \mathrm{pair}(K, \mathrm{pair}(E, \mathrm{pair}(M, Y))))$. The row check row runs at a cell $\langle z, j\rangle$. It reads the justification $\mathrm{entry}(\mathrm{slot}_7 \circ \mathrm{left}, \mathrm{slot}_6 \circ \mathrm{left}, \mathrm{right})$ and the row $\mathrm{entry}(\mathrm{slot}_4 \circ \mathrm{left}, \mathrm{slot}_3 \circ \mathrm{left}, \mathrm{right})$, takes their fields by projections, and returns the conjunction of the guard tests $K = s + 1, n \leq s$ with the disjunction of the ten case tests of Table 20.2, each the conjunction of the equality, order and named-row tests of its line. A named row $j' \mapsto (k', e', n', y')$ is tested by $\mathrm{lt}(\mathrm{right}, j')$, $\mathrm{lt}(j', \mathrm{slot}_5 \circ \mathrm{left})$ and the row comparison at j'.

Lemma K.5 (The test programs)**.** *There are derivations of: ζ returns* 1 *on* 0, 0 *on every successor, and* 0 *or* 1 *on every input; $\dot{-}$ on $\langle a, m\rangle$ returns y when $m + y = a$ and* 0 *when $a \leq m$;* add *and* mul *on $\langle a, m\rangle$ return $a + m$ and $a \cdot m$; if two programs return a and b on n, their equality, order and strict order tests return values on n that are positive exactly when $a = b$, $a \leq b$ and $a < b$, and their conjunction and disjunction return $a \cdot b$ and $a + b$;* rem *on $\langle m, b + 1\rangle$ returns the remainder of m modulo $b + 1$; and the entry program returns the value w with $\beta(A, B, i, w)$. Every search-free program returns a value on every input.*

Proof. Each recursion program is correct by induction along its count, using the recursion laws. Truncated difference returns y on $\langle a, m\rangle$ when $m + y = a$, by induction on m, and 0 on $\langle a, a + d\rangle$, by induction on d. Addition and multiplication are inductions on m. The remainder program keeps the invariant that after m steps its value r satisfies $m = q(b + 1) + r$ and $r + (s + 1) = b + 1$ for some q, s; each step resets to 0 or adds one. The predecessor and ζ are recursions whose step ignores the recursive value. The "only this value" halves follow from functionality: for example, if ζ returned 1 on $k + 1$ it would also return 0 there, giving $1 = 0$. For the tests: if $a = b$ both differences are 0 and ζ returns 1; if $a \neq b$ the order split makes one difference a successor, so the sum is a successor and ζ returns 0. Totality of search-free programs is an induction on the program: the basic laws, the pair and composition laws with pairing totality, and for recursion an induction on the count. □

Proof of Lemma 20.6. The bounded test multiplies the values of the row check at the cells $\langle z, 0\rangle, \ldots, \langle z, N - 1\rangle$ by a recursion on the number of cells and normalizes the product to 0 or 1. By induction on N, it returns a value that is positive exactly when every cell value is positive, since a product of natural numbers is positive exactly when its factors are. For the row check, the graph $G(X, j, p)$ and the projection laws give the field values at p, the entry program gives the justification w with $\beta(C, D, j, w)$ and the row, and the decoder reads their fields. Each atomic test returns a value that is positive exactly when its relation holds of the fields read, by Lemma K.5; a named-row test computes the entry at j' and compares it with the packed row, and pairing injectivity identifies the four coordinates. Products and sums turn these into the case tests, their disjunction and the guard, and the resulting equivalence has the explicit check of Definition 20.4 on its right side. Every program here is search-free, so every value exists, and no value is found by a search: every number the check compares is a field of w or of a named row. Finally T returns ζ of the value of Ver, which is 0 or 1. □

K.4 Closures

For a number a, let κ_a be the program $\mathrm{succ} \circ (\cdots \circ (\mathrm{succ} \circ \mathrm{zero}))$ with a successors; it returns a on every input. Its code $\mathrm{quote}(a)$ satisfies $\mathrm{quote}(0) = 0$ and $\mathrm{quote}(a+1) = 4\langle 1, \mathrm{quote}(a)\rangle + 6$. The *quotation program* qt computes quote by primitive recursion, with pairing, multiplication by 4 and addition of a constant in its step. The *assembler* asm, on input $\langle e, a\rangle$, returns the code

$$4\big\langle e,\ 4\langle \mathrm{quote}(a), \ulcorner \mathrm{id} \urcorner\rangle + 4\big\rangle + 6$$

of the program $e \circ \mathrm{pair}(\kappa_a, \mathrm{id})$, where $\ulcorner \mathrm{id} \urcorner$ is the code of id. The *closure generator* of a program c is

$$\Lambda_c \ := \mathrm{asm} \circ \mathrm{pair}(\kappa_{\ulcorner c \urcorner}, \mathrm{id}).$$

On an environment R it returns the code of $c \circ \mathrm{pair}(\kappa_R, \mathrm{id})$. The body c occurs only inside the constant $\ulcorner c \urcorner$, so constructing the closure never runs c.

Proof of Lemma 20.13. The generator returns. The programs qt, asm, $\kappa_{\ulcorner c \urcorner}$ and id contain no search, so by Lemma K.5 Λ_c returns a value f on every R, and the closure laws show that f is the code displayed above, with every pairing witness retained.

Quoted constants. By induction on a: the program with code $\mathrm{quote}(a)$ returns a on every input. At 0 it is zero. At $a+1$ its code is $4\langle 1, \mathrm{quote}(a)\rangle + 6$, the composition of the successor with the program of code $\mathrm{quote}(a)$, which returns a on every input by the induction hypothesis; the composition and successor laws give $a+1$ on every input. The induction formula quantifies over all inputs.

Behavior. Take x, p, y with $G(R, x, p)$ and $\mathrm{App}(c, p, y)$. The quoted constant returns R on x and id returns x, so the pair law with $G(R, x, p)$ gives the paired value p, and the composition law with $\mathrm{App}(c, p, y)$ gives $\mathrm{App}(f, x, y)$. □

K.5 Reading a variable

Lemma K.6 (Dropping entries)**.** *Let k be at most the length of Θ, and let Θ_k be Θ with its first k entries removed. A context that derives $R \approx_\Theta R'$ derives that some z, z' satisfy $\mathrm{App}(d_k, R, z)$, $\mathrm{App}(d_k, R', z')$ and $z \approx_{\Theta_k} z'$.*

Proof. Recurse on k. At 0 take $z = R$, $z' = R'$, with the identity law. At $k+1$, $\Theta = A, \Theta'$; open $R \approx_{A,\Theta'} R'$ to witnesses r, r', x, x' with $G(r, x, R)$, $G(r', x', R')$ and $r \approx_{\Theta'} r'$. The recursive construction at k gives z, z' for r, r'. The left-projection laws give $\mathrm{App}(\mathrm{left}, R, r)$ and its counterpart, and the composition law gives $\mathrm{App}(d_{k+1}, R, z)$, since $d_{k+1} = d_k \circ \mathrm{left}$. The conclusion contains none of the opened witnesses, so the eliminations close. □

For the variable case of Theorem 20.15, let x_k have type A, so $\Theta_k = A, \Theta''$. The lemma gives $z \approx_{A,\Theta''} z'$; open it to $G(s, v, z)$, $G(s', v', z')$ and $v \simeq_A v'$. The right-projection law gives $\mathrm{App}(\mathrm{right}, z, v)$, and the composition law gives $E_{x_k}(R, v)$, since $c(x_k) = \mathrm{right} \circ d_k$; likewise $E_{x_k}(R', v')$.

K.6 The conversion cases

The remaining contractions in the proof of Theorem 20.22 follow the two compiled programs in the same way. In each, the parts b, g, n of the redex step to b', g', n', and the induction hypotheses relate their values at R and R'.

Iteration at zero, $\mathsf{I}(B, b, g, 0) \Rrightarrow b'$. At R the compiled program evaluates the step to γ, the seed to v and the count to 0, packs a with $G(\gamma, v, a)$ and $\langle a, 0\rangle$, and the recursion-start law with $\mathrm{App}(\mathrm{right}, a, v)$ returns v. The induction hypothesis relates v to the value of b' at R'.

Indexed recursion at zero, $\mathsf{R}(B, b, g, 0) \Rrightarrow b'$: the same, with $\mathsf{It}^{\mathrm{ind}}$.

Indexed recursion at a successor, $\mathsf{R}(B, b, g, S(n)) \Rrightarrow g'\, n'\, \mathsf{R}(B, b', g', n')$. At R the recursion-step law shows that $\mathsf{It}^{\mathrm{ind}}$ on $\langle a, m+1\rangle$ returns s through a previous value x at count m, an output h of γ on m, and an output s of h on x, each application run through U and identified by universal application and functionality. At R' the right side applies γ', related to γ, to the value m of n', and the resulting code to the value x' of $\mathsf{R}(B, b', g', n')$, which the congruence case relates to x. The arrow clause of $\gamma \simeq_{O\to(B\to B)} \gamma'$ at $m = m$ relates h to the code obtained on the right, and its arrow clause at $x \simeq x'$ relates s to the output on the right.

Congruences. A step that rebuilds a constructor around stepped parts is related by the case of Theorem 20.15 for that constructor, applied to the related values of the parts at R and R'. For an abstraction $\lambda A.\, b \Rrightarrow \lambda A.\, b'$ the arrow clause between the two closure codes is derived as in that theorem, with the induction hypothesis for $b \Rrightarrow b'$ at the related extended environments.

K.7 The type conversion case

In Lemma 20.34, a term of type A may be given type B when $A \equiv B$. The reading Adm_T depends on T only through its *skeleton* $\|T\|$: the type obtained by keeping O, $\mathbf{0}$, products and D, and replacing $\mathrm{Id}_A(t, u)$ by $\mathrm{Id}_{|A|}(|t|, |u|)$ and $D(t)$ by $D(|t|)$. Erasure commutes with substitution and sends each generating equation of conversion to an equation between skeletons: the function, iteration, indexed recursion and dependent eliminator equations to computation equations (20.1) of the language of functions; the identity-elimination equation to $|d| = |d|$; and the two discriminator equations to themselves. So conversion of skeletons is generated by the five contractions inside terms and the two discriminator contractions $D(0) \Rrightarrow \mathrm{Id}_O(0, 0)$ and $D(S(t)) \Rrightarrow \mathbf{0}$. These seven contractions are left-linear and do not overlap; erasure has removed the identity-elimination equation, whose left side repeats a variable, so the complete-development argument of Lemma 20.1 gives $\|A\|$ and $\|B\|$ a common reduct, and every erased term on the way stays typed.

The reading moves along each parallel step in both directions. Inside an identity or discriminator type the step changes a term s to s' with $s \equiv s'$; the computation rule proves $s = s'$, and replacement moves each conjunct. At $D(0) \Rrightarrow \mathrm{Id}_O(0, 0)$ the reading $(0 =_O 0) \wedge (v =_O 0)$ becomes $(v =_O 0) \wedge (0 =_O 0)$, which exchanges the conjuncts. At $D(S(t)) \Rrightarrow \mathbf{0}$ the reading $(S(|t|) =_O 0) \wedge (v =_O 0)$ gives $\bot$ by the rule *successor is not zero*, and $\bot$ gives it back by the rule for falsehood. At a product, the step acts on the domain and the codomain, and the induction hypotheses move the antecedent backward and the consequent forward. No step depends on the fragment, so the case holds in each fragment, with or without the discriminator.

Appendix L

One universe and bounded arithmetic: the proofs

This appendix proves Theorems 20.44 and 20.46. Sections L.1–L.8 prove the first: the calculus $\mathscr{F}_U$ with one universe derives the negative translation of Con(PA), extends $\mathscr{E}^+$, and is sound for a set model. Sections L.9–L.12 prove the second: over bounded arithmetic, pair formation and exponentiation derive each other. The two parts are independent.

The first part is long because Con(PA) is long. The sentence says that no finite tables describe an accepted proof of $\bot$, and an accepted proof involves every schema of the checker, every syntactic operation the schemas use, and the bookkeeping that keeps each code in range. The idea is short: inside $\mathscr{F}_U$ every formula code receives a type, built by recursion into the universe; every line the tables certify is shown to have an inhabited type; and the type of $\bot$ is empty. The rest of the part makes that idea precise.

L.1 The checker and the sentence Con(PA)

Codes. Pairs are coded by $P(a,b) = 2^a(2b+1) - 1$. Every number n has exactly one representation $n+1 = 2^a(2b+1)$, so P is a bijection from pairs of numbers onto numbers, and $a \le P(a,b)$ and $b \le P(a,b)$. Lists are coded by $L([\,]) = 0$ and $L(x :: xs) = 1 + P(x, L(xs))$, and a *node* with tag j and children $t_1, \dots, t_m$ by

$$C_j(t_1, \dots, t_m) = 1 + P\big(j, L([t_1, \dots, t_m])\big).$$

Every positive number is exactly one node: decoding $n-1 = P(j,\ell)$ and the list ℓ gives its tag $\mathrm{tag}(n) = j$ and its children, and each child is smaller than n. We put $\mathrm{tag}(0) = 0$ and give 0 no children. The ith child of n, or 0 when there is none, is written $a_i(n)$ for $i = 1, 2, 3$.

The tags have fixed meanings. Natural data are $C_0()$ and $C_1(n)$, with value nv: $\mathrm{nv}(C_1(n)) = \mathrm{nv}(n) + 1$ and $\mathrm{nv} = 0$ otherwise. Terms are variables $C_2(k)$, with k natural data giving a de Bruijn index, zero $C_3()$, successor $C_4(t)$, sum $C_5(s,t)$ and product $C_6(s,t)$. Formulas are equations $C_7(s,t)$, falsehood $C_8()$, implications $C_9(A,B)$ and universal quantifications $C_{10}(A)$, whose body has the bound variable at index 0. Lists of parameters are $C_{15}()$ and $C_{16}(h,\ell)$. Proof nodes are axiom nodes $C_{12}(c,j,\ell)$, modus ponens nodes $C_{13}(c,p,q)$ and generalization nodes $C_{14}(c,p)$; their first child c is the stored conclusion. The code of the zero term is $C_3() = 1 + P(3,0) = 8$. A code *parses* as a term or a formula when its tags and arities are those listed, recursively.

Operations on codes. Four operations act on codes by recursion on the code, leaving a code with any other tag unchanged:

- the *term shift* $\mathrm{tsh}(t,d)$ adds d to the index of every variable of t;

- the *substitution* $\mathrm{sub}(x, d, t)$ replaces the variable with index d by $\mathrm{tsh}(t, d)$, lowers every larger index by one, keeps every smaller index, and passes under C_{10} with $d + 1$ in place of d;
- the *lifting* $\mathrm{lift}(x, c)$ raises every index at least c by one, passing under C_{10} with $c + 1$;
- the *successor shift* $\mathrm{plus}(x, d)$ replaces the variable with index d by its successor, passing under C_{10} with $d + 1$.

Write $A[t]$ for $\mathrm{sub}(A, 0, t)$, $\uparrow A$ for $\mathrm{lift}(A, 0)$ and A^{+} for $\mathrm{plus}(A, 0)$, and $\neg A$ for $C_9(A, C_8())$.

The checker. The fourteen schemas take a list of parameters, each of which must parse as stated (A, B, C formulas, s, t terms):

0	$A \to (B \to A)$	7	$\neg(S(t) = 0)$
1	$(A \to (B \to C)) \to ((A \to B) \to (A \to C))$	8	$S(s) = S(t) \to s = t$
2	$(\neg B \to \neg A) \to (A \to B)$	9	$s + 0 = s$
3	$\forall A \to A[t]$	10	$s + S(t) = S(s + t)$
4	$\forall(\uparrow A \to B) \to (A \to \forall B)$	11	$s \cdot 0 = 0$
5	$t = t$	12	$s \cdot S(t) = s \cdot t + s$
6	$s = t \to (A[s] \to A[t])$	13	$A[0] \to (\forall(A \to A^{+}) \to \forall A)$

The checker with fuel k is K_k: $K_0(p) = 0$, and $K_{k+1}(p) = 1$ exactly when $p \neq 0$ and one of the following holds.

- $p = C_{12}(c, j, \ell)$, c parses as a formula, j is natural data, ℓ is a list of parameters, and c is the instance of schema $\mathrm{nv}(j)$ at ℓ.
- $p = C_{13}(c, p_1, q_1)$, $K_k(p_1) = K_k(q_1) = 1$, c parses as a formula, and the stored conclusion of q_1 is C_9(stored conclusion of p_1, c).
- $p = C_{14}(c, p_1)$, $K_k(p_1) = 1$, c parses as a formula, and $c = C_{10}$(stored conclusion of p_1).

Otherwise $K_{k+1}(p) = 0$. The checker accepts p when $K_{p+1}(p) = 1$; since children are smaller than their parents, the fuel $p + 1$ is enough. An *accepted proof of* $\bot$ is an accepted p whose stored conclusion is $C_8()$. The checker is primitive recursive: each of its parts is, and every recursion it uses is on a smaller code or a smaller fuel.

Certificate tables. A proof is described by thirteen finite tables: tag, a_1, a_2, a_3, the *slacks* w_1, w_2, w_3 with $a_i(x) + S(w_i(x)) = x$ for a node x, nv, the fuel table $K(f, q)$, and the tables $\mathrm{sub}(x, d, t)$, $\mathrm{tsh}(t, d)$, $\mathrm{lift}(x, c)$ and $\mathrm{plus}(x, d)$. A table is a function of numbers; only its values at arguments at most a bound B are constrained. The *clauses* are universal implications between equations and negated equations of table values, with an equation or $\bot$ as conclusion. There are 247 of them, in eleven families, summarized here and listed in full below. In the summary, $x \leq B$ abbreviates $x + k = B$ with a further variable k of the clause.

(a) *Children* (3): $x \leq B \to \mathrm{tag}(x) = S(t) \to a_i(x) + S(w_i(x)) = x$, for $i = 1, 2, 3$.

(b) *Zero* (2): $8 \le B$ and $\mathrm{tag}(8) = 3$.

(c) *Fuel* (2): $K(0,x) = 0$ for $x \le B$; and if $f, q \le B$ and $K(S(f), q) = 1$, then $\mathrm{tag}(q)$ is 12, 13 or 14, in the form $\mathrm{tag}(q) \neq 12 \to \mathrm{tag}(q) \neq 13 \to \mathrm{tag}(q) \neq 14 \to \bot$.

(d) *Modus ponens* (6): if $f, q \le B$, $K(S(f), q) = 1$ and $\mathrm{tag}(q) = 13$, then $K(f, a_2(q)) = K(f, a_3(q)) = 1$, $\mathrm{tag}(a_1(a_3(q))) = 9$, $a_1(a_1(a_3(q))) = a_1(a_2(q))$, $a_2(a_1(a_3(q))) = a_1(q)$, and $\mathrm{tag}(a_3(q)) \neq 0$.

(e) *Generalization* (3): under the same premises with tag 14, $K(f, a_2(q)) = 1$, $\mathrm{tag}(a_1(q)) = 10$ and $a_1(a_1(q)) = a_1(a_2(q))$.

(f) *Axioms* (143): under the premises with tag 12, the schema number $\mathrm{nv}(a_2(q))$ is one of $0, \dots, 13$, in the form $\mathrm{nv}(a_2(q)) \neq 0 \to \cdots \to \mathrm{nv}(a_2(q)) \neq 13 \to \bot$; and, for each schema, the list $a_3(q)$ has as many cells (tag 16) as the schema has parameters, and the stored conclusion $a_1(q)$ has the decoded shape of the instance, read through the tags and children of its nodes. For schema 0, for example, with parameters $P_1 = a_1(a_3(q))$ and $P_2 = a_1(a_2(a_3(q)))$, the seven clauses say that $a_3(q)$ and $a_2(a_3(q))$ have tag 16, that $a_1(q)$ and $a_2(a_1(q))$ have tag 9, and that $a_1(a_1(q)) = P_1$, $a_1(a_2(a_1(q))) = P_2$ and $a_2(a_2(a_1(q))) = P_1$. Where a schema uses sub, lift or plus, the clause names the table value; and where it substitutes a term parameter, a clause refutes each of the formula tags 7, 8, 9, 10 for that parameter.

(g) *Substitution* (23), *term shift* (16), *lifting* (22) and *successor shift* (23): if the table gives the result y of the operation at its arguments, under the guards

$$\begin{aligned} \mathrm{sub}(x,d,t) = y &: \quad x + d \le B,\ t \le B,\ y \le B; \\ \mathrm{tsh}(t,d) = y &: \quad t \le B,\ d \le B,\ y \le B; \\ \mathrm{lift}(x,c) = y &: \quad x + c \le B,\ y \le B; \\ \mathrm{plus}(x,d) = y &: \quad x + d \le B,\ y \le B, \end{aligned}$$

then y has the tag and the children that the recursion of the operation prescribes, case by case on the tag of the argument; for a variable the cases compare its index with the depth; and a code with any other tag is returned unchanged. For the term shift, a result with a formula tag comes from an argument with the same tag. The depth is bounded together with the code: at a node x with tag 10 a clause reads the body $a_1(x)$ at depth $d+1$, and $a_1(x) + d + 1 \le x + d \le B$, so every depth or level that a clause reads is at most B.

(h) *Root* (4): $p \le B$, $K(S(p), p) = 1$, $\mathrm{tag}(a_1(p)) = 8$, and $\mathrm{tag}(p) \neq 0$.

The clauses in (f) are 1 + 142 in number: 7, 16, 13, 10, 11, 4, 18, 7, 11, 6, 11, 6, 12 and 10 for schemas 0 to 13.

The clauses. The clause C_i, for $i = 0, \dots, 246$, is the universal closure, over the variables named below in the order given, of the displayed implication. For a group whose clauses share hypotheses, the shared ones are stated once and come first, in the order shown; each line then lists the remaining hypotheses and the conclusion. We write $a_1 a_3\, q$ for $a_1(a_3(q))$, and

$h \neq m \to \cdots \to h \neq n$ for the hypotheses $h \neq m$, $h \neq m+1$, ..., $h \neq n$ in this order. A hypothesis $u \neq v$ is $\neg(u = v)$, a numeral n is $S^n(0)$, and the variables k, k', k'', k_f, k_q are the slacks of the bounds.

- C_0, C_1, C_2 (children), over x, k, t: $x + k = B \to \mathrm{tag}(x) = S(t) \to a_i(x) + S(w_i(x)) = x$, for $i = 1, 2, 3$ in this order.
- C_3, C_4 (zero): $8 + k_8 = B$; $\mathrm{tag}(8) = 3$.
- C_5 (fuel), over x, k: $x + k = B \to K(0, x) = 0$.

The clauses C_6 to C_{158} are over f, k_f, q, k_q and share the hypotheses $f + k_f = B$, $q + k_q = B$ and $K(S(f), q) = 1$.

- C_6 (fuel): $\mathrm{tag}(q) \neq 12 \to \mathrm{tag}(q) \neq 13 \to \mathrm{tag}(q) \neq 14 \to \bot$.
- C_7 to C_{12} (modus ponens), each after $\mathrm{tag}(q) = 13$: $K(f, a_2\, q) = 1$; $K(f, a_3\, q) = 1$; $\mathrm{tag}(a_1 a_3\, q) = 9$; $a_1 a_1 a_3\, q = a_1 a_2\, q$; $a_2 a_1 a_3\, q = a_1\, q$; $\mathrm{tag}(a_3\, q) = 0 \to \bot$.
- C_{13} to C_{15} (generalization), each after $\mathrm{tag}(q) = 14$: $K(f, a_2\, q) = 1$; $\mathrm{tag}(a_1\, q) = 10$; $a_1 a_1\, q = a_1 a_2\, q$.
- C_{16} (axiom range): $\mathrm{tag}(q) = 12 \to \mathrm{nv}(a_2\, q) \neq 0 \to \cdots \to \mathrm{nv}(a_2\, q) \neq 13 \to \bot$.

The axiom clauses C_{17} to C_{158} have, after the shared hypotheses, the two hypotheses $\mathrm{tag}(q) = 12$ and $\mathrm{nv}(a_2\, q) = s$ for the schema number s; each entry below gives what follows them.

- Schema 0, C_{17} to C_{23}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_2 a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 9$; $a_1 a_1\, q = a_1 a_3\, q$; $\mathrm{tag}(a_2 a_1\, q) = 9$; $a_1 a_2 a_1\, q = a_1 a_2 a_3\, q$; $a_2 a_2 a_1\, q = a_1 a_3\, q$.
- Schema 1, C_{24} to C_{39}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_2 a_3\, q) = 16$; $\mathrm{tag}(a_2 a_2 a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 9$; $\mathrm{tag}(a_1 a_1\, q) = 9$; $a_1 a_1 a_1\, q = a_1 a_3\, q$; $\mathrm{tag}(a_2 a_1 a_1\, q) = 9$; $a_1 a_2 a_1 a_1\, q = a_1 a_2 a_3\, q$; $a_2 a_2 a_1 a_1\, q = a_1 a_2 a_2 a_3\, q$; $\mathrm{tag}(a_2 a_1\, q) = 9$; $\mathrm{tag}(a_1 a_2 a_1\, q) = 9$; $a_1 a_1 a_2 a_1\, q = a_1 a_3\, q$; $a_2 a_1 a_2 a_1\, q = a_1 a_2 a_3\, q$; $\mathrm{tag}(a_2 a_2 a_1\, q) = 9$; $a_1 a_2 a_2 a_1\, q = a_1 a_3\, q$; $a_2 a_2 a_2 a_1\, q = a_1 a_2 a_2 a_3\, q$.
- Schema 2, C_{40} to C_{52}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_2 a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 9$; $\mathrm{tag}(a_1 a_1\, q) = 9$; $\mathrm{tag}(a_1 a_1 a_1\, q) = 9$; $a_1 a_1 a_1 a_1\, q = a_1 a_2 a_3\, q$; $\mathrm{tag}(a_2 a_1 a_1 a_1\, q) = 8$; $\mathrm{tag}(a_2 a_1 a_1\, q) = 9$; $a_1 a_2 a_1 a_1\, q = a_1 a_3\, q$; $\mathrm{tag}(a_2 a_2 a_1 a_1\, q) = 8$; $\mathrm{tag}(a_2 a_1\, q) = 9$; $a_1 a_2 a_1\, q = a_1 a_3\, q$; $a_2 a_2 a_1\, q = a_1 a_2 a_3\, q$.
- Schema 3, C_{53} to C_{62}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_2 a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 9$; $\mathrm{tag}(a_1 a_1\, q) = 10$; $a_1 a_1 a_1\, q = a_1 a_3\, q$; $a_2 a_1\, q = \mathrm{sub}(a_1 a_3\, q, 0, a_1 a_2 a_3\, q)$; $\mathrm{tag}(a_1 a_2 a_3\, q) = 7 \to \bot$; $\mathrm{tag}(a_1 a_2 a_3\, q) = 8 \to \bot$; $\mathrm{tag}(a_1 a_2 a_3\, q) = 9 \to \bot$; $\mathrm{tag}(a_1 a_2 a_3\, q) = 10 \to \bot$.
- Schema 4, C_{63} to C_{73}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_2 a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 9$; $\mathrm{tag}(a_1 a_1\, q) = 10$; $\mathrm{tag}(a_1 a_1 a_1\, q) = 9$; $a_1 a_1 a_1 a_1\, q = \mathrm{lift}(a_1 a_3\, q, 0)$; $a_2 a_1 a_1 a_1\, q = a_1 a_2 a_3\, q$; $\mathrm{tag}(a_2 a_1\, q) = 9$; $a_1 a_2 a_1\, q = a_1 a_3\, q$; $\mathrm{tag}(a_2 a_2 a_1\, q) = 10$; $a_1 a_2 a_2 a_1\, q = a_1 a_2 a_3\, q$.
- Schema 5, C_{74} to C_{77}: $\mathrm{tag}(a_3\, q) = 16$; $\mathrm{tag}(a_1\, q) = 7$; $a_1 a_1\, q = a_1 a_3\, q$; $a_2 a_1\, q = a_1 a_3\, q$.

- Schema 6, C_{78} to C_{95}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_2a_3\,q) = 16$; $\mathrm{tag}(a_2a_2a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 9$; $\mathrm{tag}(a_1a_1\,q) = 7$; $a_1a_1a_1\,q = a_1a_2a_3\,q$; $a_2a_1a_1\,q = a_1a_2a_2a_3\,q$; $\mathrm{tag}(a_2a_1\,q) = 9$; $a_1a_2a_1\,q = \mathrm{sub}(a_1a_3\,q, 0, a_1a_2a_3\,q)$; $a_2a_2a_1\,q = \mathrm{sub}(a_1a_3\,q, 0, a_1a_2a_2a_3\,q)$; $\mathrm{tag}(a_1a_2a_3\,q) = 7 \to \bot$; $\mathrm{tag}(a_1a_2a_3\,q) = 8 \to \bot$; $\mathrm{tag}(a_1a_2a_3\,q) = 9 \to \bot$; $\mathrm{tag}(a_1a_2a_3\,q) = 10 \to \bot$; $\mathrm{tag}(a_1a_2a_2a_3\,q) = 7 \to \bot$; $\mathrm{tag}(a_1a_2a_2a_3\,q) = 8 \to \bot$; $\mathrm{tag}(a_1a_2a_2a_3\,q) = 9 \to \bot$; $\mathrm{tag}(a_1a_2a_2a_3\,q) = 10 \to \bot$.
- Schema 7, C_{96} to C_{102}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 9$; $\mathrm{tag}(a_1a_1\,q) = 7$; $\mathrm{tag}(a_1a_1a_1\,q) = 4$; $a_1a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 3$; $\mathrm{tag}(a_2a_1\,q) = 8$.
- Schema 8, C_{103} to C_{113}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_2a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 9$; $\mathrm{tag}(a_1a_1\,q) = 7$; $\mathrm{tag}(a_1a_1a_1\,q) = 4$; $a_1a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 4$; $a_1a_2a_1a_1\,q = a_1a_2a_3\,q$; $\mathrm{tag}(a_2a_1\,q) = 7$; $a_1a_2a_1\,q = a_1a_3\,q$; $a_2a_2a_1\,q = a_1a_2a_3\,q$.
- Schema 9, C_{114} to C_{119}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 7$; $\mathrm{tag}(a_1a_1\,q) = 5$; $a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 3$; $a_2a_1\,q = a_1a_3\,q$.
- Schema 10, C_{120} to C_{130}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_2a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 7$; $\mathrm{tag}(a_1a_1\,q) = 5$; $a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 4$; $a_1a_2a_1a_1\,q = a_1a_2a_3\,q$; $\mathrm{tag}(a_2a_1\,q) = 4$; $\mathrm{tag}(a_1a_2a_1\,q) = 5$; $a_1a_1a_2a_1\,q = a_1a_3\,q$; $a_2a_1a_2a_1\,q = a_1a_2a_3\,q$.
- Schema 11, C_{131} to C_{136}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 7$; $\mathrm{tag}(a_1a_1\,q) = 6$; $a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 3$; $\mathrm{tag}(a_2a_1\,q) = 3$.
- Schema 12, C_{137} to C_{148}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_2a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 7$; $\mathrm{tag}(a_1a_1\,q) = 6$; $a_1a_1a_1\,q = a_1a_3\,q$; $\mathrm{tag}(a_2a_1a_1\,q) = 4$; $a_1a_2a_1a_1\,q = a_1a_2a_3\,q$; $\mathrm{tag}(a_2a_1\,q) = 5$; $\mathrm{tag}(a_1a_2a_1\,q) = 6$; $a_1a_1a_2a_1\,q = a_1a_3\,q$; $a_2a_1a_2a_1\,q = a_1a_2a_3\,q$; $a_2a_2a_1\,q = a_1a_3\,q$.
- Schema 13, C_{149} to C_{158}: $\mathrm{tag}(a_3\,q) = 16$; $\mathrm{tag}(a_1\,q) = 9$; $a_1a_1\,q = \mathrm{sub}(a_1a_3\,q, 0, 8)$; $\mathrm{tag}(a_2a_1\,q) = 9$; $\mathrm{tag}(a_1a_2a_1\,q) = 10$; $\mathrm{tag}(a_1a_1a_2a_1\,q) = 9$; $a_1a_1a_1a_2a_1\,q = a_1a_3\,q$; $a_2a_1a_1a_2a_1\,q = \mathrm{plus}(a_1a_3\,q, 0)$; $\mathrm{tag}(a_2a_2a_1\,q) = 10$; $a_1a_2a_2a_1\,q = a_1a_3\,q$.

The substitution clauses C_{159} to C_{181} are over x, d, k, t, k', y, k'' (and a further variable j where it occurs, last), with the shared hypotheses $x + d + k = B$, $t + k' = B$, $\mathrm{sub}(x, d, t) = y$ and $y + k'' = B$. After them:

- C_{159}: $\mathrm{tag}(x) = 3 \to \mathrm{tag}(y) = 3$.
- C_{160}: $\mathrm{tag}(x) = 4 \to \mathrm{tag}(y) = 4$.
- C_{161}: $\mathrm{tag}(x) = 5 \to \mathrm{tag}(y) = 5$.
- C_{162}: $\mathrm{tag}(x) = 6 \to \mathrm{tag}(y) = 6$.
- C_{163}: $\mathrm{tag}(x) = 7 \to \mathrm{tag}(y) = 7$.
- C_{164}: $\mathrm{tag}(x) = 8 \to \mathrm{tag}(y) = 8$.
- C_{165}: $\mathrm{tag}(x) = 9 \to \mathrm{tag}(y) = 9$.
- C_{166}: $\mathrm{tag}(x) = 10 \to \mathrm{tag}(y) = 10$.
- C_{167}: $\mathrm{tag}(x) = 4 \to a_1\,y = \mathrm{sub}(a_1\,x, d, t)$.
- C_{168}: $\mathrm{tag}(x) = 5 \to a_1\,y = \mathrm{sub}(a_1\,x, d, t)$.
- C_{169}: $\mathrm{tag}(x) = 6 \to a_1\,y = \mathrm{sub}(a_1\,x, d, t)$.
- C_{170}: $\mathrm{tag}(x) = 7 \to a_1\,y = \mathrm{sub}(a_1\,x, d, t)$.
- C_{171}: $\mathrm{tag}(x) = 9 \to a_1\,y = \mathrm{sub}(a_1\,x, d, t)$.
- C_{172}: $\mathrm{tag}(x) = 5 \to a_2\,y = \mathrm{sub}(a_2\,x, d, t)$.
- C_{173}: $\mathrm{tag}(x) = 6 \to a_2\,y = \mathrm{sub}(a_2\,x, d, t)$.
- C_{174}: $\mathrm{tag}(x) = 7 \to a_2\,y = \mathrm{sub}(a_2\,x, d, t)$.
- C_{175}: $\mathrm{tag}(x) = 9 \to a_2\,y = \mathrm{sub}(a_2\,x, d, t)$.
- C_{176}: $\mathrm{tag}(x) = 10 \to a_1\,y = \mathrm{sub}(a_1\,x, S(d), t)$.
- C_{177}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\,x) + S(j) = d \to y = x$.
- C_{178}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\,x) = d \to y = \mathrm{tsh}(t, d)$.

- C_{179}: $\mathrm{tag}(x) = 2 \to d + S(j) = \mathrm{nv}(a_1\, x) \to \mathrm{tag}(y) = 2$.
- C_{180}: $\mathrm{tag}(x) = 2 \to d + S(j) = \mathrm{nv}(a_1\, x) \to S(\mathrm{nv}(a_1\, y)) = \mathrm{nv}(a_1\, x)$.
- C_{181}: $\mathrm{tag}(x) \neq 2 \to \cdots \to \mathrm{tag}(x) \neq 10 \to y = x$.

The term-shift clauses C_{182} to C_{197} are over t, k, d, k', y, k'' (and a further variable j where it occurs, last), with the shared hypotheses $t + k = B$, $d + k' = B$, $\mathrm{tsh}(t, d) = y$ and $y + k'' = B$. After them:

- C_{182}: $\mathrm{tag}(t) = 3 \to \mathrm{tag}(y) = 3$.
- C_{183}: $\mathrm{tag}(t) = 4 \to \mathrm{tag}(y) = 4$.
- C_{184}: $\mathrm{tag}(t) = 5 \to \mathrm{tag}(y) = 5$.
- C_{185}: $\mathrm{tag}(t) = 6 \to \mathrm{tag}(y) = 6$.
- C_{186}: $\mathrm{tag}(t) = 4 \to a_1\, y = \mathrm{tsh}(a_1\, t, d)$.
- C_{187}: $\mathrm{tag}(t) = 5 \to a_1\, y = \mathrm{tsh}(a_1\, t, d)$.
- C_{188}: $\mathrm{tag}(t) = 6 \to a_1\, y = \mathrm{tsh}(a_1\, t, d)$.
- C_{189}: $\mathrm{tag}(t) = 5 \to a_2\, y = \mathrm{tsh}(a_2\, t, d)$.
- C_{190}: $\mathrm{tag}(t) = 6 \to a_2\, y = \mathrm{tsh}(a_2\, t, d)$.
- C_{191}: $\mathrm{tag}(t) = 2 \to \mathrm{tag}(y) = 2$.
- C_{192}: $\mathrm{tag}(t) = 2 \to \mathrm{nv}(a_1\, y) = \mathrm{nv}(a_1\, t) + d$.
- C_{193}: $\mathrm{tag}(t) \neq 2 \to \cdots \to \mathrm{tag}(t) \neq 6 \to y = t$.
- C_{194}: $\mathrm{tag}(y) = 7 \to \mathrm{tag}(t) = 7$.
- C_{195}: $\mathrm{tag}(y) = 8 \to \mathrm{tag}(t) = 8$.
- C_{196}: $\mathrm{tag}(y) = 9 \to \mathrm{tag}(t) = 9$.
- C_{197}: $\mathrm{tag}(y) = 10 \to \mathrm{tag}(t) = 10$.

The lifting clauses C_{198} to C_{219} are over x, c, k, y, k' (and a further variable j where it occurs, last), with the shared hypotheses $x + c + k = B$, $\mathrm{lift}(x, c) = y$ and $y + k' = B$. After them:

- C_{198}: $\mathrm{tag}(x) = 3 \to \mathrm{tag}(y) = 3$.
- C_{199}: $\mathrm{tag}(x) = 4 \to \mathrm{tag}(y) = 4$.
- C_{200}: $\mathrm{tag}(x) = 5 \to \mathrm{tag}(y) = 5$.
- C_{201}: $\mathrm{tag}(x) = 6 \to \mathrm{tag}(y) = 6$.
- C_{202}: $\mathrm{tag}(x) = 7 \to \mathrm{tag}(y) = 7$.
- C_{203}: $\mathrm{tag}(x) = 8 \to \mathrm{tag}(y) = 8$.
- C_{204}: $\mathrm{tag}(x) = 9 \to \mathrm{tag}(y) = 9$.
- C_{205}: $\mathrm{tag}(x) = 10 \to \mathrm{tag}(y) = 10$.
- C_{206}: $\mathrm{tag}(x) = 4 \to a_1\, y = \mathrm{lift}(a_1\, x, c)$.
- C_{207}: $\mathrm{tag}(x) = 5 \to a_1\, y = \mathrm{lift}(a_1\, x, c)$.
- C_{208}: $\mathrm{tag}(x) = 6 \to a_1\, y = \mathrm{lift}(a_1\, x, c)$.
- C_{209}: $\mathrm{tag}(x) = 7 \to a_1\, y = \mathrm{lift}(a_1\, x, c)$.
- C_{210}: $\mathrm{tag}(x) = 9 \to a_1\, y = \mathrm{lift}(a_1\, x, c)$.
- C_{211}: $\mathrm{tag}(x) = 5 \to a_2\, y = \mathrm{lift}(a_2\, x, c)$.
- C_{212}: $\mathrm{tag}(x) = 6 \to a_2\, y = \mathrm{lift}(a_2\, x, c)$.
- C_{213}: $\mathrm{tag}(x) = 7 \to a_2\, y = \mathrm{lift}(a_2\, x, c)$.
- C_{214}: $\mathrm{tag}(x) = 9 \to a_2\, y = \mathrm{lift}(a_2\, x, c)$.
- C_{215}: $\mathrm{tag}(x) = 10 \to a_1\, y = \mathrm{lift}(a_1\, x, S(c))$.
- C_{216}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\, x) + S(j) = c \to y = x$.
- C_{217}: $\mathrm{tag}(x) = 2 \to c + j = \mathrm{nv}(a_1\, x) \to \mathrm{tag}(y) = 2$.
- C_{218}: $\mathrm{tag}(x) = 2 \to c + j = \mathrm{nv}(a_1\, x) \to \mathrm{nv}(a_1\, y) = S(\mathrm{nv}(a_1\, x))$.
- C_{219}: $\mathrm{tag}(x) \neq 2 \to \cdots \to \mathrm{tag}(x) \neq 10 \to y = x$.

The successor-shift clauses C_{220} to C_{242} are over x, d, k, y, k' (and a further variable j where it occurs, last), with the shared hypotheses $x + d + k = B$, $\mathrm{plus}(x, d) = y$ and $y + k' = B$. After them:

- C_{220}: $\mathrm{tag}(x) = 3 \to \mathrm{tag}(y) = 3$.
- C_{221}: $\mathrm{tag}(x) = 4 \to \mathrm{tag}(y) = 4$.
- C_{222}: $\mathrm{tag}(x) = 5 \to \mathrm{tag}(y) = 5$.
- C_{223}: $\mathrm{tag}(x) = 6 \to \mathrm{tag}(y) = 6$.
- C_{224}: $\mathrm{tag}(x) = 7 \to \mathrm{tag}(y) = 7$.
- C_{225}: $\mathrm{tag}(x) = 8 \to \mathrm{tag}(y) = 8$.
- C_{226}: $\mathrm{tag}(x) = 9 \to \mathrm{tag}(y) = 9$.
- C_{227}: $\mathrm{tag}(x) = 10 \to \mathrm{tag}(y) = 10$.

- C_{228}: $\mathrm{tag}(x) = 4 \to a_1\, y = \mathrm{plus}(a_1\, x, d)$.
- C_{229}: $\mathrm{tag}(x) = 5 \to a_1\, y = \mathrm{plus}(a_1\, x, d)$.
- C_{230}: $\mathrm{tag}(x) = 6 \to a_1\, y = \mathrm{plus}(a_1\, x, d)$.
- C_{231}: $\mathrm{tag}(x) = 7 \to a_1\, y = \mathrm{plus}(a_1\, x, d)$.
- C_{232}: $\mathrm{tag}(x) = 9 \to a_1\, y = \mathrm{plus}(a_1\, x, d)$.
- C_{233}: $\mathrm{tag}(x) = 5 \to a_2\, y = \mathrm{plus}(a_2\, x, d)$.
- C_{234}: $\mathrm{tag}(x) = 6 \to a_2\, y = \mathrm{plus}(a_2\, x, d)$.
- C_{235}: $\mathrm{tag}(x) = 7 \to a_2\, y = \mathrm{plus}(a_2\, x, d)$.
- C_{236}: $\mathrm{tag}(x) = 9 \to a_2\, y = \mathrm{plus}(a_2\, x, d)$.
- C_{237}: $\mathrm{tag}(x) = 10 \to a_1\, y = \mathrm{plus}(a_1\, x, S(d))$.
- C_{238}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\, x) = d \to \mathrm{tag}(y) = 4$.
- C_{239}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\, x) = d \to \mathrm{tag}(a_1\, y) = 2$.
- C_{240}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\, x) = d \to \mathrm{nv}(a_1 a_1\, y) = d$.
- C_{241}: $\mathrm{tag}(x) = 2 \to \mathrm{nv}(a_1\, x) \neq d \to y = x$.
- C_{242}: $\mathrm{tag}(x) \neq 2 \to \cdots \to \mathrm{tag}(x) \neq 10 \to y = x$.

The root clauses C_{243} to C_{246} are $p + k_p = B$, $K(S(p), p) = 1$, $\mathrm{tag}(a_1\, p) = 8$ and $\mathrm{tag}(p) = 0 \to \bot$.

Each table is coded by two numbers through Gödel's β: the value of a table with codes c, d at the index i is the remainder of c modulo $1 + (i+1)d$. The index of one argument a is a; of two, $a + (B+1)b$; of three, $a + (B+1)(b + (B+1)c)$; and the fuel table $K(f, q)$ uses $q + (B+1)f$, with $B + 1$ written $S(B)$. In a clause, a lookup $T(\vec{a}) = v$ is written

$$\forall v\, \forall q\, \forall j \left(c_T = v + S(m) \cdot q \to v + S(j) = S(m) \to \cdots \right), \qquad m = S(i) \cdot d_T,$$

with i the index of $\vec{a}$: it says that v is the remainder of c_T modulo $S(m)$. Each occurrence of a table value in a clause is replaced by its own lookup, as follows. The hypotheses are taken in order and then the conclusion; in an equation, the lookups of its left side come before those of its right side; in a term, the lookups of the arguments of a table come before the lookup of that table. The three quantifiers and two equations of a lookup are placed immediately before the hypothesis or conclusion in which its value occurs, and that value v replaces the table value there. A negated hypothesis $\neg(u = v)$ has its lookups placed before it in the same way.

Definition L.1 (The consistency sentence)**.** Con(PA) is the sentence

$$\forall B\, \forall p\, \forall k_p\, \forall k_8\, \forall c_1\, \forall d_1 \cdots \forall c_{13}\, \forall d_{13}\, \left(C_0 \to C_1 \to \cdots \to C_{246} \to \bot \right)$$

over thirty variables, where $C_0, \ldots, C_{246}$ are the clauses listed above, written with β-lookups, k_8 is the slack of $8 \leq B$ and k_p that of $p \leq B$, and $(c_1, d_1), \ldots, (c_{13}, d_{13})$ code the tables tag, a_1, a_2, a_3, w_1, w_2, w_3, nv, K, sub, tsh, lift and plus, in this order. It is built from $=$, $\bot$, $\to$ and $\forall$ only, and it is closed.

In $\mathbb{N}$, a lookup clause holds exactly when v is the remainder, so Con(PA) is true in $\mathbb{N}$ exactly when no values of the thirty variables satisfy all 247 clauses.

Lemma L.2 (An accepted proof of $\bot$ refutes the sentence)**.** *If the checker accepts a proof p of $\bot$, then* Con(PA) *is false in* $\mathbb{N}$.

Proof. Put $B = \max(p, 8)$ and take the actual tables of the checker: tag, the children and their slacks, nv, K and the four operations, each listed at every index below $(B+2)^3$ and coded by β through the Chinese remainder theorem. Every clause is then a true statement about the checker. The guards of the operation clauses keep every argument of a lookup at most B: at a node with tag 10 the depth $d + 1$ satisfies $a_1(x) + d + 1 \leq x + d \leq B$, and the other recursive

calls keep or lower the sum of code and depth. So every index a clause reads is the index of the arguments it names, and the value found there is the actual value of the operation. The child and zero clauses are the decoding facts above. The fuel, modus ponens, generalization and axiom clauses restate the definition of K_{k+1} at an accepted node. The operation clauses restate the recursions of sub, tsh, lift and plus. The root clauses hold because p is accepted, $p \neq 0$, and its stored conclusion is $C_8()$. So these values satisfy every clause, and the sentence fails at them. □

L.2 The calculus with one universe and its arithmetic

$\mathscr{F}_U$ has the types and terms of $\mathscr{E}^+$ except the primitive discriminator, and adds a type U of codes, a decoding $\mathrm{El}(a)$ of each $a : U$, and four code constructors: $\hat{O}$, $\hat{\mathbf{0}}$, $\widehat{\mathrm{Id}}(a,t,u)$ for $t,u : \mathrm{El}(a)$, and $\hat{\Pi}(a,b)$ for $a : U$ and a family b of codes over $\mathrm{El}(a)$. The decoding equations are conversions:

$$\mathrm{El}(\hat{O}) \equiv O, \quad \mathrm{El}(\hat{\mathbf{0}}) \equiv \mathbf{0}, \quad \mathrm{El}(\widehat{\mathrm{Id}}(a,t,u)) \equiv \mathrm{Id}_{\mathrm{El}(a)}(t,u), \quad \mathrm{El}(\hat{\Pi}(a,b)) \equiv \textstyle\prod_{x:\mathrm{El}(a)} \mathrm{El}(b(x)).$$

The iterator, the indexed recursor and the dependent eliminator of the orbit are kept, and the motive of the dependent eliminator may be any type, including U and products containing U. There is no code for U itself. We write $\hat{\to}$, $\hat{\neg}$ and $\hat{\mathbf{1}} = \widehat{\mathrm{Id}}(\hat{O},0,0)$ for the codes of function types, of negations and of a type with one element, and $\hat{\leftrightarrow}(a,b)$ for the code of $(\mathrm{El}\,a \to \mathrm{El}\,b) \times (\mathrm{El}\,b \to \mathrm{El}\,a)$, built as a product over a selector in O.

Lemma L.3 (Arithmetic in $\mathscr{F}_U$)**.** *$\mathscr{F}_U$ has terms for addition and multiplication (by iteration on the second argument), the predecessor, and an equality test* $\mathrm{eq} : O \to O \to O$*, and derives:*

(a) start separation $\prod_{n:O}(\mathrm{Id}_O(0,Sn) \to \mathbf{0})$ *and injectivity of S;*

(b) $\mathrm{eq}(x,x) = 1$*;* $\mathrm{eq}(x,y) = S(k)$ *gives* $\mathrm{Id}_O(x,y)$*;* $\mathrm{eq}(x,y) = 0$ *refutes it, and a refuted identity has* $\mathrm{eq}(x,y) = 0$*; hence identity on O is decidable and stable:* $\neg\neg\,\mathrm{Id}_O(x,y) \to \mathrm{Id}_O(x,y)$*;*

(c) the laws of addition: associativity, commutativity, $S(x)+y = S(x+y)$*, and cancellation;*

(d) division with remainder: there are terms $\mathrm{rem}(a,d)$*,* $\mathrm{quot}(a,d)$ *and* $\mathrm{slack}(a,d)$ *with* $a = \mathrm{rem}(a,d) + S(d)\cdot\mathrm{quot}(a,d)$ *and* $\mathrm{rem}(a,d) + S(\mathrm{slack}(a,d)) = S(d)$*;*

(e) strong induction: from $\prod_n\big((\prod_{y,j}(y + Sj = n \to \Phi(y))) \to \Phi(n)\big)$ *it derives* $\prod_x \Phi(x)$*, for every family* Φ*.*

Proof. (a) Let $\delta(t)$ be the code defined by the dependent eliminator into U with $\delta(0) = \hat{\mathbf{1}}$ and $\delta(Sn) = \hat{\mathbf{0}}$. Then $\mathrm{El}\,\delta(0) \equiv \mathrm{Id}_O(0,0)$ has the element refl_0, and transporting it along a path from 0 to Sn in the family $\mathrm{El}\,\delta(y)$ gives an element of $\mathrm{El}\,\delta(Sn) \equiv \mathbf{0}$. Injectivity is Theorem 9.2, whose proof uses only the indexed recursor. So δ plays the part of the discriminator D of $\mathscr{E}^+$: its two equations $\mathrm{El}\,\delta(0) \equiv \mathrm{Id}_O(0,0)$ and $\mathrm{El}\,\delta(Sn) \equiv \mathbf{0}$ are conversions.

(b) Define eq by iteration on the first argument, into functions $O \to O$: $\mathrm{eq}(0,y)$ is 1 at $y = 0$ and 0 at a successor, $\mathrm{eq}(Sx,0) = 0$ and $\mathrm{eq}(Sx,Sy) = \mathrm{eq}(x,y)$. The four facts are inductions on x with y general, using (a). Given $\neg\neg\,\mathrm{Id}_O(x,y)$, the value $\mathrm{eq}(x,y)$ is 0 or a successor; 0 would

refute $\mathrm{Id}_O(x, y)$ and contradict the hypothesis, so it is a successor, and the path follows. A test of a tag against a numeral j is $\mathrm{eq}(\mathrm{tag}\, x, j)$, read as true at a successor.

(c) Each law is an induction on one argument with the dependent eliminator, from the recursion equations of addition.

(d) Define the remainder by iteration on a: $\mathrm{rem}(0, d) = 0$, and $\mathrm{rem}(Sa, d)$ is 0 when $\mathrm{rem}(a, d) = d$ and $S(\mathrm{rem}(a, d))$ otherwise; the quotient rises by one exactly when the remainder returns to 0, and the slack is d minus the remainder. Both equations are proved by induction on a, splitting on the test $\mathrm{eq}(\mathrm{rem}(a, d), d)$ with the path or refutation it provides.

(e) Apply the dependent eliminator to the family $Q(n) = \prod_{y,j}(y + Sj = n \to \Phi(y))$. $Q(0)$ holds by start separation. From $Q(n)$ and the hypothesis at n follows $\Phi(n)$, and with $Q(n)$ this gives $Q(Sn)$: a y with $y + Sj = Sn$ is n when $j = 0$, by injectivity, and otherwise satisfies $y + S(j') = n$. Then $\Phi(x)$ follows from $Q(Sx)$ at $y = x$, $j = 0$. □

L.3 The interpretation of codes

Fix in $\mathscr{F}_U$ a bound B, the numbers p, k_p and k_8, and thirteen tables, functions of numbers with one, two or three arguments, and assume the 247 clauses as hypotheses, with Id_O for equality. This context is the *core context*. Within it, codes are evaluated and interpreted. An *environment* is a function $\rho : O \to O$; it assigns values to de Bruijn indices.

Definition L.4 (Evaluation and interpretation with fuel)**.** Let $E_0(x, \rho) = 0$ and $T_0(x, \rho) = \hat{\mathbf{1}}$, and define E_{k+1} and T_{k+1} by the iterator, with types $O \to (O \to O) \to O$ and $O \to (O \to O) \to U$:

$$E_{k+1}(x, \rho) = \begin{cases} \rho(\mathrm{nv}(a_1 x)) & \mathrm{tag}\, x = 2, \\ 0 & \mathrm{tag}\, x = 3, \\ S(E_k(a_1 x, \rho)) & \mathrm{tag}\, x = 4, \\ E_k(a_1 x, \rho) + E_k(a_2 x, \rho) & \mathrm{tag}\, x = 5, \\ E_k(a_1 x, \rho) \cdot E_k(a_2 x, \rho) & \mathrm{tag}\, x = 6, \\ 0 & \text{otherwise}, \end{cases}$$

$$T_{k+1}(x, \rho) = \begin{cases} \hat{\neg}\hat{\neg}\, \widehat{\mathrm{Id}}\big(\hat{O}, E(a_1 x, \rho), E(a_2 x, \rho)\big) & \mathrm{tag}\, x = 7, \\ \hat{\mathbf{0}} & \mathrm{tag}\, x = 8, \\ T_k(a_1 x, \rho) \mathbin{\hat{\to}} T_k(a_2 x, \rho) & \mathrm{tag}\, x = 9, \\ \hat{\Pi}\big(\hat{O},\ m \mapsto T_k(a_1 x, m \cdot \rho)\big) & \mathrm{tag}\, x = 10, \\ \hat{\mathbf{1}} & \text{otherwise}, \end{cases}$$

where $m \cdot \rho$ is the environment with $0 \mapsto m$ and $i + 1 \mapsto \rho(i)$. The *canonical* evaluation and interpretation are $E = E_{SB}$ and $T = T_{SB}$; the equation case uses E. The case distinctions test the tag against the numerals with eq.

So an equation is read as the double negation of an identity, falsehood as the empty type, implication as the function type and the universal quantifier as the product over O; a code that is not a formula is read as a type with one element. The recursion into U is what the universe adds: $\mathscr{E}^+$ has one type depending on a number, the discriminator $D(t)$, but cannot define a type by recursion on a number.

Lemma L.5 (Unfolding). *For every k, x and ρ: if $\operatorname{tag} x = j$, then $E_{k+1}(x, \rho)$ equals the case j of the definition, and $\operatorname{El} T_{k+1}(x, \rho)$ has maps in both directions to the decoding of the case j; if the tag is none of the listed values, $E_{k+1}(x, \rho) = 0$ and $\operatorname{El} T_{k+1}(x, \rho)$ is inhabited.*

Proof. The step function is applied to $\operatorname{tag} x$; transport along the path $\mathrm{Id}_O(\operatorname{tag} x, j)$ in the family of step values moves the claim to the numeral j, where the tests compute. For the default case, each test against a listed numeral returns 0, because the tag differs from it (Lemma L.3(b)). □

Lemma L.6 (Fuel). *If $x \le B$ and $x + S(j) = k$, then $E_k(x, \rho) = E_{k+1}(x, \rho)$ and $\operatorname{El} T_k(x, \rho) \leftrightarrow \operatorname{El} T_{k+1}(x, \rho)$. Consequently, for every $x \le B$ the canonical E and T satisfy the unfolding equations of Lemma L.5 with E and T on both sides: for instance $E(x, \rho) = S(E(a_1 x, \rho))$ when $\operatorname{tag} x = 4$, and $\operatorname{El} T(x, \rho) \leftrightarrow \prod_m \operatorname{El} T(a_1 x, m \cdot \rho)$ when $\operatorname{tag} x = 10$.*

Proof. Induct on k. At $k = 0$ there is no such x, by start separation. At $k + 1$, unfold both sides at the tag of x. The children of a node $x \le B$ are smaller than x by the child clauses (a), so they satisfy the hypothesis at k, and the induction hypothesis identifies the values or the types of the children. The second statement applies the first at $k = B$ to the children of x. □

L.4 Environments and the syntactic lemmas

Environments are compared pointwise: $\rho \approx \rho'$ when $\rho(i) = \rho'(i)$ for every i; the calculus is not asked for function extensionality. Let $\operatorname{tl} \rho(i) = \rho(Si)$ and $\operatorname{sh}_d \rho(i) = \rho(i + d)$, and define by recursion on d and c:

$$\begin{aligned} \operatorname{ins}_0(\rho, w) &= w \cdot \rho, & \operatorname{ins}_{d+1}(\rho, w) &= \rho(0) \cdot \operatorname{ins}_d(\operatorname{tl} \rho, w), \\ \operatorname{del}_0 \rho &= \operatorname{tl} \rho, & \operatorname{del}_{c+1} \rho &= \rho(0) \cdot \operatorname{del}_c(\operatorname{tl} \rho), \\ \operatorname{upd}_0 \rho &= S(\rho(0)) \cdot \operatorname{tl} \rho, & \operatorname{upd}_{d+1} \rho &= \rho(0) \cdot \operatorname{upd}_d(\operatorname{tl} \rho). \end{aligned}$$

They insert w at position d, delete position c, and raise the value at position d by one. By induction on d and c: $\operatorname{ins}_d(\rho, w)$ has $\rho(i)$ at $i < d$, w at d, and $\rho(d + m)$ at $S(d + m)$; $\operatorname{del}_c \rho$ has $\rho(i)$ at $i < c$ and $\rho(S(c + m))$ at $c + m$; $\operatorname{upd}_d \rho$ has $S(\rho(d))$ at d and $\rho(i)$ elsewhere; and each operation preserves $\approx$ and commutes with $m \cdot -$ by raising the position, for instance $m \cdot \operatorname{ins}_d(\rho, w) \approx \operatorname{ins}_{d+1}(m \cdot \rho, w)$.

Each of the following lemmas is proved by strong induction on the code x (Lemma L.3(e)), case by case on its tag. In each case the table clauses of family (g) give the tag and the children of the result, the unfolding equations of Lemma L.6 reduce the claim to the children, which are smaller and in range by the child clauses, and the induction hypothesis finishes. Only the variable cases need more, and they are given.

Lemma L.7 (Agreement). *If $x \le B$ and $\rho \approx \rho'$, then $E(x, \rho) = E(x, \rho')$ and $\operatorname{El} T(x, \rho) \leftrightarrow \operatorname{El} T(x, \rho')$.*

Proof. A variable is evaluated by applying the environment, and the environments agree there. Under C_{10} the environments $m \cdot \rho$ and $m \cdot \rho'$ agree pointwise. □

Lemma L.8 (Term shift). *If $t \le B$, $d \le B$ and $\mathrm{tsh}(t,d) = y \le B$, then $E(y,\rho) = E(t, \mathrm{sh}_d\,\rho)$.*

Proof. For a variable with index i the result is the variable with index $i{+}d$, and $\rho(i{+}d) = \mathrm{sh}_d\,\rho(i)$. The other term tags commute with the shift. □

Lemma L.9 (Substitution). *Let $x + d \le B$, $t \le B$ and $\mathrm{sub}(x,d,t) = y \le B$, and put $\sigma = \mathrm{ins}_d\big(\rho, E(t, \mathrm{sh}_d\,\rho)\big)$. Then $E(y,\rho) = E(x,\sigma)$. If moreover $\mathrm{tag}\,t$ is not 7, 8, 9 or 10, then $\mathrm{El}\,T(y,\rho) \leftrightarrow \mathrm{El}\,T(x,\sigma)$.*

Proof. Let x be a variable with index i, and compare i with d by trichotomy. If $i < d$, then $y = x$, and $\sigma(i) = \rho(i)$. If $i = d$, then $y = \mathrm{tsh}(t,d)$, whose value is $E(t, \mathrm{sh}_d\,\rho)$ by Lemma L.8, which is $\sigma(d)$. If $i = S(d+m)$, then y is the variable with index $d+m$, and $\sigma(S(d+m)) = \rho(d+m)$. Under C_{10} the depth becomes $d+1$ and the environment $m \cdot \rho$, and $m \cdot \sigma \approx \mathrm{ins}_{d+1}(m \cdot \rho, w)$ with the same w, because $\mathrm{sh}_{d+1}(m \cdot \rho) \approx \mathrm{sh}_d\,\rho$; Lemma L.7 absorbs the pointwise equality. For the interpretation, a variable code is read as $\hat{\mathbf{1}}$; its image under substitution is either a variable or $\mathrm{tsh}(t,d)$, which by the term-shift clauses has a formula tag only if t has, so it is read as $\hat{\mathbf{1}}$ too. □

Lemma L.10 (Lifting and successor shift). *If $x + c \le B$ and $\mathrm{lift}(x,c) = y \le B$, then $E(y,\rho) = E(x, \mathrm{del}_c\,\rho)$ and $\mathrm{El}\,T(y,\rho) \leftrightarrow \mathrm{El}\,T(x, \mathrm{del}_c\,\rho)$. If $x + d \le B$ and $\mathrm{plus}(x,d) = y \le B$, then $E(y,\rho) = E(x, \mathrm{upd}_d\,\rho)$ and $\mathrm{El}\,T(y,\rho) \leftrightarrow \mathrm{El}\,T(x, \mathrm{upd}_d\,\rho)$.*

Proof. For lifting, a variable with index $i < c$ is kept and $\mathrm{del}_c\,\rho(i) = \rho(i)$; a variable with index $c+m$ becomes $S(c+m)$, and $\mathrm{del}_c\,\rho(c+m) = \rho(S(c+m))$. For the successor shift, the variable with index d becomes its successor, whose value is $S(\rho(d)) = \mathrm{upd}_d\,\rho(d)$, and every other variable is kept, with $\mathrm{upd}_d\,\rho(i) = \rho(i)$ for $i \ne d$. Under C_{10} the cutoff or depth rises by one and the environment operations commute with $m \cdot -$. □

Lemma L.11 (Stability). *If $x \le B$, then $\neg\neg\,\mathrm{El}\,T(x,\rho) \to \mathrm{El}\,T(x,\rho)$.*

Proof. An equation is read as a negation, and a negation is stable. The empty type is stable. An implication is stable when its conclusion is, and a product when its body is, by the induction hypothesis. The type with one element is inhabited. □

L.5 The checker is sound inside $\mathscr{F}_U$

Lemma L.12 (The fourteen schemas). *Let $f \le B$, $q \le B$, $K(Sf,q) = 1$, $\mathrm{tag}\,q = 12$ and $\mathrm{nv}(a_2 q) = s$ with $s \le 13$. Then $\mathrm{El}\,T(a_1 q,\rho)$ for every ρ.*

Proof. The axiom clauses for schema s decode the stored conclusion $c = a_1 q$ into nodes whose tags and children are the schema's, with the parameters P_1, P_2, P_3 read from the list $a_3 q$. The unfolding equations of Lemma L.6 then turn $\mathrm{El}\,T(c,\rho)$ into the schema's type built from $\mathrm{El}\,T(P_i,\cdot)$ and $E(P_i,\cdot)$.

0, 1. The types $\alpha \to (\beta \to \alpha)$ and $(\alpha \to (\beta \to \gamma)) \to ((\alpha \to \beta) \to (\alpha \to \gamma))$ have the usual combinators as elements.

2. From $\neg\beta \to \neg\alpha$ and α follows $\neg\neg\beta$, and Lemma L.11 gives β.

3. From $\prod_m \mathrm{El}\, T(A, m \cdot \rho)$ take $m = E(t, \rho)$. Lemma L.9 at $d = 0$, whose term t is not a formula code by the refuting clauses, identifies $\mathrm{El}\, T(A[t], \rho)$ with $\mathrm{El}\, T(A, E(t, \rho) \cdot \rho)$, since $\mathrm{ins}_0(\rho, w) = w \cdot \rho$ and $\mathrm{sh}_0\, \rho \approx \rho$.

4. Given $h : \prod_m(\mathrm{El}\, T(\uparrow A, m \cdot \rho) \to \mathrm{El}\, T(B, m \cdot \rho))$ and $a : \mathrm{El}\, T(A, \rho)$, return $m \mapsto h(m)(a')$, where a' is a moved along Lemma L.10: $\uparrow A$ at $m \cdot \rho$ is A at $\mathrm{del}_0(m \cdot \rho) = \rho$.

5. $\lambda k.\, k(\mathrm{refl})$ inhabits $\neg\neg\, \mathrm{Id}(\nu, \nu)$.

6. From $\neg\neg\, \mathrm{Id}(E(s, \rho), E(t, \rho))$ and $\mathrm{El}\, T(A[s], \rho)$, assume $\neg\, \mathrm{El}\, T(A[t], \rho)$. A path from $E(s, \rho)$ to $E(t, \rho)$ would transport the second hypothesis, read through Lemma L.9 as A at $E(s, \rho) \cdot \rho$, to A at $E(t, \rho) \cdot \rho$, which is $A[t]$ at ρ; so there is no path, against the first hypothesis. Hence $\neg\neg\, \mathrm{El}\, T(A[t], \rho)$, and Lemma L.11 removes the double negation.

7. $\neg\neg\, \mathrm{Id}(S(E(t, \rho)), 0) \to \mathbf{0}$ follows from start separation.

8. From $\neg\neg\, \mathrm{Id}(Su, Sv)$ derive $\neg\neg\, \mathrm{Id}(u, v)$ by composing with injectivity of S.

9–12. The evaluation equations of Lemma L.6 give the identities $E(s + 0) = E(s)$, $E(s + St) = S(E(s + t))$, $E(s \cdot 0) = 0$ and $E(s \cdot St) = E(s \cdot t + s)$ from the recursion equations of addition and multiplication; a path gives its double negation.

13. Let $b : \mathrm{El}\, T(A[0], \rho)$ and $h : \prod_m(\mathrm{El}\, T(A, m \cdot \rho) \to \mathrm{El}\, T(A^+, m \cdot \rho))$. Apply the dependent eliminator to the family $n \mapsto \mathrm{El}\, T(A, n \cdot \rho)$, a family of types obtained from codes in U. The base is b, moved by Lemma L.9 at the zero code 8, whose value is 0 by the zero clauses. The step from n to Sn applies $h(n)$ and moves the result by Lemma L.10: A^+ at $n \cdot \rho$ is A at $\mathrm{upd}_0(n \cdot \rho) \approx S(n) \cdot \rho$. The result is $\prod_n \mathrm{El}\, T(A, n \cdot \rho)$, the reading of $\forall A$. This is the one schema whose proof needs the universe: the motive varies with the code A, which is data inside the derivation.

In each case the clauses give the tags that select the unfolding equations, and the hypotheses $f \le B$ and $q \le B$, with the child clauses, keep every code in range. □

Lemma L.13 (Every certified line is true)**.** *For every f with $f \le SB$: if $q \le B$ and $K(f, q) = 1$, then $\mathrm{El}\, T(a_1 q, \rho)$ for every ρ.*

Proof. Induct on f. At $f = 0$ the fuel clause $K(0, q) = 0$ contradicts $K(0, q) = 1$ by start separation. At Sf, decide tag q against 12, 13 and 14. With tag 12, the schema number is one of $0, \ldots, 13$ by the axiom-range clause, and Lemma L.12 applies. With tag 13, the modus ponens clauses give $K(f, a_2 q) = K(f, a_3 q) = 1$ and an implication $a_1(a_3 q)$ from $a_1(a_2 q)$ to $a_1 q$; the induction hypothesis gives the two premises at ρ, and the unfolding equation for tag 9 applies the second to the first. With tag 14, the generalization clauses give $K(f, a_2 q) = 1$ and $a_1 q = C_{10}(a_1(a_2 q))$ in decoded form; the induction hypothesis at $m \cdot \rho$, for every m, gives the product that reads $a_1 q$. Any other tag contradicts the fuel clause. The bound $f \le SB$ keeps the predecessor fuel within B. □

Proposition L.14 (The core derives $\bot$)**.** *In the core context, $\mathscr{F}_U$ derives* $\mathbf{0}$.

Proof. By the root clauses, $K(Sp, p) = 1$ with $p \le B$, so $Sp \le SB$, and Lemma L.13 gives $\mathrm{El}\, T(a_1 p, \rho_0)$ at the environment ρ_0 that is constantly 0. The tag of p is not 0, so its first child is in range, and its tag is 8; the unfolding equation for tag 8 turns the element into one of $\mathbf{0}$. □

L.6 From the core to the sentence

The negative translation of Con(PA) is the product, over thirty variables of type O and one hypothesis for each clause, of $\mathbf{0}$; the hypothesis of a clause is its negative translation, in which every equation $u = v$ becomes $\neg\neg\, \mathrm{Id}_O(u, v)$. We build a term of this type from Proposition L.14 by substituting for every variable of the core context.

Lemma L.15 (The core context from the hypotheses)**.** *Under the thirty variables and the translated clause hypotheses, $\mathscr{F}_U$ derives every entry of the core context at the following values: the bound and the variables p, k_p, k_8 are themselves; each table T is the lookup $\vec{a} \mapsto \mathrm{rem}(c_T, m)$, the remainder modulo $S(m)$, with $m = S(i) \cdot d_T$ and i the index of $\vec{a}$; and the evaluation and interpretation are E_k and T_k of Definition L.4, whose unfolding equations are Lemma L.5.*

Proof. Take a clause with its table form and its translated arithmetic form. Each lookup in the arithmetic form is a universal statement over v, q and j; instantiate it at $v = \mathrm{rem}(c_T, m)$, $q = \mathrm{quot}(c_T, m)$ and $j = \mathrm{slack}(c_T, m)$ of Lemma L.3(d), and supply its two equations, which division with remainder proves, under double negation by $\lambda k.\, k(\cdot)$. A hypothesis $u = v$ of the table form gives the translated hypothesis $\neg\neg\, \mathrm{Id}(u, v)$ in the same way; a negated equation is its own translation, since $\neg\neg\neg\alpha$ and $\neg\alpha$ imply each other. The conclusion of the arithmetic form is $\neg\neg\, \mathrm{Id}(u, v)$ or $\mathbf{0}$, and stability of identity on O, Lemma L.3(b), gives the identity the table form asks for. The three arithmetic facts used here, division with remainder, the bound on the remainder and stability, are closed derivations of $\mathscr{F}_U$. □

Proof of Theorem 20.44(1). Substituting the values of Lemma L.15 into the derivation of Proposition L.14 gives a derivation of $\mathbf{0}$ in the context of the thirty variables and the translated clause hypotheses, with the three arithmetic facts cut against their closed derivations. Abstracting over that context, in order, gives a closed term of the negative translation of Con(PA). The sentence is closed, the checker is primitive recursive, and by Lemma L.2 an accepted proof of $\bot$ would refute the sentence in $\mathbb{N}$. □

L.7 The embedding and the strictness

This section proves parts (2) and (4); part (3) is proved in Section L.8.

Proof of Theorem 20.44(2). Send each type and term of $\mathscr{E}^+$ to itself, except the discriminator, which goes to $\mathrm{El}\, \delta(t)$ with the code δ of Lemma L.3(a). The two discriminator equations become the decoding conversions of δ, and every other rule of $\mathscr{E}^+$ is a rule of $\mathscr{F}_U$, so induction on derivations sends each derivation of $\mathscr{E}^+$ to one of $\mathscr{F}_U$ of the translated judgment. A negative

arithmetic type contains no discriminator, so it is sent to itself. If Peano arithmetic derives σ, then $\mathscr{E}^+$ proves σ^N by Theorem 20.39, and so does $\mathscr{F}_U$. □

Proof of Theorem 20.44(4). Peano arithmetic is consistent, by Theorem 20.41, so by Theorem 20.42 it does not derive Con(PA). Proposition 20.43 then says that $\mathscr{E}^+$ does not prove $\mathrm{Con(PA)}^N$, and part (1) says that $\mathscr{F}_U$ does. □

L.8 The set model

This section proves part (3). We work in set theory with a *universe of sets*: a transitive set $\mathbb{U}$, closed under pairs, unions, power sets and images of its members under maps into $\mathbb{U}$, and containing the set N of numerals defined below. The sets of rank below a strongly inaccessible cardinal form such a universe. In a type-theoretic metatheory with a hierarchy of type universes $\mathscr{U}_0$, $\mathscr{U}_1$, $\mathscr{U}_2$, the well-founded sets built over $\mathscr{U}_1$ can serve as the sets; those built over $\mathscr{U}_0$, each lifted to the higher level, then form a universe in this sense, and their collection is itself one of the sets. The members of $\mathbb{U}$ are called *small*.

Sets for the constructions. The numerals are $\nu_0 = \emptyset$ and $\nu_{n+1} = \{\nu_n\}$; they are distinct, $N = \{\nu_n : n \in \mathbb{N}\}$, and $\mathrm{dec}(\nu)$ is n when $\nu = \nu_n$ and 0 for any other set, with $\mathrm{s}(\nu) = \nu_{\mathrm{dec}(\nu)+1}$. For a set A and a map F from A to sets, $\Pi(A, F)$ is the set of functions $f \subseteq A \times \bigcup_{x \in A} F(x)$ with domain A and $f(x) \in F(x)$ for every $x \in A$; the graph of a map h on A is $\{(x, h(x)) : x \in A\}$; the application $\mathrm{ap}(f, x)$ is a y with $(x, y) \in f$ when there is one, chosen once and for all, and $\emptyset$ otherwise; and $\mathrm{Id}(x, y)$ is $\{\emptyset\}$ when $x = y$ and $\emptyset$ otherwise. Iteration $\mathrm{it}(b, G, \nu)$ applies G $\mathrm{dec}(\nu)$ times to b, and recursion $\mathrm{rec}(b, G, \nu)$ is the value at $\mathrm{dec}(\nu)$ of the sequence that starts at b and passes from its value y at n to $G(\nu_n, y)$.

Lemma L.16 (The small sets)**.** *N, $\emptyset$ and every $\mathrm{Id}(x, y)$ are small. If A is small and $F(x)$ is small for every $x \in A$, then $\Pi(A, F)$ is small.*

Proof. N is small by assumption, and $\emptyset$ and $\{\emptyset\}$ are built from it by power sets and pairs. $\Pi(A, F)$ is a subset of the power set of $A \times \bigcup_{x \in A} F(x)$; the union of the image of A under F is small, the product of two small sets is built by pairs and power sets, and a subset of a small set is a member of its power set, hence small by transitivity. □

Definition L.17 (The interpretation)**.** An *environment* ρ assigns a set to each variable index; $\rho.x$ puts x at index 0 and $\rho(k)$ at $k+1$. Raw types and terms of $\mathscr{F}_U$, typed or not, receive values $[\![A]\!]_\rho$ and $[\![t]\!]_\rho$:

$$
\begin{array}{lllll}
[\![O]\!] & = N & & [\![\mathbf{0}]\!] & = \emptyset \\
[\![U]\!] & = \mathbb{U} & & [\![\mathrm{El}\, a]\!]_\rho & = [\![a]\!]_\rho \\
[\![x_k]\!]_\rho & = \rho(k) & & [\![0]\!] & = \nu_0 \\
[\![St]\!]_\rho & = \mathrm{s}([\![t]\!]_\rho) & & [\![ft]\!]_\rho & = \mathrm{ap}([\![f]\!]_\rho, [\![t]\!]_\rho) \\
[\![\textstyle\prod_A B]\!]_\rho & = \Pi([\![A]\!]_\rho,\ x \mapsto [\![B]\!]_{\rho.x}) & & [\![\mathrm{Id}_A(t,u)]\!]_\rho & = \mathrm{Id}([\![t]\!]_\rho, [\![u]\!]_\rho)
\end{array}
$$

The value of $\lambda A.\, b$ is the graph of $x \mapsto [\![b]\!]_{\rho.x}$ on $[\![A]\!]_\rho$; refl and the elimination of $\mathbf{0}$ have the value $\emptyset$, and path elimination has the value of its base. The iterator with base b, step g

and argument t has value $\mathrm{it}(\llbracket b\rrbracket_\rho, \mathrm{ap}(\llbracket g\rrbracket_\rho, \cdot), \llbracket t\rrbracket_\rho)$; the indexed recursor and the dependent eliminator have value $\mathrm{rec}(\llbracket b\rrbracket_\rho, (n, y) \mapsto \mathrm{ap}(\mathrm{ap}(\llbracket g\rrbracket_\rho, n), y), \llbracket t\rrbracket_\rho)$. The codes have the values of the types they decode to: $\hat{O}$ has N, $\hat{\mathbf{0}}$ has $\varnothing$, $\widehat{\mathrm{Id}}(a, t, u)$ has $\mathrm{Id}(\llbracket t\rrbracket_\rho, \llbracket u\rrbracket_\rho)$, and $\hat{\Pi}(a, b)$ has $\Pi(\llbracket a\rrbracket_\rho, x \mapsto \llbracket b\rrbracket_{\rho.x})$. So the four decoding conversions preserve values.

Lemma L.18 (Values and substitution)**.** *For a substitution σ, write $\sigma\rho$ for the environment $k \mapsto \llbracket \sigma_k\rrbracket_\rho$. Then $\llbracket A\sigma\rrbracket_\rho = \llbracket A\rrbracket_{\sigma\rho}$ and $\llbracket t\sigma\rrbracket_\rho = \llbracket t\rrbracket_{\sigma\rho}$; in particular $\llbracket b[t]\rrbracket_\rho = \llbracket b\rrbracket_{\rho.\llbracket t\rrbracket_\rho}$.*

Proof. Simultaneous induction on A and t, with σ and ρ general. Under a binder the substitution is lifted, and the lifted substitution evaluated at $\rho.x$ is $(\sigma\rho).x$, since a weakened term has at $\rho.x$ the value it has at ρ. Every other clause of Definition L.17 is computed from the values of the parts. □

Raw conversion does not preserve these values as it stands. The application of $\lambda\mathbf{0}.\, S(0)$ to 0 converts by β to $S(0)$, whose value is ν_1; but the value of the abstraction is the empty graph, so the application has the value $\mathrm{ap}(\varnothing, \nu_0) = \varnothing = \nu_0$. A conversion between two typed expressions may pass through untyped ones, so the values are controlled by an external condition.

Definition L.19 (Safety)**.** Safety of a type or a term at an environment ρ is defined by recursion on the expression. The types O, $\mathbf{0}$ and U, the variables, 0, refl, the elimination of $\mathbf{0}$, $\hat{O}$ and $\hat{\mathbf{0}}$ are safe. Otherwise:

- $\prod_A B$ is safe when A is, and B is safe at $\rho.x$ for every $x \in \llbracket A\rrbracket_\rho$; $\lambda A.\, b$ and $\hat{\Pi}(a, b)$ likewise, with b and with $\llbracket a\rrbracket_\rho$ for the domain;
- $\mathrm{Id}_A(t, u)$ and $\widehat{\mathrm{Id}}(a, t, u)$ are safe when t and u are; $\mathrm{El}\, a$ when a is; path elimination when its base is;
- St is safe when t is and $\llbracket t\rrbracket_\rho \in N$;
- ft is safe when f and t are and there are A and F with $\llbracket f\rrbracket_\rho \in \Pi(A, F)$ and $\llbracket t\rrbracket_\rho \in A$;
- an iterator with base b, step g and argument t is safe when b, g, t are, $\llbracket t\rrbracket_\rho \in N$, and there is a set V with $\llbracket b\rrbracket_\rho \in V$ and $\llbracket g\rrbracket_\rho \in \Pi(V, x \mapsto V)$; an indexed recursor likewise, with $\llbracket g\rrbracket_\rho \in \Pi(N, n \mapsto \Pi(V, y \mapsto V))$; a dependent eliminator likewise, with a family Q of sets in place of V: $\llbracket b\rrbracket_\rho \in Q(\nu_0)$ and $\llbracket g\rrbracket_\rho \in \Pi(N, n \mapsto \Pi(Q(n), y \mapsto Q(\mathrm{s}(n))))$.

If every σ_k is safe at ρ and A is safe at $\sigma\rho$, then $A\sigma$ is safe at ρ, and likewise for terms: by induction on the expression, with Lemma L.18 for the conditions on values and the lifted substitution under binders. In particular $b[t]$ is safe at ρ when b is safe at $\rho.\llbracket t\rrbracket_\rho$ and t is safe at ρ.

Definition L.20 (Parallel reduction)**.** Parallel reduction $\Rightarrow$ on raw types and terms is the least relation that is closed under every constructor (each part reduces in parallel, and every expression reduces to itself) and contains:

- $(\lambda A.\, b)\, t \Rightarrow b'[t']$ when $b \Rightarrow b'$ and $t \Rightarrow t'$;

- for each of the three eliminators, the step at 0 to the reduct of the base, and the step at St: the iterator to $g'(\mathrm{it}\,\ldots\,t')$ and the indexed recursor and dependent eliminator to $g'\,t'\,(\mathrm{rec}\,\ldots\,t')$, with all parts reduced in parallel;
- the four decodings $\mathrm{El}\,\hat{O} \Rightarrow O$, $\mathrm{El}\,\hat{\mathbf{0}} \Rightarrow \mathbf{0}$, $\mathrm{El}\,\widehat{\mathrm{Id}}(a,t,u) \Rightarrow \mathrm{Id}_{\mathrm{El}\,a'}(t',u')$ and $\mathrm{El}\,\hat{\Pi}(a,b) \Rightarrow \prod_{\mathrm{El}\,a'} \mathrm{El}\,b'$;
- the erasures: path elimination with base d reduces to the reduct of d, and $\mathrm{refl}(t)$ and the elimination of $\mathbf{0}$ reduce to $\mathrm{refl}(0)$.

The erasures are not conversions of $\mathscr{F}_U$; they are allowed here because the values ignore those fields, and they make the conversion β of path elimination at refl a reduction.

Lemma L.21 (Parallel reduction preserves safety and value)**.** *If $A \Rightarrow B$ and A is safe at ρ, then B is safe at ρ and $[\![A]\!]_\rho = [\![B]\!]_\rho$; likewise for terms.*

Proof. Induction on the reduction, with ρ general. The closure cases follow from the induction hypotheses part by part; under a binder the domain has the same value before and after, so the hypothesis applies at every $\rho.x$ with x in it. For $(\lambda A.\,b)\,t$: safety gives A_0, F with the graph of $x \mapsto [\![b]\!]_{\rho.x}$ on $[\![A]\!]_\rho$ in $\Pi(A_0,F)$, and $[\![t]\!]_\rho \in A_0$; a graph in $\Pi(A_0,F)$ has domain A_0, so $A_0 = [\![A]\!]_\rho$, the application has the value $[\![b]\!]_{\rho.[\![t]\!]_\rho}$, and b is safe there. By the induction hypotheses and Lemma L.18 this is the value of $b'[t']$, which is safe by the remark after Definition L.19. For an eliminator at St: the value of St is a numeral ν_{n+1} with $n = \mathrm{dec}[\![t]\!]_\rho$, so the eliminator's value is the step applied to its value at t; that value lies in V (or in $Q(\nu_n)$), by induction on n, and the step lies in $\Pi(V, x \mapsto V)$ (or the corresponding product), so the reduct is safe with the same value. At 0 the value is that of the base. The decodings have equal values by Definition L.17, and their safety conditions coincide. Path elimination has the value of its base; $\mathrm{refl}(t)$, $\mathrm{refl}(0)$ and the elimination of $\mathbf{0}$ all have the value $\varnothing$ and are safe. □

Lemma L.22 (Triangle property and confluence)**.** *Let A^* be the complete development of A: every redex of A that is present when A is read from the root is contracted, the parts first, and every other constructor is kept with its parts developed. If $A \Rightarrow B$, then $B \Rightarrow A^*$; likewise for terms. Hence if $A \Rightarrow^* B$ and $A \Rightarrow^* C$ there is D with $B \Rightarrow^* D$ and $C \Rightarrow^* D$.*

Proof. Induction on $A \Rightarrow B$. In a closure case where A is not itself a redex, A^* is the same constructor applied to the developments of the parts, and the induction hypotheses give the step. If A is a redex and the step contracted it, the parts of B reduce to the developments of the parts of A, and parallel reduction is closed under substitution of related terms, so the contractum of B's parts reduces to A^*. If A is a redex and the step kept it, the step from B contracts the same redex in B, with the same result. The cases of the decodings and the erasures are direct. The triangle property makes $\Rightarrow$ satisfy the diamond property, with A^* as the common reduct of any two one-step reducts, and the diamond property passes to $\Rightarrow^*$ by the usual tiling. □

Lemma L.23 (Every conversion joins)**.** *If two raw types are convertible in $\mathscr{F}_U$, both reduce by $\Rightarrow^*$ to a common type; likewise for terms.*

Proof. Write $A \downarrow B$ when A and B have a common reduct. By Lemma L.22 this relation is an equivalence; it is a congruence, since parallel reduction is closed under every constructor; and it is closed under substitution, since parallel reduction is. Each basic conversion of $\mathscr{F}_U$, β for products and for path elimination, the six equations of the eliminators and the four decodings, is a single parallel step. Induction on the conversion therefore gives $A \downarrow B$. □

Corollary L.24 (Coherence)**.** *If A and B are convertible and both safe at ρ, then $[\![A]\!]_\rho = [\![B]\!]_\rho$; likewise for terms.*

Proof. Follow both reduction sequences to the common reduct of Lemma L.23; by Lemma L.21, each step keeps safety and value. □

Proposition L.25 (Soundness of the set model)**.** *Say that ρ satisfies a context when each $\rho(k)$ lies in the value of the type of the kth entry, read at the tail of ρ. Then for every derivable judgment and every ρ that satisfies its context: a derivable type is safe; a derivable term $t : A$ is safe and $[\![t]\!]_\rho \in [\![A]\!]_\rho$; derivable equalities of types or of terms relate safe expressions with equal values; and a derivable substitution sends ρ to an environment that satisfies the source context, with safe terms.*

Proof. Induction on derivations. Variables are the satisfaction of the context. An abstraction has as value a graph in the product, and an application of a function in $\Pi(A, F)$ to a member of A is safe with value in the fiber, which is the value of $B[t]$ by Lemma L.18. The rule of conversion uses Corollary L.24: the derivation of the target type makes it safe, and the induction hypothesis makes the source safe. refl lies in $\mathrm{Id}(x, x) = \{\emptyset\}$. For path elimination, a member of $\mathrm{Id}([\![x]\!], [\![y]\!])$ forces the two values to be equal and the path to be $\emptyset$, the value of refl, so the motive at (y, p) has the value it has at (x, refl), where the base lies. The elimination of $\mathbf{0}$ is vacuous, since nothing lies in $\emptyset$. For the three eliminators of O, the argument is a numeral, the motive's values give the set V or the family Q required for safety, and the value lies in the motive at the argument by induction on the numeral. The universe rules use Lemma L.16: the codes of $\mathscr{F}_U$ have small values, and El is the identity on values. The equality rules hold by the same computations, the β- and ι-rules by Lemma L.21. □

Proof of Theorem 20.44(3). By Proposition L.25, a closed term of $\mathbf{0}$ would have a value in $[\![\mathbf{0}]\!] = \emptyset$; so there is none. A negative arithmetic type is inhabited at an environment of numerals exactly when its formula is true at the decoded environment, by induction on the formula: $\neg\neg\,\mathrm{Id}$ is inhabited exactly when the identity is, a product over N is inhabited exactly when every instance is, and functions between inhabited or empty sets exist exactly as implication says. So every arithmetic sentence whose negative translation $\mathscr{F}_U$ derives is true. A Peano derivation of $\bot$ would give, by part (2), a closed term of $\mathbf{0}$; so Peano arithmetic is consistent. With part (1), Con(PA) is true, and by Lemma L.2 the checker accepts no proof of $\bot$. □

L.9 Completeness and the models of bounded arithmetic

The second part works with the classical rules: the rules of Chapter 5 with excluded middle, without the omniscience and Markov rules. Formulas have de Bruijn variables $x_0, x_1, \ldots$, and a *sentence* has none free. A *structure* interprets 0, S, $+$ and $\cdot$ on a set and satisfies the six *rule checks*: $S(x) \neq 0$, injectivity of S, and the recursion equations of addition and multiplication. A formula is *bounded* when it is built from equations and $\bot$ by $\wedge$, $\vee$, $\to$ and the two bounded quantifiers

$$\forall y \forall z (y + z = t \to \psi), \qquad \exists y \exists z (y + z = t \wedge \psi),$$

read $\forall y \leq t \psi$ and $\exists y \leq t \psi$. A *model of* $I\Delta_0$ is a structure in which every induction instance $\varphi(0) \to \forall x (\varphi(x) \to \varphi(Sx)) \to \forall x \varphi(x)$ of a bounded formula φ holds at every assignment to its other variables. $I\Delta_0$ *derives* φ from a list E when a classical derivation from E has only induction nodes on bounded formulas.

For a set T of formulas, $T \vdash \varphi$ means that finitely many members of T derive φ by the classical rules with no induction node; T is *consistent* when $T \nvdash \bot$.

Theorem L.26 (Completeness of the classical rules)**.** *Let T be a set of sentences and φ a sentence. If φ holds in every structure that satisfies every member of T, then $T \vdash \varphi$.*

Proof. This is Gödel's completeness theorem, proved by Henkin's construction [11]. The calculus has no constants besides 0 and none can be added, so free variables serve as witnesses. The argument uses Zorn's lemma, in the classical metatheory.

Witnesses. Give every formula ψ a variable index w_ψ, injective in ψ and larger than the index of every free variable of ψ; for instance the pair of a code of ψ and a bound on its free variables. The *Henkin axiom* of ψ is $H_\psi = \exists \psi \to \psi[x_{w_\psi}/x_0]$; its free variables lie below $w_\psi + 1$.

Adding the Henkin axioms keeps a consistent set of sentences consistent. Suppose $T, H_{\psi_1}, \ldots, H_{\psi_n} \vdash \bot$ with distinct ψ_i, and let $\psi = \psi_n$ have the largest witness w. The variable x_w is free in no member of T, in no other H_{ψ_i} (whose free variables lie below $w_{\psi_i} + 1 \leq w$), and not in $\exists \psi$. From the hypotheses without H_ψ, the derivation gives $\neg H_\psi$, hence $\exists \psi$ and $\neg \psi[x_w/x_0]$ by classical logic. Generalizing over the fresh x_w gives $\forall x_0 \neg \psi$, which contradicts $\exists \psi$. So the hypotheses without H_ψ already derive $\bot$, and induction on n removes all Henkin axioms.

A maximal set. The union of a chain of consistent sets is consistent, because a derivation uses finitely many members. By Zorn's lemma a consistent set extends to a maximal consistent set S. Such an S contains every formula it derives, contains exactly one of χ and $\neg \chi$, contains a conjunction, disjunction or implication exactly when the truth table on its parts says so, and, if it contains every Henkin axiom, contains $\forall a$ exactly when it contains $a[t]$ for every term t: if $\forall a \notin S$, then $\neg \forall a \in S$, so $\exists \neg a \in S$, and the Henkin axiom of $\neg a$ puts $\neg a[x_w]$ in S. The existential quantifier is treated in the same way.

The term model. Call terms t and s equivalent when $t = s$ is in S. The rules for equality make this a congruence for S, $+$ and $\cdot$, so the classes form a structure, and it satisfies the six rule checks because S contains their instances. At the assignment sending x_i to its class, the value of a term is its class, and by induction on the number of connectives and quantifiers, which substitution does not change, a formula is true exactly when it is in S.

Completeness. If $T \nvdash \varphi$, then $T \cup \{\neg\varphi\}$ is consistent; add the Henkin axioms and extend to a maximal S. The term model satisfies every member of T and $\neg\varphi$, all of them sentences, so φ fails in a structure satisfying T. □

Theorem L.27 (Bounded arithmetic is sound and complete for its models)**.** *For sentences E and φ, $I\Delta_0$ derives φ from E exactly when φ holds in every model of $I\Delta_0$ in which every member of E holds.*

Proof. Soundness is induction on the derivation: each rule preserves truth at every assignment in a structure with the rule checks, and an induction node on a bounded formula is an instance that holds in every model of $I\Delta_0$.

For completeness, let T consist of E and the universal closures of the induction instances of all bounded formulas. A structure that satisfies T is a model of $I\Delta_0$, since an instance at a given assignment follows from its closure, and it satisfies E; so φ holds in it. Theorem L.26 gives finitely many members of T that derive φ without induction. Each closed induction axiom used has its own derivation: one induction node on its bounded formula, followed by generalizations. Substituting these derivations gives an $I\Delta_0$ derivation of φ from E. □

So to show that $I\Delta_0$ derives a sentence from E, it is enough to show the sentence true in an arbitrary model of $I\Delta_0$ satisfying E, and that is what the next three sections do. In such a model every predicate below is defined by a bounded formula with the same truth condition, so every induction used is an instance of bounded induction.

L.10 Arithmetic in a model of bounded arithmetic

Fix a model M of $I\Delta_0$.

Lemma L.28 (Induction, order and division)**.** *In M:*

(a) For a bounded φ: induction; strong induction, from $\forall v(\forall w < v\varphi(w) \to \varphi(v))$ to $\forall v\varphi(v)$; and the least number principle.

(b) Addition and multiplication are associative and commutative, multiplication distributes over addition, 0 and 1 are neutral, and addition cancels.

(c) Every element is 0 or a successor. The relation $x \le y$, defined by $\exists z(x + z = y)$, is a total order, $x < y + 1$ exactly when $x \le y$, and the order is compatible with addition and with multiplication by any element; a product is 0 only when a factor is.

(d) For $d \neq 0$, every a is $q \cdot d + r$ with $r < d$, and q and r are unique.

Proof. Induction for bounded formulas is an axiom of $I\Delta_0$; we prove (b) and (c) first, by induction alone, and then the strong forms in (a). (b) Each law is an induction on an equation, in the order of Chapter 3. (c) The first statement is an induction on $x = 0 \vee \exists y \le x(x = y + 1)$; totality is an induction on y, with x fixed, in the bounded formula $\exists z \le y(x + z = y) \vee \exists z \le x(y + z = x)$; the rest follows by cancellation. (a) Strong induction is induction on the bounded

formula $\forall w \le n\, \varphi(w)$, using $w \le 0 \to w = 0$ and $w \le n+1 \to w \le n \vee w = n+1$ from (c), and the least number principle is strong induction applied to $\neg\varphi$. (d) Existence is an induction on a in $\exists q \le a\, \exists r \le d (a = q \cdot d + r \wedge r < d)$: at $a+1$ either $r+1 < d$, or $r+1 = d$ and q rises by one. Uniqueness: if $q < q'$ then $q' \cdot d + r' \ge q \cdot d + d > q \cdot d + r$. □

Write $\mathrm{quo}(a,d)$ and $\mathrm{rem}(a,d)$ for the quotient and remainder. They satisfy $\mathrm{rem}(a + k \cdot m, d) = \mathrm{rem}(a,d)$ and $\mathrm{rem}(\mathrm{rem}(a,m),d) = \mathrm{rem}(a,d)$ whenever d divides m, by uniqueness. The *digit block* of B at a is $\mathrm{val}(B,a) = \mathrm{rem}(\mathrm{quo}(B,a),a)$; it is unchanged by adding a multiple of m, or by passing to the remainder modulo m, when $a \cdot a$ divides m, and $\mathrm{val}(B,a) = \mathrm{quo}(B,a)$ when $B < a \cdot a$. Every element is $2k$ or $2k+1$ and not both, by division by 2.

An element u is a *power of two* when $u \ne 0$ and in every factorization $u = d \cdot e$ with $d, e \le u$ the factor d is 1 or even.

Lemma L.29 (Powers of two)**.** *In M:* 1 *is a power of two; every divisor of a power of two is a power of two; if* w *is a power of two so is* $2w$*; a power of two other than* 1 *is* $2w$ *for a power of two* w*; if* $u \le v$ *are powers of two then* u *divides* v*; if* $u < v$ *then* $2u \le v$*; a product of powers of two is a power of two; and every* $m \ne 0$ *has a power of two* u *with* $u \le m < 2u$*.*

Proof. The first four facts follow from the definition and parity: an odd divisor of $2w$ other than 1 would divide w, or would make $2w$ odd. Divisibility of comparable powers is a strong induction on v in the bounded formula

$$v \text{ a power of two} \to \forall u \le v (u \text{ a power of two} \to \exists k \le v (v = u \cdot k)) \ :$$

if $v = 1$ then $u = 1$; otherwise $v = 2v'$ and either $u = v$, or $u = 1$, or $u = 2u'$ with $u' \le v'$, and the hypothesis at v' gives $u' \mid v'$. If $u < v$, then $v = u \cdot k$ with $k \ne 1$ a power of two, so k is even and $v \ge 2u$. Products are a strong induction on the second factor, through $u \cdot 2w' = 2(u \cdot w')$. The last fact is an induction on m: if $m < 2u$ fails at $m+1$, then $m+1 = 2u$, and $2u$ is the new power. □

Say that a is a *digit* of N, written $\mathrm{Bit}(a,N)$, when $N = (2q+1) \cdot a + r$ with $r < a$; for a power of two this is binary digit $\log_2 a$. For $a \ne 0$, $\mathrm{Bit}(a,N)$ holds exactly when $a \le \mathrm{rem}(N, 2a)$; it is unchanged by adding a multiple of m or passing to the remainder modulo m when $2a$ divides m; it implies $a \le N$; and $a \le N < 2a$ implies it.

L.11 The exponentiation graph

The graph says $y = 2^x$ by exhibiting the computation of 2^x by repeated squaring, read from the top binary digit of x down. With $x_j = \lfloor x / 2^j \rfloor$, the checkpoints $y_j = 2^{x_j}$ satisfy $y_j = y_{j+1}^2 \cdot 2^{b_j}$, where b_j is a binary digit of x. A certificate stores the checkpoints as the binary digits of one number N and the exponents x_j in the digit blocks of one number B at the checkpoints.

Definition L.30 (The graph)**.** A *step at u* for N and B is one of

- $1 < u$, $\mathrm{Bit}(u^2, N)$, $\mathrm{rem}(N, u^2) < 2u$ and $\mathrm{val}(B, u^2) = 2\,\mathrm{val}(B, u)$;
- $\mathrm{Bit}(2u^2, N)$, $\mathrm{rem}(N, 2u^2) < 2u$ and $\mathrm{val}(B, 2u^2) = 2\,\mathrm{val}(B, u) + 1$.

$\mathrm{Cert}(x, y, N, B)$ says: y is a power of two, $N < 2y$, $\mathrm{Bit}(1, N)$, $\mathrm{Bit}(y, N)$, $B < y^2$, $\mathrm{val}(B, y) = x$, and every power of two $u < y$ with $\mathrm{Bit}(u, N)$ has a step at u. The graph is

$$\mathrm{Pow}_2(x, y) \;:=\; \exists N \le 2y\, \exists B \le y \cdot y\ \mathrm{Cert}(x, y, N, B),$$

with remainders, quotients and digit blocks written through their bounded definitions. It is a bounded formula with free variables x and y.

A step at u names the next checkpoint $w = (1 + b)u^2$ with $b \in \{0, 1\}$ and $u < w$: the digit of N at w is one, no digit of N lies strictly between u and w (the condition $\mathrm{rem}(N, w) < 2u$), and the stored exponent doubles, plus b.

Lemma L.31 (First facts)**.** $\mathrm{Cert}(x, y, N, B)$ *gives* $x < y$*, and* $\mathrm{Pow}_2(x, y)$ *makes y a power of two.* $\mathrm{Pow}_2(0, 1)$ *holds, with* $N = 1$ *and* $B = 0$*, and* $\mathrm{Pow}_2(x, 1)$ *gives* $x = 0$.

Proof. $x = \mathrm{val}(B, y) < y$. At $y = 1$ there is no power of two below y, and every remainder modulo 1 is 0. □

Lemma L.32 (Extension)**.** *If* $\mathrm{Pow}_2(x', y')$*,* $b \in \{0, 1\}$ *and* $y' < (1 + b)y'^2$*, then* $\mathrm{Pow}_2(2x' + b, (1 + b)y'^2)$.

Proof. Let (N', B') certify (x', y'), and put $y = (1 + b)y'^2$, $x = 2x' + b$, $N = N' + y$ and $B = B' + x \cdot y$. Then y is a power of two, $2y' \le y$, and $x < y$ because $x' < y'$. So $N < 2y$, $B < y^2$, $\mathrm{Bit}(y, N)$ since $y \le N < 2y$, and $\mathrm{Bit}(1, N)$ because adding y, a multiple of 2, keeps it. The block of B at y is x, since $B' < y$; blocks at powers $a \le y'$ are unchanged, since a^2 divides y. Let $u < y$ be a power of two with $\mathrm{Bit}(u, N)$. Then $\mathrm{Bit}(u, N')$, because $2u$ divides y, so $u \le N' < 2y'$ and $u \le y'$. If $u < y'$, the old step at u leads to some $w \le y'$, and its three conditions survive, since $2w$ divides y and the blocks at u and w are unchanged. If $u = y'$, the new step leads to y: $\mathrm{rem}(N, y) = N' < 2y'$, and the block at y is $x = 2\,\mathrm{val}(B', y') + b$. □

Lemma L.33 (Decomposition)**.** *If* $\mathrm{Pow}_2(x, y)$ *and* $y \ne 1$*, then there are* x'*,* y' *and* $b \in \{0, 1\}$ *with* $\mathrm{Pow}_2(x', y')$*,* $y' < y$*,* $y = (1 + b)y'^2$ *and* $x = 2x' + b$.

Proof. Let (N, B) certify (x, y) and $m = \mathrm{rem}(N, y)$. Since y is even, $\mathrm{Bit}(1, m)$, so $m \ne 0$; let u be the power of two with $u \le m < 2u$. Then $u < y$ and $\mathrm{Bit}(u, N)$, so there is a step at u to some w. If $w < y$, the digit of m at $w \ge 2u$ would put $w \le m < 2u$; if $w > y$, the top digit y of N would be a digit of $\mathrm{rem}(N, w) < 2u \le y$. So $w = y$, and with $x' = \mathrm{val}(B, u)$ the step gives $y = (1 + b)u^2$ and $x = 2x' + b$. The pair $(\mathrm{rem}(N, 2u), \mathrm{rem}(B, u^2))$ certifies (x', u): its digits are those of N below $2u$, its blocks those of B at powers up to u, and every step at a power $a < u$ leads to a $w_a \le u$ (a larger w_a would see the digit u of N inside $\mathrm{rem}(N, w_a) < 2a \le u$), so it survives the remainders. □

Theorem L.34 (The laws of the graph)**.** *In every model of $I\Delta_0$:*

(a) $\mathrm{Pow}_2(0,1)$*, and* $\mathrm{Pow}_2(0,y) \to y = 1$*;*

(b) upward recursion: $\mathrm{Pow}_2(x,y) \to \mathrm{Pow}_2(x+1,2y)$*;*

(c) downward recursion: $\mathrm{Pow}_2(x+1,q) \to \exists p \le q\,(q = p+p \wedge \mathrm{Pow}_2(x,p))$*;*

(d) functionality: $\mathrm{Pow}_2(x,p) \to \mathrm{Pow}_2(x,p') \to p = p'$*;*

(e) positive values: $\mathrm{Pow}_2(x,p) \to p \neq 0$*;*

(f) initial-segment domain: $\mathrm{Pow}_2(x,p) \to \forall y \le x \exists p'\ \mathrm{Pow}_2(y,p')$*.*

Proof. Each is a strong induction on the power v, over a bounded formula with v as the induction variable; Lemma L.33 supplies the smaller power and Lemma L.32 rebuilds. Positive values hold because p is a power of two.

(a) The first is Lemma L.31. For the second, if $\mathrm{Pow}_2(0,v)$ with $v \neq 1$, decomposition gives $0 = 2x' + b$, so $x' = b = 0$, and $\mathrm{Pow}_2(0,y')$ with $y' < v$ and $v = y'^2$; the hypothesis gives $y' = 1$, hence $v = 1$.

(b) Induct on v in $\forall a \le v(\mathrm{Pow}_2(a,v) \to \mathrm{Pow}_2(a+1,2v))$. At $v = 1$, $a = 0$, and extension with $b = 1$ gives $\mathrm{Pow}_2(1,2)$. Otherwise decompose $a = 2x' + b$, $v = (1+b)y'^2$. If $b = 0$, extend (x',y') with $b = 1$: $(2x'+1, 2y'^2) = (a+1, 2v)$. If $b = 1$, the hypothesis at $y' < v$ gives $\mathrm{Pow}_2(x'+1, 2y')$, and extension with $b = 0$ gives $(2x'+2, 4y'^2) = (a+1, 2v)$.

(c) Induct on v in $\forall a \le v(\mathrm{Pow}_2(a+1,v) \to \exists p \le v(v = p+p \wedge \mathrm{Pow}_2(a,p)))$. At $v = 1$ the exponent would be 0. Otherwise decompose $a + 1 = 2x' + b$, $v = (1+b)y'^2$. If $b = 0$, then $x' = x_0 + 1$ and $a = 2x_0 + 1$; the hypothesis at y' gives $y' = 2p_0$ with $\mathrm{Pow}_2(x_0,p_0)$, and extension with $b = 1$ gives $\mathrm{Pow}_2(2x_0+1, 2p_0^2)$, where $v = 4p_0^2 = 2p_0^2 + 2p_0^2$. If $b = 1$, then $a = 2x'$; at $y' = 1$ take $p = 1$, and otherwise extension with $b = 0$ gives $\mathrm{Pow}_2(2x', y'^2)$, where $v = 2y'^2$.

(d) Induct on v in $\forall a \le v \forall c \le p'\,(\mathrm{Pow}_2(a,v) \to \mathrm{Pow}_2(a,c) \to v = c)$. At $v = 1$, $a = 0$ and $c = 1$ by (a). Otherwise $a \neq 0$, so $c \neq 1$; decompose both: $a = 2x_1 + b_1 = 2x_2 + b_2$ gives $x_1 = x_2$ and $b_1 = b_2$ by parity, the hypothesis at $y_1 < v$ gives $y_1 = y_2$, and $v = (1+b_1)y_1^2 = c$.

(f) Induct on v in $\forall a \le v(\mathrm{Pow}_2(a,v) \to \forall c \le a \exists p' \le v\ \mathrm{Pow}_2(c,p'))$. If $c = a$ take v. If $c < a$, then $a = a_0 + 1$, downward recursion gives $v = 2p_0$ with $\mathrm{Pow}_2(a_0,p_0)$, and the hypothesis at $p_0 < v$ applies to $c \le a_0$. □

Lemma L.35 (The graph in $\mathbb{N}$)**.** *In* $\mathbb{N}$*,* $\mathrm{Pow}_2(x,p)$ *holds exactly when* $p = 2^x$*.*

Proof. $\mathbb{N}$ is a model of $I\Delta_0$. $\mathrm{Pow}_2(n,2^n)$ follows from $\mathrm{Pow}_2(0,1)$ by upward recursion, and functionality gives the converse. □

L.12 Pair formation from exponentiation

Recall from Section 20.3.11 that $w\ \varepsilon\ z$ abbreviates $\exists p \le z \exists q \le z \exists r < p(\mathrm{Pow}_2(w,p) \wedge z = (2q+1)p + r)$: the digit of z at 2^w is one.

Lemma L.36 (Multiplicativity)**.** *In a model of $I\Delta_0$: if $\mathrm{Pow}_2(a,p)$ and $\mathrm{Pow}_2(a+k,q)$, then $q = p \cdot r$ for some r with $\mathrm{Pow}_2(k,r)$. Consequently, if $\mathrm{Pow}_2(a,p)$, $\mathrm{Pow}_2(b,q)$ and $a < b$, then $q = 2m \cdot p$ with $m \neq 0$, and $2p \leq q$.*

Proof. Induct on k in $\forall c \leq q\,(\mathrm{Pow}_2(a+k,c) \to \exists r \leq c\,(\mathrm{Pow}_2(k,r) \wedge c = p \cdot r))$. At $k = 0$, $c = p$ by functionality, and $r = 1$. At $k+1$, downward recursion writes $c = c_0 + c_0$ with $\mathrm{Pow}_2(a+k,c_0)$; the hypothesis gives $c_0 = p \cdot r_0$, and $r = 2r_0$ satisfies $\mathrm{Pow}_2(k+1,r)$ by upward recursion. For the consequence write $b = a + (k+1)$; then r is the value at a positive exponent, which downward recursion writes as $2m$ with $m \neq 0$ a value of the graph. □

Division by a nonzero p is unique, so $(2q+1)p + r = 2m \cdot p + s$ with $r, s < p$ is impossible: the quotients $2q+1$ and $2m$ would be equal.

Theorem L.37 (Exponentiation gives pair formation)**.** *Let M be a model of $I\Delta_0$ in which every x has a p with $\mathrm{Pow}_2(x,p)$. Then for all x and y some z satisfies $w \,\varepsilon\, z \leftrightarrow (w = x \vee w = y)$ for every w.*

Proof. Let $\mathrm{Pow}_2(x,X)$ and $\mathrm{Pow}_2(y,Y)$.

If $x = y$, take $z = X$. Then $x \,\varepsilon\, z$ with $q = r = 0$. If $w \,\varepsilon\, z$ through p, q, r, and $w < x$, then $X = 2m_1 \cdot p$ by Lemma L.36, and $(2q+1)p + r = 2m_1 p + 0$ is impossible; if $w > x$, then $2X \leq p \leq z = X$, which is impossible. So $w = x$.

If $x < y$, take $z = X + Y$, where $Y = 2m \cdot X$ with $m \neq 0$ and $2X \leq Y$. Then $x \,\varepsilon\, z$ because $z = (2m+1)X + 0$, and $y \,\varepsilon\, z$ because $z = 1 \cdot Y + X$ with $X < Y$. Conversely, let $w \,\varepsilon\, z$ through p, q, r. If $w < x$, then $X = 2m_1 p$ and $Y = 2m_2 p$, and $z = 2(m_1 + m_2)p + 0$ contradicts the odd quotient. If $x < w < y$, then $Y = 2m_2 p$ and $X < 2X \leq p$, so $z = 2m_2 p + X$ with $X < p$, again a contradiction. If $w > y$, then $X + Y < 2Y \leq p \leq z$, which is impossible. So $w = x$ or $w = y$. The case $y < x$ is symmetric. □

Proof of Theorem 20.46. Take Pow_2 of Definition L.30. It is bounded, its free variables are x and p, and it defines $p = 2^x$ in $\mathbb{N}$ by Lemma L.35. Its six laws hold in every model of $I\Delta_0$ (Theorem L.34), so $I\Delta_0$ derives them by Theorem L.27: it is a standard bounded graph. The translated pairing axiom holds in every model of $I\Delta_0$ that satisfies $\forall x \exists p\ \mathrm{Pow}_2(x,p)$ (Theorem L.37), so $I\Delta_0$ derives it from that sentence, again by Theorem L.27. With Proposition 20.45, each derives the other. □

Appendix M

Incompleteness and finite set theory: the proofs

This appendix gives the full arguments behind Theorems 20.42 and 20.47, whose proofs in Section 20.3.11 name the classical sources and state the steps. Both run through models: each statement that Peano arithmetic must derive is shown true in an arbitrary model of Peano arithmetic and then read back as a derivation.

M.1 Models of Peano arithmetic

A *model of Peano arithmetic* is a structure for 0, S, $+$ and $\cdot$ that satisfies the six rule checks and every induction instance, at every assignment. A derivation of Peano arithmetic is sound in every model, by induction on the derivation.

Theorem M.1 (Completeness of Peano arithmetic for its models)**.** *A formula true in every model of Peano arithmetic at every assignment has a derivation in Peano arithmetic.*

Proof. Its universal closure ψ is a sentence true in every model. Apply Theorem L.26 with T the universal closures of all induction instances: a structure satisfying T is a model, so finitely many closed induction axioms derive ψ by the classical rules, each axiom has a derivation with one induction node, and instantiation returns the formula. □

In a model of Peano arithmetic, induction holds for every property defined by a formula with parameters, so the arithmetic of Section L.10 holds there with induction on all formulas: the semiring laws, cancellation, the discrete linear order, the least number principle, division with remainder, parity, the pairing (10.3) and Gödel's β. The pairing is $\pi(a,b) = b \cdot b + a$ when $a < b$ and $a \cdot a + a + b$ otherwise; Peano arithmetic derives that its graph is total, functional, injective and onto (Lemma 20.2, proved in Appendix K.1), and that β is total and functional and can extend any sequence by one entry (Lemmas K.1–K.4 of Appendix K.2), so in every model these are functions with the same laws.

M.2 Codes and certificates

Codes. A node with tag j and children a, b, c (unused children 0) has code $\pi(\pi(a, \pi(b, c)), j) - 1$. The tags are those of Section L.1, except that a variable has its de Bruijn index as a raw number and an axiom node its schema number as a raw number: variable 2, zero 3, successor 4, sum 5, product 6, equation 7, falsehood 8, implication 9, universal quantifier 10, axiom $12(c, s, \ell)$, modus ponens $13(c, \text{minor}, \text{major})$, generalization $14(c, p)$, list cells 15 and $16(h, t)$. The zero term has code 8 and $\bot$ has code 63. Every child of a code is at most the code, and smaller when the code and its tag are both positive. The code 0 decodes as tag 1 with all children 0; where tables are built from this decoding (Proposition M.7) we put $\text{tag}(0) = 0$, as in Section L.1.

A formula with $\wedge$, $\vee$ or $\exists$ is coded through the classical definitions $A \wedge B = \neg(A \to \neg B)$, $A \vee B = \neg A \to B$ and $\exists A = \neg\forall\neg A$; write $\ulcorner\varphi\urcorner$ for the code of φ and $\underline{n}$ for the numeral $S^n(0)$.

Certificates. A *certificate* is a length n, a root p, and five sequences of length n, each coded by Gödel's β: a kind sequence and four field sequences. Its records are

- kind 0, a proof node q;
- kind 1, a substitution record (x, d, t, y): $y = \mathrm{sub}(x, d, t)$;
- kind 2, a lifting record (x, c, y): $y = \mathrm{lift}(x, c)$;
- kind 3, a term-shift record (t, d, y): $y = \mathrm{tsh}(t, d)$;
- kind 4, a successor-shift record (x, d, y): $y = \mathrm{plus}(x, d)$.

A record is *locally correct* when it agrees with the other records of the certificate as the clauses of Con(PA) say. A proof record has tag 12, 13 or 14, and an axiom node's schema number is at most 13. A proof node of tag 13 has its minor and major premises among the proof records and the major premise's conclusion is the implication from the minor's conclusion to the node's; a node of tag 14 has its premise among the proof records and concludes the universal quantification of its conclusion; a node of tag 12 has as many list cells as its schema has parameters and its conclusion is the schema's instance, read through decoding and through records of kinds 1–4 for the operations the schema uses, with the term parameters of schemas 3 (one) and 6 (two) not tagged as a formula, that is, with no tag among 7, 8, 9, 10; a record of kind 1–4 has the value that the recursion of its operation prescribes from records at the children. Every record relation occurs positively, so local correctness survives adding records.

$\mathrm{Prov}(x)$ says that some certificate has its root among the proof records, with conclusion x, and has every record locally correct. All quantifiers inside are bounded by the certificate's numbers, so Prov is twelve existential quantifiers over a bounded formula. Let $\mathrm{Pr}(\varphi) = \mathrm{Prov}(\underline{\ulcorner\varphi\urcorner})$.

Lemma M.2 (Certificates in a model)**.** *In every model M of Peano arithmetic:*

(a) two certificates concatenate into one, and a record that is correct against the extended store may be added; all records stay correct;

(b) for every x, d, t some certificate contains a substitution record for (x, d, t), and likewise for the other three operations;

(c) two correct certificates give the same value to records with the same arguments, so the four operations are functions of M with their recursion equations;

(d) at numerals of codes of actual terms and formulas, these functions give the numerals of the codes of the actual results.

Proof. (a) Concatenation and extension are β-comprehension: the sequence of the first n entries followed by the second m is defined by a formula, and induction on the length builds its code by extending one entry at a time. Correctness is monotone. (b) Course-of-values

induction on the code x in the formula "some correct certificate has a record for (x, d, t), for every d and t": the records for the children come first, by the induction hypothesis, the certificates are concatenated, and the record for x is added. (c) Merge the two certificates and compare the two values by course-of-values induction on the code, using the local correctness of each record. (d) Induction on the actual term or formula, reading each record at decoded numeral codes, where the decoding of M agrees with that of $\mathbb{N}$. □

M.3 The first, second and fourth conditions

The first condition rests on a syntactic step: a derivation by the rules of Peano arithmetic (Definition 8.10) becomes a Hilbert derivation of the checker's calculus. Write $\Gamma \vdash_H A$ when A has a Hilbert derivation from the hypotheses Γ: its leaves are members of Γ and instances of the fourteen schemas of Section L.1, and its steps are modus ponens and generalization, which passes from $\uparrow\Gamma \vdash_H A$ to $\Gamma \vdash_H \forall A$, where $\uparrow\Gamma$ lifts every hypothesis, as universal introduction does. With Γ empty these are the proofs the checker accepts. Let $A^\star$ replace $\wedge$, $\vee$ and $\exists$ by their classical definitions $\neg(A \to \neg B)$, $\neg A \to B$ and $\neg\forall\neg A$; codes are assigned through these definitions, so A and $A^\star$ have the same code.

Lemma M.3 (Natural deduction into the Hilbert calculus)**.**

(a) $(\cdot)^\star$ *commutes with lifting, with substitution and with the step* $A \mapsto A^+$ *of the induction rule, whose code is* $\mathrm{plus}(\ulcorner A \urcorner, 0)$.

(b) (Deduction theorem.) If $A, \Gamma \vdash_H B$, *then* $\Gamma \vdash_H A \to B$.

(c) $\Gamma \vdash_H A \to A$. *If* $\Gamma \vdash_H \bot$, *then* $\Gamma \vdash_H A$. *If* $\Gamma \vdash_H \neg\neg A$, *then* $\Gamma \vdash_H A$. *If* $\neg A, \Gamma \vdash_H \bot$, *then* $\Gamma \vdash_H A$.

(d) If $\Gamma \vdash_{\mathrm{PA}} \varphi$, *then* $\Gamma^\star \vdash_H \varphi^\star$. *In particular a theorem* φ *of Peano arithmetic has a closed Hilbert derivation whose conclusion has the code* $\ulcorner \varphi \urcorner$.

Proof. (a) Induction on the formula; the definitions are built from $\to$, $\bot$ and $\forall$, on which lifting and substitution act part by part. The step of the induction rule replaces the variable 0 by its successor and keeps the others, which is the successor shift at depth 0.

(c), first part. $A \to A$ comes from the instance $(A \to ((A \to A) \to A)) \to ((A \to (A \to A)) \to (A \to A))$ of schema 1 and two instances of schema 0 by modus ponens twice.

(b) Induction on the derivation of B. If B is A, use $A \to A$. If B is another hypothesis or an axiom, schema 0 gives $B \to (A \to B)$. A modus ponens step from $C \to B$ and C becomes, by the induction hypotheses $A \to (C \to B)$ and $A \to C$, two modus ponens steps with schema 1. A generalization step concludes $\forall C$ from $\uparrow A, \uparrow\Gamma \vdash_H C$; the induction hypothesis gives $\uparrow\Gamma \vdash_H \uparrow A \to C$, generalization gives $\Gamma \vdash_H \forall(\uparrow A \to C)$, and schema 4 with modus ponens gives $A \to \forall C$.

(c), the rest. From $\bot$: $\bot \to \bot$ is $\neg\bot$, schema 0 gives $\neg A \to \neg\bot$, and schema 2 gives $(\neg A \to \neg\bot) \to (\bot \to A)$. From $\neg\neg A$: schema 0 gives $\neg\neg\neg\neg A \to \neg\neg A$, schema 2 turns it into $\neg A \to \neg\neg\neg A$ and that into $\neg\neg A \to A$. The last statement is the deduction theorem followed by double-negation elimination.

(d) Induction on the derivation. Each rule of Definition 8.10 becomes Hilbert steps as listed below, where "by contradiction from $\neg C$" means: derive $\bot$ with the further hypothesis $\neg C$ and apply the last statement of (c). By (a) the translated premises and conclusions are the translations of the rule's formulas. □

Rule	Hilbert derivation of the translation
hypothesis	the hypothesis
arithmetic axiom	an instance of schemas 7–12
reflexivity $t = t$	schema 5
from $s = t$ and $A[s]$, $A[t]$	schema 6 and modus ponens twice
introduction of $\to$	the deduction theorem
elimination of $\to$	modus ponens
from A and B, $A \wedge B$	under the hypothesis $A \to \neg B$, modus ponens with A and then with B gives $\bot$; the deduction theorem gives $\neg(A \to \neg B)$
from $A \wedge B$, A	by contradiction from $\neg A$: $A \to \neg B$ by the deduction theorem, since A and $\neg A$ give $\bot$ and $\bot$ gives $\neg B$; modus ponens with $\neg(A \to \neg B)$
from $A \wedge B$, B	by contradiction from $\neg B$: schema 0 gives $A \to \neg B$; modus ponens with $\neg(A \to \neg B)$
from A, $A \vee B$	under the hypothesis $\neg A$, A gives $\bot$ and so B; the deduction theorem gives $\neg A \to B$
from B, $A \vee B$	schema 0 gives $\neg A \to B$
from $A \vee B$, $A \vdash C$ and $B \vdash C$, C	by contradiction from $\neg C$: the deduction theorem gives $A \to C$ and $B \to C$; with $\neg C$, A gives $\bot$, so $\neg A$; then B from $\neg A \to B$, C, and $\bot$
from $\bot$, any A	ex falso, (c)
introduction of $\forall$	generalization
from $\forall A$, $A[t]$	schema 3 and modus ponens
from $A[t]$, $\exists A$	under the hypothesis $\forall\neg A$, schema 3 gives $\neg A[t]$, and $A[t]$ gives $\bot$; the deduction theorem gives $\neg\forall\neg A$
from $\exists A$ and $A, \uparrow\Gamma \vdash \uparrow C$, C	by contradiction from $\neg C$: under the lifted hypotheses, which include $\uparrow\neg C$, the premise turns A into $\uparrow C$ and so into $\bot$; the deduction theorem gives $\neg A$, generalization gives $\forall\neg A$, and modus ponens with $\neg\forall\neg A$ gives $\bot$
induction, from $A[0]$ and $\forall(A \to A^{+})$, $\forall A$	schema 13 and modus ponens twice
excluded middle $A \vee \neg A$	$\neg A \to \neg A$, by (c)

Proposition M.4 (D1). *If Peano arithmetic derives φ, it derives* $\mathrm{Pr}(\varphi)$.

Proof. By Lemma M.3(d), a derivation of φ gives a closed Hilbert derivation of the checker's calculus whose conclusion has the code $\ulcorner\varphi\urcorner$. Fix a model M. Every axiom instance of the derivation has a certificate in M: one axiom node over records of kinds 1–4, which exist by Lemma M.2(b) and carry the standard values by (d). Modus ponens and generalization extend certificates by (a). So $\mathrm{Pr}(\varphi)$ holds in M; by Theorem M.1, Peano arithmetic derives it. □

Proposition M.5 (D2)**.** *Peano arithmetic derives* $\mathrm{Pr}(\varphi \to \psi) \to \mathrm{Pr}(\varphi) \to \mathrm{Pr}(\psi)$.

Proof. In a model, concatenate the two certificates and add the modus ponens node $13(\ulcorner\psi\urcorner, \text{root for } \varphi, \text{root for } \varphi \to \psi)$; it is correct against the concatenation. Theorem M.1 finishes. □

Proposition M.6 (D4)**.** *There is a sentence* G *such that Peano arithmetic derives* $G \to \neg\,\mathrm{Pr}(G)$ *and* $\neg\,\mathrm{Pr}(G) \to G$.

Proof. Let $\mathrm{Num}(x, t)$ say that some β-sequence starting at the code 8 of 0, each entry the successor node of the previous one, has t at position x; in a model, at a standard x it holds exactly for the code of $\underline{x}$. Let $\mathrm{Dg}(x, y)$ say that some correct certificate has a substitution record putting the numeral code of x for variable 0 in x, with value y. At the numeral of a formula code $\ulcorner A\urcorner$ it holds, in every model, exactly for $y = \ulcorner A[\underline{\ulcorner A\urcorner}/0]\urcorner$, by Lemma M.2(c) and (d). Put $\theta(x) = \forall y(\mathrm{Dg}(x, y) \to \neg\,\mathrm{Prov}(y))$ and $G = \theta(\underline{\ulcorner\theta\urcorner})$. In every model, G holds exactly when Prov fails at the one y with $\mathrm{Dg}(\ulcorner\theta\urcorner, y)$, which is $\ulcorner G\urcorner$; that is, exactly when $\mathrm{Pr}(G)$ fails. Theorem M.1 gives both implications. □

The proof uses nothing about $\neg\,\mathrm{Prov}$ beyond its being a formula in y; Theorem 20.48 states the general form.

M.4 The bridge to the consistency sentence

Proposition M.7 (D5)**.** *Peano arithmetic derives* $\mathrm{Con}(\mathrm{PA}) \to \neg\,\mathrm{Pr}(\bot)$.

Proof. Let M be a model with a certificate C for the code 63 of $\bot$, with root p. Put $B = p + 8$ and define tables on numbers at most B: the tag and children by decoding, with $\mathrm{tag}(0) = 0$; the slacks from the child sizes; nv as the identity, since natural data are raw numbers in this coding; $K(f, q) = 1$ exactly for the proof records $q < f$ of C; and the four operations by the functions of Lemma M.2(c), indices read in base $B + 1$ as in Section L.1. Each table is defined by a formula, so β-comprehension gives codes for it on any prefix. Now check the 247 clauses. The child clauses hold because children are smaller than nodes; the zero clauses because the zero term has code $8 \le B$ and tag 3; the fuel, modus ponens, generalization and axiom clauses because $K(f, q) = 1$ only at proof records below f, whose local correctness says what each clause asks; the operation clauses because the operations satisfy their recursion equations; and the root clauses because p is a proof record with conclusion 63, whose tag is 8. Under the guards of the operation clauses (Section L.1) every argument of a lookup is at most B, so each lookup reads the entry of the arguments it names. So these values satisfy every clause, and M refutes $\mathrm{Con}(\mathrm{PA})$. In every model, therefore, $\mathrm{Con}(\mathrm{PA})$ implies $\neg\,\mathrm{Pr}(\bot)$, and Theorem M.1 gives the derivation. □

The clauses constrain only the values of the tables, not the coding behind them, so a certificate in this coding gives tables that satisfy the clauses of Definition L.1; the coding was chosen so that the zero term has code 8 and the list cells and schema tags agree.

M.5 The third condition

Fix a model M. Its elements, standard or not, have numerals inside M: by induction in M, every m has a unique *numeral code* $\mathrm{nc}(m)$, with $\mathrm{nc}(0) = 8$ and $\mathrm{nc}(m+1)$ the successor node of $\mathrm{nc}(m)$; at standard m it is the code of $\underline{m}$. Numeral codes are closed: substitution and term shifts leave them unchanged. For a standard formula A and a list c of closed codes, let $\mathrm{cf}_k(c, A)$ be the code of A with the free variables from k on replaced by the codes in c.

Lemma M.8 (Tools for the third condition)**.** *In M:*

(a) Code substitution*: for closed t and closed codes c, substituting t for variable k in $\mathrm{cf}_{k+1}(c, A)$ gives $\mathrm{cf}_k(t :: c, A)$.*

(b) Internal validity*: if a standard formula F with free variables below n holds in every model of Peano arithmetic, then for any n closed term codes c the code $\mathrm{cf}_0(c, F)$ has a certificate.*

(c) Numeral arithmetic*: for all a, b in M the codes of $\underline{a}+\underline{b} = \underline{a+b}$ and $\underline{a}\cdot\underline{b} = \underline{ab}$ have certificates, and so does that of $\neg(\underline{a} = \underline{b})$ when $a \neq b$.*

(d) Bounded completeness*: for a bounded formula A, an assignment e and the numeral codes c of its values, if A holds at e then $\mathrm{cf}_0(c, A)$ has a certificate, and if it fails then the negation of that code has one.*

Proof. (a) Induction on the actual formula A, using the recursion equations of the substitution function and that the plugged codes are closed.

(b) The universal closure of F is a theorem of Peano arithmetic by Theorem M.1, so it has a certificate in M by the construction in the proof of Proposition M.4. Instantiate it n times with schema 3 and modus ponens; by (a) the instances have the codes $\mathrm{cf}_0(c, F)$. The plugged terms are closed and not formula codes, as schema 3 requires.

(c) Induction in M on b. At $b = 0$ the code is an instance of schema 9 or 11. From b to $b+1$, schemas 10 and 12, the induction hypothesis and equality substitution (schema 6) combine by modus ponens; each combination is an instance of (b). For $a \neq b$, induct on the smaller with schemas 7 and 8.

(d) Induction on the actual formula A. For terms, the code of $t[c] = \underline{t(e)}$ has a certificate, by induction on t with (c). An equation follows by symmetry and transitivity, and a false one by (c). The connectives use instances of propositional tautologies, from (b). A true bounded existential quantifier gives its witness's numeral and existential introduction; a false one is the bounded universal quantifier of the negation. A bounded universal quantifier $\forall y \le t\, A(y)$ is an induction in M on the value T of the bound: the induction predicate is "the code of $\forall y \le \underline{T}\, A(y)$ has a certificate", defined by a formula, and each step combines the induction hypothesis, the certificate for $A(\underline{T}+1)$ from the outer induction, and the theorem $\forall n\,\big((\forall y \le n\, A(y)) \to A(Sn) \to \forall y \le Sn\, A(y)\big)$ of Peano arithmetic, through (b); the base is the theorem $(\forall y \le 0\, A(y)) \leftrightarrow A(0)$. □

Proposition M.9 (D3)**.** *Peano arithmetic derives* $\mathrm{Pr}(\varphi) \to \mathrm{Pr}(\mathrm{Pr}(\varphi))$.

Proof. In a model M, let a certificate with twelve components show $\mathrm{Prov}(x)$. The bounded matrix of Prov holds at x and these components, so by Lemma M.8(d) its code with the twelve numeral codes plugged in has a certificate; twelve existential introductions give a certificate for the code of $\mathrm{Prov}(\underline{x})$. At $x = \ulcorner\varphi\urcorner$ this is the code of $\mathrm{Pr}(\varphi)$. So $\mathrm{Pr}(\varphi) \to \mathrm{Pr}(\mathrm{Pr}(\varphi))$ holds in every model, and Theorem M.1 gives the derivation. □

With (D1)–(D5), the propositional argument in the proof of Theorem 20.42 completes the proof of that theorem.

M.6 Finite set theory and binary membership

The calculus of $\mathrm{ZF}^*_{\mathrm{fin}}$ has the natural-deduction rules of the arithmetic calculus with excluded middle, over the language of $\in$ and $=$, with variables as the only terms. Its axioms are extensionality, the empty set, pairing, union, power set, separation and replacement (in the form: if every $u \in x$ has exactly one v with $\psi(u, v)$, some y contains such a v for every $u \in x$) for every formula, foundation (every inhabited set has an $\in$-minimal element), the negation of infinity (no set contains an empty set and, with each of its members y, the set $y \cup \{y\}$), and transitive containment. The completeness argument of Theorem L.26, with Henkin witnesses among the variables, proves: a sentence true in every structure satisfying the axioms has a derivation.

Lemma M.10 (Binary membership in a model of arithmetic)**.** *Let* Pow_2 *be as in Theorem 20.47 and M a model of Peano arithmetic. With $x \in y$ read as $x\ \varepsilon\ y$, M satisfies every axiom of* $\mathrm{ZF}^*_{\mathrm{fin}}$.

Proof. In M, Pow_2 is total, by induction from $\mathrm{Pow}_2(0, 1)$ and upward recursion, and functional, so $x\ \varepsilon\ y$ says that digit x of y is one. A number is determined by its digits, by induction on the larger of two numbers with the same digits: this is extensionality. Every number below 2^b has its digits below b, and for every property defined by a formula and every bound b some number has exactly the digits $x < b$ with the property, by induction on b, adding 2^b when b has it. This *bounded comprehension* gives the empty set (0), pairing ($2^x + 2^y$, or 2^x), union (digits of digits of x lie below x), power set (a number whose digits are digits of x is at most x, so comprehension below $x + 1$ collects them), and separation. Transitive containment: the number with every digit below x contains x, and a digit of one of its digits is again below x. Replacement: for each digit u of x the unique v exists, and by induction on the digits of x there is a bound for all of them; comprehension below that bound collects them. Foundation: the least digit y of an inhabited x has no digit in x, because the digits of y are smaller than y. Negation of infinity: a nonzero number has a largest digit y, and $y \cup \{y\}$, the number $y + 2^y$, is larger, so it is not a digit. □

Lemma M.11 (Arithmetic in a model of finite set theory)**.** *Let V be a nonempty model of $\mathrm{ZF}^*_{\mathrm{fin}}$. Its natural numbers ω^V (the von Neumann numerals), with addition and multiplication defined by recursion, form a model of Peano arithmetic, and the decoder $\mathrm{dec}(n) = \{\mathrm{dec}(k) : \text{digit } k \text{ of } n \text{ is one}\}$, defined by course-of-values recursion on ω^V, is a bijection from ω^V onto V with $\mathrm{dec}(k) \in \mathrm{dec}(n)$ exactly when $k \in n$.*

Proof. Transitive containment and foundation give $\in$-induction for every formula. Recursion on ω^V is justified by sets of finite approximations, which exist by separation and replacement and are unique by induction; it defines addition, multiplication and dec. Satisfaction of an arithmetic formula in ω^V is defined by a formula of set theory, so separation gives induction for every arithmetic formula: ω^V is a model of Peano arithmetic. The decoder is injective, by course-of-values induction, since two numbers with the same decoded digits have the same digits. It is onto, by $\in$-induction: the members of a set x are decoded numbers, by the induction hypothesis; by the negation of infinity a set of natural numbers is bounded, so the indices of those members are the digits of one number n, built by induction on a bound, and $\mathrm{dec}(n) = x$ by extensionality. □

Proof of Theorem 20.47. If $\mathrm{ZF}^*_{\mathrm{fin}}$ derives φ and M is a model of Peano arithmetic, then M read through ε is a model of $\mathrm{ZF}^*_{\mathrm{fin}}$ by Lemma M.10, so φ holds there, which says that φ^a holds in M; by Theorem M.1 Peano arithmetic derives φ^a. Conversely, if Peano arithmetic derives φ^a and V is a nonempty model of $\mathrm{ZF}^*_{\mathrm{fin}}$, then φ^a holds in ω^V, and the decoder of Lemma M.11 carries binary membership on ω^V to membership in V, so φ holds in V; by completeness of the set-theoretic calculus, $\mathrm{ZF}^*_{\mathrm{fin}}$ derives φ. The last assertion is Theorem 20.39. □

Appendix N

Notation and glossary

Symbols are local to the mathematical object under discussion. In particular, O denotes a proof ledger in Chapter 6 and an orbit type in Chapter 9; and $\approx$ is a congruence of signed records in Chapter 7 but the relation of naming the same point in Chapter 12; and $\beta_{\sim}$ is the collision search of a congruence, while $\beta\mathbb{N}$ is the space of ultrafilters on the natural numbers, both in Chapter 7. The accompanying type or definition decides which reading is intended. Two clashes are avoided by a change of type face: the italic I and U are an identity matrix and a unitary in Part V, while the sans-serif I is the iterator of Chapter 9 and U the universal program of Section 20.3. Chapters 18, 19 and 20 recall this at first use. This guide groups the notation by its use; Section N.6 collects the notation of Parts VI to VIII.

Dropped subscripts. The subscript δ marks a constructed object where it is introduced: the start 0_δ, the orbit $\mathbb{N}_\delta$, the signed records $\mathbb{Z}_\delta$, the ratios $\mathbb{Q}_\delta$ and the line $\mathbb{R}_\delta$. Once a construction has been read faithfully into familiar notation, the book drops the subscript on its elements and operations, with the following fixed meaning. From Chapter 3 on, 0 is the start 0_δ, and $1, 2, 3, \ldots$ are $S(0_\delta)$, $S(S(0_\delta))$, $S(S(S(0_\delta)))$, and so on; a numeral n names the orbit expression with n steps, which is legitimate because reading and expansion are inverse, Theorem 1.4. On $\mathbb{Z}_\delta$ and $\mathbb{Q}_\delta$, the symbols 0, 1, $+$, $\cdot$ and $<$ are the constructed operations on classes, and an orbit record n written there stands for its image $\iota(n) = [n, 0]$, or for the ratio $\langle \iota(n); 1 \rangle$; these inclusions preserve the operations, as the formulas (4.2) and (4.5) show, so no equation changes its meaning. In Part II, 0, S, $+$ and $\cdot$ are also symbols of the arithmetic language, and Definition 5.3 reads them as the constructed operations; where it matters, the text says whether a symbol or its value is meant. In Parts III and IV a ratio such as $1/(k+1)$ is a ratio record of $\mathbb{Q}_\delta$, and $\eta(q)$ is the point of $\mathbb{R}_\delta$ it names; where Chapters 13 and 14 use a ratio as a point, it stands for that point. In Part V, 0 and I are the zero and identity matrices of the stated size.

N.1 Arithmetic and maps

$\mathbb{N}_\delta, 0, S$ The carrier of finite orbit expressions, its start, and its step. An expression is 0 or $S(a)$ for an earlier expression a. Chapters 1–3.

r, e The reading of an orbit expression as a natural number and the expansion of a natural number as an orbit expression. Their two round trips are Theorem 1.4.

(M, b, s) A pointed step system: a carrier M, a start b and a map $s : M \to M$. The canonical reading into it is R_M. Chapter 2.

$f \circ g$ Composition, with g acting first. Thus $(f \circ g)(x) = f(g(x))$.

$f : A \to B$ A map with domain A and specified target B. Its range is the set of outputs it actually takes.

$[a, b]$ A class of signed pairs in Chapter 4, when used as the representative of a difference. For rational endpoints in Parts III and IV the same bracket shape denotes a closed interval; the chapter and the type distinguish the two uses.

$\sim$ An equivalence relation specified at its use. Balance of signed pairs, equality of ratios by cross-multiplication, and recognition congruences have different definitions.

$\sim_{i,p}$ The index-period congruence: points before i remain distinct, and the tail from i repeats with positive period p. Definition 7.2 gives the exact relation.

ι The inclusion $n \mapsto [n, 0]$ of the orbit into the constructed integers. Theorem 4.13.

$\langle u; d \rangle$ The class of a ratio record with signed numerator u and nonzero orbit denominator d. Definition 4.9.

N.2 Formulas, judgments and resources

φ, ψ, χ Formulas of the language under discussion. Letters t, u ordinarily denote terms.

$\bot$ The false formula. Negation $\neg\varphi$ abbreviates $\varphi \to \bot$.

$\wedge, \vee, \to$ Conjunction, disjunction and implication. Their introduction and elimination rules appear in Chapter 5 and Appendix D.

$\forall, \exists$ Universal and existential quantification. An existential witness supplies an object and its required property.

$\Gamma \vdash \varphi$ A derivability judgment: there is a finite argument for φ from context Γ using the specified rules. A context is a finite list of formulas.

$\rho \vDash \varphi$ Truth of a formula under an assignment ρ in the stated interpretation. Derivability and truth are different notions, connected in one direction by soundness.

$x_0, x_1, \ldots$ Variable positions. Immediately inside a quantifier, x_0 is its new bound variable. Earlier positions move up.

$\varphi\uparrow, \Gamma\uparrow$ Lift free variable positions past a new binder, in a formula or throughout a context.

$\varphi(t)$ Substitute t at the designated variable position, avoiding capture. It does not mean textual replacement without regard to binders.

$(e, \ell, m; i)$ Four Boolean ledger entries: EM, LPO, MP and induction on a quantified formula. Combining ledgers with $\sqcup$ takes inclusive-or in each coordinate.

EM Excluded middle for every proposition, or its explicitly specified object-language schema.

LPO The limited principle of omniscience. For a decidable predicate, it gives a witness or says that all instances fail. The arithmetic schema applies to every formula and, with induction on every formula, proves every instance of the EM schema. Chapter 6.

MP Markov's principle. For a decidable predicate, double-negated existence yields existence. The arithmetic schema in this book is restricted to quantifier-free formulas, and so restricted, with induction on every formula, it is derivable from the base rules. With induction on quantifier-free formulas only, some instance is not, Proposition 6.14. Chapter 6.

WLPO, LLPO Weak and lesser limited principles of omniscience. Their forms for binary sequences, and their different conclusions, are specified in Definition 7.8 and used again in Chapter 12. The abbreviations do not identify them with LPO or with each other: no two of MP, LLPO, WLPO, LPO and EM are equivalent over intuitionistic second-order arithmetic, Theorem 7.38.

$\mathrm{MP}_{\mathrm{bin}}$ Markov's principle for binary sequences, Definition 7.8. With supplied decisions it is the same principle as MP. Intuitionistic second-order arithmetic does not prove it, Theorem 7.38. In Chapter 12 it is the exact price of a sign for a nonzero quantity, Theorem 12.11.

AC_{ω} Countable choice, Definition 12.21. It selects a sequence of witnesses and decides nothing: intuitionistic arithmetic with variables for sequences and countable choice for numbers and for sequences proves none of LPO, WLPO, LLPO and $\mathrm{MP}_{\mathrm{bin}}$ and refutes none of them, Theorem 12.22. Without unique choice, excluded middle does not replace it in four completeness assertions, Theorem 12.63.

WEM Weak excluded middle: $\neg P \vee \neg\neg P$ for every proposition P. Chapter 12; as a sentence of intuitionistic second-order arithmetic, Definition 7.39.

WMP, $\mathrm{W}(X)$ Ishihara's weak Markov principle and its hypothesis, Definition 7.39; with $\mathrm{MP}^{\vee}$ it splits $\mathrm{MP}_{\mathrm{bin}}$, Remark 7.40.

LLPO_n**,** $\mathrm{C}_i^n(X)$ A decidable set with at most one member misses one of the n residue classes modulo n; $\mathrm{C}_i^n(X)$ says it misses the class of i, Definition 7.39.

FAN_{Δ}**,** FAN_c**,** FAN The decidable, c-set and full fan theorems, Definition 13.2. Heine–Borel for $[0,1]$ is equivalent to FAN_{Δ} with no choice principle, Theorem 13.6; without unique choice, excluded middle with the countable choice that a search can witness does not prove it, Theorem 13.11.

$\mathrm{WLPO}_{\mathrm{seq}}$**,** $\mathrm{LLPO}_{\mathrm{seq}}$ WLPO and LLPO for a whole double sequence of questions at once, Definition 13.8. Weak König's lemma is equivalent to $\mathrm{LLPO}_{\mathrm{seq}}$ with no choice principle, Proposition 13.9.

$\mathrm{MP}^{\vee}$**,** $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ LLPO for binary sequences known not to vanish, and its form for a whole sequence of them, Definition 14.18. Dominated division by nonzero points costs exactly $\mathrm{MP}^{\vee}$, with unique choice in the converse, Theorem 14.28. As a sentence of intuitionistic second-order arithmetic, Definition 7.39; its place among the prices, Theorem 7.45.

Unique choice for Π^0_1 **relations** Collecting, for each i, the one bit that passes a decidable sequence of tests, Definition 14.20; a case of the reading of maps.

$\mathrm{Dec}, \mathrm{Dec}_2, \mathrm{Z}, \mathrm{E}, \mathrm{A}, \mathrm{Eq}, \mathrm{Ev}, \mathrm{Od}, \mathrm{Cong}, \mathrm{Desc}, \mathrm{D}, \mathrm{Odd}, \mathrm{Even}$ The abbreviations of Definition 7.18 for sentences of intuitionistic second-order arithmetic about a set X or a relation R read through the pairing $J(x,y) = (x+y)\cdot(x+y)+x$. The six versions of the classification, $\mathsf{V}_{\mathrm{none}}, \dots, \mathsf{V}_{\mathrm{EM}}$, are (7.11); Theorem 7.33 derives each one's equivalence with its principle.

$[\![\varphi]\!]_{\rho,\sigma}$ The value of a formula in a system of truth values under an assignment, Definition 7.19.

$\Gamma \vdash_{\mathrm{PA}} \varphi$ Derivability in first-order Peano arithmetic, presented as a separate classical calculus in Chapter 8. Theorem 8.11 identifies it with the derivations whose ledger records neither LPO nor MP.

$S^n(0)$ The numeral with n successors. Its value in a structure M is $\nu(n) = S_M^n(0_M)$. Chapter 8.

φ^N The negative translation of φ, built from $=$, $\bot$, $\to$ and $\forall$. Section 20.3.

φ^G Friedman's translation of φ by a formula G: each equation $t = u$ becomes $(t = u) \vee G$, and $\bot$ becomes G. Definition 20.61.

N.3 Typed constructions and finite descriptions

$\Pi x : A\, B(x)$ The type of functions taking $x : A$ to an element of $B(x)$. If the output type does not depend on x, write $A \to B$.

$\mathrm{Id}_A(t,u)$ The identity type between two terms of type A in the language of Chapter 9.

$\mathbf{0}$ Its empty type. This is a type, not the orbit's starting element 0.

$\lambda x.t$ A function whose output at x is t. Application is written $f(x)$ or by juxtaposition.

$\mathsf{I}, \mathsf{R}, \mathsf{E}$ Iterator, indexed recursor and dependent eliminator, in sans-serif type. Their successive inputs are compared in Chapter 9; Appendix D repeats their computation equations.

$D(x)$ The optional type family distinguishing the start from a successor in the specified typed language.

$\mathscr{I}^-, \mathscr{R}^-, \mathscr{E}^-, \mathscr{E}^+$ The iterator, indexed and dependent fragments without the start discriminator, and the dependent fragment with it. Theorem 9.10.

U The universal program of Section 20.3. On input $\langle e, n\rangle$ it searches for a computation record of program e on input n accepted by a fixed record test, and returns the output written there. It is distinct from the unitary U of Part V.

$\mathrm{App}(e,n,y)$, $G(a,b,z)$ The arithmetic formulas saying that program e returns y on input n, and that $z = \langle a, b\rangle$. Section 20.3.3.

$e \simeq_A f$, $H_A(e)$ Hereditary extensional equality of program codes at a finite type, and admissibility $e \simeq_A e$. Section 20.3.5.

$C_\Theta(R)$, $R \approx_\Theta R'$ The condition that the environment R holds admissible values for the type context Θ, and the relation of two environments that hold related values. Section 20.3.5.

$c(t)$, $E_t(R, y)$, $\mathrm{Rd}_R(P)$ The program compiled from a term, the formula saying that it returns y at the environment R, and the reading of a formula as an arithmetic formula about programs. Sections 20.3.5 and 20.3.6.

$\mathrm{Ty}(A)$, $|t|$, Adm_T The type of $\mathscr{E}^+$ expressing a negative formula, the erasure of a typed term, and the reading of a type of $\mathscr{E}^+$ in the language of functions. Section 20.3.10.

$\mathrm{Con}(\mathrm{PA})$, $\mathscr{F}_U$ The consistency sentence of a fixed proof checker for Peano arithmetic, and $\mathscr{E}^+$ extended by one universe. Section 20.3.11.

$I\Delta_0$, $\mathrm{ZF}^*_{\mathrm{fin}}$, φ^a Bounded arithmetic, finite set theory with infinity negated and transitive containment, and the Ackermann reading of a set-theoretic sentence by binary membership. Section 20.3.11.

$\mathrm{Prov}(x)$, $\mathrm{Pr}(\ulcorner\varphi\urcorner)$, $\ulcorner\varphi\urcorner$ The provability formula of Appendix M.2; the sentence $\mathrm{Prov}(\ulcorner\varphi\urcorner)$, which says that Peano arithmetic derives φ and which Appendix M writes $\mathrm{Pr}(\varphi)$; and the code of φ, inside a formula its numeral. Section 20.3.12.

$\Gamma \Rightarrow \varphi$, Pr_Γ, $\mathrm{Con}(\mathrm{PA} + \Gamma)$ For a finite list $\Gamma = (\gamma_1, \dots, \gamma_n)$ of sentences: the implication $\gamma_1 \to (\gamma_2 \to \cdots \to (\gamma_n \to \varphi))$, the sentence $\mathrm{Pr}_\Gamma(\ulcorner\varphi\urcorner) = \mathrm{Pr}(\ulcorner\Gamma \Rightarrow \varphi\urcorner)$, and $\neg\,\mathrm{Pr}_\Gamma(\ulcorner\bot\urcorner)$. For Γ empty this is $\neg\,\mathrm{Pr}(\ulcorner\bot\urcorner)$, which is not the checker sentence $\mathrm{Con}(\mathrm{PA})$ above; (D5) derives it from $\mathrm{Con}(\mathrm{PA})$. Section 20.3.12.

T_k, A_k The tower $T_0 = \mathrm{PA}$, $T_{k+1} = T_k + \mathrm{Con}(T_k)$, and the sentence $A_k = \mathrm{Pr}_{T_k}(\ulcorner\bot\urcorner)$, so that $\mathrm{Con}(T_k)$ is $\neg A_k$. Theorems 20.53 and 20.54.

Σ_1 **sentence** A sentence $\exists x_1 \cdots \exists x_k\, B$ whose matrix B is bounded: built from equations and $\bot$ by $\wedge$, $\vee$, $\to$ and the bounded quantifiers $\forall y \le t$ and $\exists y \le t$. Section 20.3.12.

$\equiv$ Conversion under that language's computation rules. It is not an unstated equality-reflection principle. In Chapter 16, $A \equiv B$ means instead that the calculus derives both $A \vdash B$ and $B \vdash A$.

F_n The finite stage of tallies within the budget n. Definition 10.1 fixes its boundary convention.

$[\ell_n, u_n]$ The rational enclosure requested at precision index n. Its width is at most $1/(n+1)$, and later intervals lie inside earlier ones.

$v(p)$ The displayed classical real value of interval protocol p. Chapter 11 specifies the classical comparison.

$p \simeq q$ Observational equality: the two protocols' intervals overlap at every matching precision. It is weaker than equality of their finite descriptions.

$\mathbb{R}_\delta$ The line built from ratios: regular sequences of ratio records taken up to $\approx$. Definition 12.14.

$s \approx t$ The regular sequences s and t name the same point: for every k they eventually agree within $1/(k+1)$.

$\eta(q)$ The point of $\mathbb{R}_\delta$ named by the constant sequence of a ratio record q.

within $1/(k+1)$ For points x, y of $\mathbb{R}_\delta$: $x \le y + \eta(1/(k+1))$ and $y \le x + \eta(1/(k+1))$. Section 12.9.

certified real A sequence (a_n) of integers with $|a_m/2^m - a_n/2^n| \le 2^{-m} + 2^{-n}$ for all m, n; the integer a_n is its answer at precision n, Definition 15.1.

$g \Vdash_0 A$, $g \Vdash_1 A$ The object g of the context belongs to the reading of the formula A of the calculus of δ's objects at the earlier or at the later stage, Table 16.1; the computable calculus and its model of named objects are Definitions 16.18 and 16.20.

N.4 Physical records and finite matrices

$r : W \to \mathscr{R}$ In Chapter 17, the record produced from a world or preparation. A reader d recovers a target f exactly when $d \circ r = f$.

B^m The capacity of m answer positions from an alphabet of size B. Adaptive stopping is represented by padded transcripts whose padding is ignored by the reader.

ε An error tolerance. Each theorem specifies the distance or observable to which it applies.

$A^*, A^\dagger$ The adjoint, or conjugate transpose, of a complex matrix. The two notations denote the same operation.

I The identity matrix on the space indicated by the equation. In a block display, its dimension is fixed by that block.

$\mathrm{tr}, \|\cdot\|, \|\cdot\|_1$ Trace, operator norm and trace norm. The state-error convention uses the full trace norm, without a factor of one half.

ρ A state matrix: positive with trace one. A pure state can be specified by a unit column vector.

$[A, B]$ The commutator $AB - BA$.

$\otimes$ Tensor product. In Part V it retains the coordinates of both named systems; it does not authorize discarding a factor.

$C_y, K_{y,z}$ A Choi block for instrument outcome y and its Kraus matrices. The additional index z labels the finite factorization. Chapter 18.

V, U An isometry and a unitary, respectively, in the dilation construction. Their input and output spaces are stated there.

H_0, N, P_c Native core energy, occupation and the projection whose collective count is derived from the two conserved charges. Chapter 19 and Appendix B.

r, e **in the recorder theorem** The number of native recorder cells and the uniform event-probability error. Here r is an integer resource count, not the reading map used in earlier chapters.

N.5 Glossary

Additive congruence. An equivalence relation preserved by the addition operation. A recognition rule with this property remains consistent when records are extended. Chapter 7.

Ambient mathematics. The surrounding language and reasoning in which a construction, formal calculus or interpretation is studied. It must be distinguished from the object language defined inside it. Chapters 1, 5 and 9.

Bishop compact. A set of points with internal nets, for every k a finite list of members within $1/(k+1)$ of every member, that is complete: every Cauchy sequence of members converges to a member. The nets exist without being handed over. Every presented set is Bishop compact exactly when every Cauchy sequence of points converges, with no choice either way, Theorem 13.37. Definition 13.36.

Cancellative congruence. An additive congruence from which a common summand can be removed: $x + z \sim y + z$ implies $x \sim y$. Exactly these extend to the signed records. Theorem 7.12.

Canonical reading. The map determined by the start and step equations into a specified target system. Its uniqueness does not imply that it is injective or onto that target. Chapter 2.

Categoricity. Uniqueness of a structure up to the specified isomorphism among structures satisfying the stated conditions. The faithfulness and generation conditions are part of the result here. Chapter 2.

Certified real. A sequence of integers a_n, one for each precision n, with $|a_m/2^m - a_n/2^n| \leq 2^{-m} + 2^{-n}$ for all m and n; Chapter 15.

Characteristic zero. A property of a field: no sum $1 + \cdots + 1$ of one or more terms equals 0. Theorem 4.15.

Commutative semiring. A set with two associative and commutative operations, a neutral element for each, multiplication by the additive neutral element giving that element, and distributivity. The orbit maps uniquely into every one. Proposition 3.11.

Complete positivity. Positivity of an operation after adjoining any finite retained reference. It preserves positivity for correlated inputs as well as for the source considered alone. Chapter 18.

Computable calculus. The calculus of δ's objects with its carriers presented and its terms and maps computed by programs; it keeps every rule. Definition 16.18.

Computation record. A finite table of evaluation facts for a program on an input, each justified through an evaluation clause by facts later in the table, with a second table of the values each justification uses. Acceptance and Record soundness, the two facts about the fixed test for such records, are stated in Section 20.3 and derived in Theorem 20.5.

Conservativity. A richer system is conservative over a smaller one, for a class of statements, when every statement of that class it proves the smaller one also proves. Theorem 20.32 proves the form used here, for negative sentences.

Cotransitivity. The property of the strict order of the line built from ratios: if $x < y$, then $x < z$ or $z < y$ for every z. Proposition 12.19.

Countable choice. The principle that a relation with a witness for every natural number has a sequence of witnesses. It selects witnesses and decides nothing, Theorem 12.22. Definition 12.21.

Countermodel. An interpretation that satisfies the retained rules and fails a proposed conclusion. It separates resources only after both rule soundness and expressibility have been checked. Chapter 9.

Cover-compact. A set K of points such that every ratio cover of K has an N with every member of K in one of the first N intervals. That $[0, 1]$, or every presented set, is cover-compact is equivalent to FAN_Δ with no choice principle, Theorems 13.6 and 13.25. Definition 13.5.

Decidable predicate. A predicate for which each supplied input admits a positive or negative answer. Decidability of individual inputs does not supply an unbounded search result. Chapter 6.

Dependent elimination. A construction whose output type may vary with the orbit point. Its step transports data from the preceding type to the next one. Chapter 9.

Effective name. One finite program that returns a valid enclosure at every requested precision under the specified protocol. The existence of separate programs for finite prefixes is weaker. Chapter 10.

Equational over constant carriers. A formula of the calculus of δ's objects with no atom, whose equations compare terms of carriers that are the same at both stages and whose quantifiers range over such carriers. The full calculus derives every true one; Proposition 16.15.

Eventually constant. A formula in one searched variable whose truth value is the same for all values beyond some bound. Every quantifier-free arithmetic formula has this property, for each assignment of its other variables, with a bound computed from that assignment. Lemma 6.8.

Exact price. A logical resource sufficient for a stated result and recoverable from that result over the stated base. The reverse direction establishes necessity within that comparison. Two exact prices differ when a model satisfies one and refutes the other; the six prices of the recognition classification all differ, Theorem 7.38. Chapters 7 and 12.

Faithful generated system. A pointed step system whose step is injective, whose start is not a step, and whose entire carrier is generated from that start in the stated inductive sense. Definition 2.4. These are exactly the systems whose canonical reading is bijective, Proposition 2.8.

Fan theorem. The statement that every bar of the binary tree is uniform: one depth works for every path. Its decidable form is equivalent, with no choice principle, to Heine–Borel for $[0, 1]$; Chapter 13.

Finite instrument. A finite family of quantum operations with a retained outcome mark, whose sum preserves trace. It describes the returned state as well as the probabilities of marks. Chapter 18.

Full calculus. The calculus of δ's objects in which a term may carry any map of carriers. It has no recursive model (Theorem 16.14) and derives every true sentence that is equational over constant carriers (Proposition 16.15); its computable form is the computable calculus.

Generation. The condition that the carrier has no extra elements outside the structure reached from the designated start. It is equivalent to surjectivity of the canonical reading, Proposition 2.8. Restricted to properties expressible by first-order formulas, it no longer excludes extra elements. Chapter 2.

Group completion. The extension of an additive structure to a commutative group through which every additive map into a group factors uniquely. Theorem 4.13.

Hereditary extensional equality. Equality of program codes at a finite type: at O, equality of numbers; at $A \to B$, the two programs return outputs on every pair of hereditarily equal inputs, and the outputs are hereditarily equal. Section 20.3.5.

Heyting arithmetic. The intuitionistic first-order theory of 0, S, $+$ and $\cdot$, with induction for every formula. The base rules with induction for every formula present it: from every finite context, the posit-free derivations prove exactly its theorems, and they are the translations of its derivations, up to the way the injectivity of the successor is written. Corollary 8.12 and Remark 6.12.

Initiality. Existence of exactly one structure-preserving map from the designated object into every target of the specified kind. The target need not itself be faithful. Theorem 2.3.

Interpretation. An assignment of objects and operations to the language that respects its formation and inference rules. A formula's truth is evaluated within an interpretation. Chapters 5, 8 and 9.

Intuitionistic second-order arithmetic. Heyting arithmetic with a second kind of variable for sets of numbers, comprehension for every formula and induction stated for every set; usually called HAS. The base over which the six principles of Chapter 7 are separated. Definition 7.14.

Last exit. For a decidable set D of strings and a binary sequence p, a number n with $D(\bar{p}(m)) = 1$ for every $m \geq n$ such that for every $j < n$ some $m \geq j$ has $D(\bar{p}(m)) = 0$. When the c-set of D is a bar it exists and is unique, Lemma 13.17, so unique choice selects it, and FAN_c is then the uniform continuity of pointwise continuous maps from binary sequences to numbers, Corollary 13.19. Definition 13.16.

Ledger. The recorded additional resources used by a particular derivation. It describes that proof, not automatically the least resources needed for its conclusion. Chapter 6.

Located cut. A pair of inhabited, disjoint sets of ratios, the lower one closed downward without a greatest element and the upper one closed upward without a least element, such that whenever $q < r$, either q lies in the lower set or r in the upper set. Section 12.9.

Model of truth values. An interpretation in which a formula's value lies in a complete system of truth values with an implication, such as the open sets of a space or a chain. Every sentence derivable in intuitionistic second-order arithmetic has the top value, so a sentence with another value is not derivable there. Definition 7.19 and Lemma 7.21.

Negative formula. A formula built from equations, $\bot$, $\to$ and $\forall$. Section 20.3.

Numeral. The term $S^n(0)$, or its value $S_M^n(0_M)$ in a structure M. Chapter 8.

Observational equality. The equivalence of interval protocols defined by overlap at every precision. In the stated classical comparison, it agrees with equality of displayed values. Chapter 11.

Peano arithmetic. First-order classical arithmetic: six axioms for the start, the step, addition and multiplication, induction for every formula, and excluded middle. The rules of Chapter 5 with the EM rule, and without LPO and MP, prove exactly its theorems. Theorem 8.11.

Posit-free. Using none of EM, LPO or MP as added arithmetic rules in the ledger of this book. It does not exclude the base rules or induction on quantified formulas. The posit-free derivations prove exactly the theorems of Heyting arithmetic, and they are the translations of its derivations, up to the way the injectivity of the successor is written, Corollary 8.12. Chapter 6.

Positive cone. A subset of a ring closed under addition and multiplication that contains exactly one of x and $-x$ for each nonzero x, and does not contain 0. Proposition 4.16.

Presented compact set. A set of points given with its nets: for each n, a finite list of named members such that every member is within 2^{-n} of one of them, and completeness for named Cauchy families; Definition 13.22.

Presented uniform map. A function on the points of a set K given with a transformer, which sends each name of a member of K to a name of its value, and a modulus μ, such that members within $1/(\mu(k)+1)$ have values within $1/(k+1)$. Positive lower bounds and infima of such maps on presented sets are equivalent to FAN_Δ with no choice principle, Theorem 13.28 and Corollary 13.30. Definition 13.27.

Quantifier prefix. A string of quantifiers placed before a quantifier-free formula. The prefixes that go up into every structure obeying the six arithmetic rules are exactly the purely existential ones, and those that come down from every such structure are exactly the purely universal ones. Proposition 8.9.

Quotient. A carrier formed by treating equivalent representatives as one element. Operations descend to the quotient only when they respect the equivalence relation. Chapter 4.

Recorder. A rule that reads the finite record of the first examinations and either announces an answer or reads on; Definition 17.12.

Reduces to. A rule reduces to a set of rules when each instance of its schema has a derivation, from no hypotheses, whose additional rules all belong to that set; the base rules are always available. The rule can then be removed from any derivation. Section 6.7.

Region certificate. A finite check on one computed trajectory of a differential equation: at level n_0 every vector of the trajectory lies in the ball of radius $M - 2^{-(n_0+2)}$. It is a hypothesis about computed ratios, not about an exact solution. Definition 15.18.

Regular sequence. A sequence (s_n) of ratio records with $|s_m - s_n| \le 1/(m+1) + 1/(n+1)$ for all m, n. Its points form the line $\mathbb{R}_\delta$, Definition 12.14.

Retained reference. A system kept in the error comparison while the operation acts on another system. It exposes errors in correlations that a comparison of isolated source states can miss. Chapter 18.

Sharp event. An event represented by an orthogonal projection. The projection identities are used in the recorder noise bound. Chapter 19.

Soundness. Every derivable judgment is valid in the specified interpretation under the stated hypotheses. It does not say that every true statement is derivable. Chapter 5.

Two-stage carrier. An earlier set, a later set and a passage map from the first to the second: the objects of the calculus of Chapter 16, Definition 16.1.

Uniformity. One supplied object or procedure works for every input in the theorem's stated range. In the recorder theorem, one fixed program state and apparatus must satisfy the error bound for every source input. Chapters 10 and 19.

Well-definedness. Independence from choices that a construction has discarded, such as the representative of a quotient class. Chapter 4.

N.6 The cost, physics and learning (Parts VI to VIII)

Parts VI to VIII keep the notation above and add the entries below. Some letters change meaning there, and each chapter fixes its reading at first use. For example, φ is the golden ratio, but it also names the partial computable functions φ_e of Chapter 29, the sign laws of Section 26.8, formulas in Chapters 28 and 29, and the area factors φ_h of hinge costs in Chapter 27; J is the cost, not the pairing (7.10); G is the cost's logarithmic form, a token's generator G_t or Newton's constant; D is a debit count, a relative entropy, a drift or the dimension of the sphere S^D; T is Gödel's system, a period, a temperature or a statement, as in "T costs exactly P", never a theory of the tower T_k; and κ is the apparatus constant of Definition 22.10, the Einstein coupling of Proposition 22.40, the frequency of the Binet clock in Chapter 25, or the background of the lattice in Chapter 27. In Section 24.11, Q is an additive charge and R a writing rule, not the form and the matrix of Definition 24.13; φ is the function of a read; and T is the tick of a tick register or a number of ticks.

Maps, data forms and prices

map In Parts VI to VIII, a rule given as data: a proof that every input has exactly one output does not by itself give a map. Section 21.1. Under the default reading of Appendix C, which has unique choice, each data form below is its principle, Remark 21.2.

the LPO, WLPO and WEM functions One map d from binary sequences to $\{0,1\}$ with $d(\alpha) = 1$ exactly when α has an entry 1, respectively exactly when α is all 0; and one map d from propositions to $\{0,1\}$ with $d(P) = 1$ exactly when $\neg\neg P$. Definition 21.1.

zero test, apartness test Maps $z, a : \mathbb{R}_\delta \to \{0,1\}$ with $z(x) = 1$ exactly when $x = 0$, and $a(x) = 1$ exactly when $x \# 0$, that is, when $x < 0$ or $x > 0$. Definition 21.1. They exist exactly when the WLPO function, respectively the LPO function, does, Theorem 28.3.

free, costs exactly, classical Free: proved with no omniscience principle and no choice principle. "T costs exactly P": each implies the other with no choice principle. A result proved in classical mathematics is a theorem about the classical real numbers, or about complex matrices or measures, with excluded middle and the axiom of choice available, and carries no price on $\mathbb{R}_\delta$. Section 21.1.

exact price, between, below, open For a step S of the forcing chain: $S \Leftrightarrow P$ with no choice principle; $S \Rightarrow P$ and $Q \Rightarrow S$; only $Q \Rightarrow S$, the last two being *bracketed*; or none of these proved. Definition 22.1.

FZ, PZ, SZ, AGG Zero tests for functions, for functions of two points and for sequences of points, and aggregation of a sequence into one point. Definition 21.28.

$\mathrm{SE}_{\mathbb{Z}}$, DEP Strong extensionality for integer-valued maps: $P(x) \neq P(y)$ gives $x \# y$ for every map $P : \mathbb{R}_\delta \to \mathbb{Z}$; and the deformation-erasure principle, an integer pairing observable that tells the pair from the split. Definition 22.22; MP implies $\mathrm{SE}_{\mathbb{Z}}$, Theorem 22.24.

The cost and the ledger

$J(x)$, $G(t)$ The cost $J(x) = \frac{1}{2}(x + x^{-1}) - 1 = (x-1)^2/(2x)$ of a comparison at the ratio $x > 0$, and its logarithmic form $G(t) = \cosh t - 1$, with $J(e^t) = G(t)$. Definition 21.11; for a matrix ratio, Definition 27.1.

composition law, calibration A comparison cost C obeys the law when $C(s+t) + C(s-t) = 2C(s)C(t) + 2C(s) + 2C(t)$, and is calibrated when $C(0) = 0$ and for every k some j has $|C(t) - t^2/2| \leq t^2/(k+1)$ whenever $|t| \leq 1/(j+1)$. Definition 21.10; the two leave exactly $C = G$, Theorem 21.14.

log, cos, sin, π_δ, q The logarithm, the circle functions and π_δ on the line, Definitions 21.4 and 21.6. A quarter period is a point q with $0 \leq q \leq 2$ and $\cos q = 0$; there is exactly one, $q = \pi_\delta/2$, Theorem 21.8, and Chapter 25 writes periods as $4q$.

φ, $\mathbb{Z}[\varphi]$ The golden ratio $\varphi = (1 + \sqrt{5})/2$, with $\varphi^{-3} = \sqrt{5} - 2$, and the ring of formal sums $a + b\varphi$ with integers a, b and $\varphi^2 = \varphi + 1$, ordered by an integer sign test at no price. Definition 21.18, Lemma 21.19.

census, d, c, W_k, b_N A census counts a recognition's independent steps and closures; the join $(i, c) \mapsto (i + c, i)$ multiplies its golden value $c + i\varphi$ by φ. The words W_k in the debit and credit letters d, c define the recognition history, and b_N is the balance, debits minus credits, of its first N letters. Definition 21.24; Theorems 21.25 and 21.26.

rate A word w read over $t + 1$ ticks has the rate $\langle \mathrm{bal}(w); t + 1 \rangle$: balances are the integers $\mathbb{Z}_\delta$ and rates the ratios $\mathbb{Q}_\delta$, Theorem 21.27.

The forcing chain and three dimensions

T1–T4, C−2 to C41, P8, R2-01 to R2-35, S1–S15 The rows of Table 22.1: the first rung, the numbered sequence (Cn is the step Recognition Science numbers Tn there), its period bound, the second rung and the constants. Section 22.10.

S^D, native chain, $H_k(S^D \setminus K) = 0$ The native D-sphere of $\mathbb{R}_\delta^{D+1}$ with the sup distance; chains are finite lists of integer multiples of uniformly continuous simplices, equivalent under explicit moves; $H_k(S^D \setminus K) = 0$ says that every k-cycle bounds there, and no quotient group is formed. Definitions 23.1–23.4.

linked, data form An embedded circle is linked when some loop of its complement bounds no 2-chain there, Definition 23.5; this happens only in dimension 3, Theorem 23.8. The data form of $H_1(S^1) = \mathbb{Z}$ is an integer winding label on all 1-chains, Definition 23.39.

Ledgers, the light cone and the register

(D, C), t, x, τ The debit and credit counts of an account's record; its cone coordinates $t = D + C$ and $x = D - C$; and the proper time $\tau(w) = 2\sqrt{D(w)C(w)}$ of a posting word, a name for a function of two counts. Reading t, x and τ as time, position and clock time are identifications. Definition 24.1.

$R(t, x)$, Q, K, Λ_A The Hermitian matrix $R(t, x) = \frac{1}{2}(t\,1 + x_1\sigma_1 + x_2\sigma_2 + x_3\sigma_3)$ with coordinates (t, x); the Minkowski form $Q = t^2 - |x|^2$; the future cone K of the points with $t \geq 0$ and $Q \geq 0$ ($\mathscr{K}$ in Chapter 27); and the matrix, on coordinates, of the coherent change $\rho \mapsto A\rho A^\dagger$. A coherent record is a Hermitian matrix ρ with $v^\dagger \rho v \geq 0$ for every v, and $R(t, x)$ is one exactly when $(t, x) \in K$. Definition 24.13; the record cone and the Lorentz group, Theorems 24.14 and 24.15.

step cost, $c_W(w)$ The charge of G on each change of count, and the comparison cost of a leg w against the whole word W. Definitions 24.18 and 24.23.

channel, triad, B In Chapter 21 a channel is binary. In Chapters 24 and 30 a channel has eight states; Chapter 30 labels them $0, \ldots, 7$, read as three bits, and the low-bit partner of a label flips its last bit. There the triad $(i, j, 7)$ carries the generator B, and $e^{\theta B}$ rotates the triad by the angle θ about $e_i + e_j + e_7$. Definitions 21.35, 24.32 and 30.19.

token, word, drive, S_k, F_l A token carries a skew-Hermitian generator G_t, a word is a list of tokens, and its drive is $\sum_t \|G_t\|$ in units of $\hbar$ (Chapter 21 calls this sum the generator cost and $\hbar$ times it the drive action). On eight-state channels S_k signs a configuration

by the state of channel k, F_l flips the low bit of channel l, and the entangling token has generator $\frac{\pi}{4}\mathrm{i}S_kF_l$; on the binary channels of Chapter 21 it has generator $\frac{\pi}{4}\mathrm{i}X$, with X an involution that flips channel l up to a sign. Definitions 21.35, 24.32 and 30.19.

holding, paid word, drift, certain change A self-adjoint holding H acts while each token runs for a time ε; the paid word W is the product of the paid tokens, its drift is $|w|\varepsilon\|H\|$ (divided by $\hbar$ in Chapter 30), and it makes a certain change when $|\langle e_v, We_u\rangle| = 1$ for some $v \neq u$. Definitions 21.35 and 30.19.

parity pattern, item time The parity pattern $p(L) \in \{0,1\}^d$ of a ledger of d accounts, $p_k(L) = (D_k - C_k) \bmod 2$, of which a post flips one bit, Proposition 24.44; a process has a uniform item time when, from every tick, the shortest pass that contains every pattern has one and the same length, Definition 24.46.

tick register, S, $\mathscr{C}$ A real vector space with a linear map T, the tick. A recognizer whose state is a function on its eight patterns has $\mathbb{R}^8$, the functions on $\mathbb{Z}/8$, with the shift $(Sf)(t) = f(t+1)$, and its core $\mathscr{C}$ holds the states with $f(t+4) = -f(t)$. Section 24.11, before Theorem 24.49.

(R1)–(R5) The read premises of Definition 24.51: a read $\mu(f, A)$ of a state f on a set A of positions is one function φ of the amplitude at each position (R1), adds over positions (R2), vanishes at amplitude 0 (R3), grows with the magnitude (R4) and does not see the phase made of ticks (R5). Theorem 24.53.

additive charge, writing rule A map $Q : \{0,1\}^3 \to G$ into a commutative monoid with $Q(000) = 0$ and $Q(x \vee y) = Q(x) + Q(y)$ when x and y have no common 1, Proposition 24.45; and a rule that gives the increment $R(s,t,n) \in \mathbb{Z}^d$ of the balance vector when account s is compared with t n times, defined before Theorem 24.56.

Orbits

polynomial field, motion A field with polynomial components and ratio coefficients, with the formal Lie derivative $\mathscr{L}_pF$; a motion is a map with $p(x(s))$ as a uniform derivative on every bounded interval. Definitions 25.1 and 25.2.

(x, v, u, m), E, L, A A Kepler state: position, velocity, a coordinate u that carries $1/|x|$, and the gravitational parameter m; the energy, the angular momentum and the Laplace–Runge–Lenz vector. Definition 25.8.

window, U_c, A_t, D_m, r The orbit field $u' = w$, $w' = a - u + bu^2$ for ratios a and b; its window $a > 0$, $b \geq 0$ and $100ab \leq 1$, with $a \leq 2u_0 \leq 3a$ for the initial value u_0; the centre U_c and half-amplitude A_t of the inverse radius, with $U_c + A_t = u_0$; and the clock constants D_m and r, with $D_m^2(1 - 2bU_c) = 1$. Definition 25.31, Lemmas 25.33 and 25.34.

H, Z, λ, (θ, T, Φ) For a window orbit of the proper-time field: the energy H, $Z = -2H$, $\lambda = am = m^2/L^2$, and a radial period, after which the radial state returns and the polar angle has grown by Φ. Definition 25.38.

p, e The semi-latus rectum and the eccentricity, read off the two apsidal inverse radii: $p(u_0 + u_1) = 2$ and $e(u_0 + u_1) = u_0 - u_1$. Theorem 25.42.

Heat, the tick and the spine

$D(q \,\|\, p)$ The relative entropy $\sum_{q_i>0} q_i \log(q_i/p_i)$, Definition 26.9; on the line $D_\eta(q \,\|\, \ell)$, with levels ℓ_i for $p_i = e^{\ell_i}$, Definition 26.1.

s, π, P, $D_n(a)$ A voxel state in $\mathbb{Z}^3$, the T9 law $\pi(s) = \varphi^{-|s|_1}/\varphi^9$, a voxel tick, and $D(P^n(a,\cdot) \,\|\, \pi)$. Definition 26.19.

the tick, (T1)–(T5) Recognition Science's tick, the voxel tick with positive holds and hold-return balance, and five numerical properties of it, stated as inputs that the book does not prove and used only where named. Definition 26.20 and the list after it.

e_n, $r(P)$ The even-return excess $P^{2n}(0,0) - \pi(0)$ and the exact rate $\sup_n e_{n+1}/e_n$, the pace. Definition 26.34.

(R) The return-probability hypothesis about the output of a finite interval computation at ticks 800 and 802; not proved here, and used only where named. Section 26.6.

(B), (M) Ball dominance and the monotone mean of one voxel's walk from the empty record: after every tick n each cost ball keeps at least its equilibrium mass, $G_n(B_j) \geq \pi(B_j)$, and the mean imbalance cost never falls, $m_n \leq m_{n+1}$. Named and not proved; Proposition 26.44 uses them only where it says so. Section 26.6.

spine, TC A finite set of voxels started at the vacuum, and the total correlation of a joint law: its relative entropy against the product of its marginals. Section 26.6, Definition 26.40.

sign law A law in one quantity built from comparisons with ratio thresholds by "and" and "or"; its price is read off seven bits at each threshold, the seventh, F, telling whether the law is visibly refuted at the threshold itself. Definition 26.51.

Gravity

J_2, FP(h, K) For a strain h, a real symmetric 4×4 matrix, at a wave K: J's long-wave form $J_2(h) = \frac{1}{2}\operatorname{tr}(h^2)$, and the Fierz–Pauli form of linearized gravity. Definition 27.1.

Π_K, **TT** The transverse projector $1 - KK^{\mathsf{T}}/|K|^2$; h is transverse-traceless at K when $hK = 0$ and $\operatorname{tr} h = 0$. Definition 27.1; on TT strains $\mathrm{FP}(h, K) = |K|^2 \cdot 2J_2(h)$, Theorem 27.3.

C_β The completion with DeWitt's β; $\beta = -1$ is Fierz–Pauli. Definition 27.9.

g_κ, R_1, E, $R(\kappa)$ The background $1 - \kappa \mathbf{1}\mathbf{1}^{\mathsf{T}}$ of the Kuhn lattice (Definition 27.19); Regge's tables at $\kappa = 1$ and at the Euclidean background $\kappa = 0$ (Table 27.1); and the table $R(\kappa)$ for every $\kappa \notin \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$, whose plane-wave form has its only pole at $\kappa = \frac{1}{4}$ (Theorem 27.28).

β_{PN} The post-Newtonian parameter (not DeWitt's β), read from the second-order static field. For J's cost on the Euclidean Kuhn lattice, the second-order equation for the static field built from two harmonic modes has no solution, so β_{PN} does not exist there; reading that field as a static mass's is an identification. Theorem 27.24, proved in classical mathematics.

definite record, locality clause Records definite in one of five senses, Definition 27.38; and the clause that each post is fixed by its site's record and one partner's, Definition 27.43.

The library and learning

ordered field, derivative convention, MON Classical structures by content, with stored decisions and $0^{-1} = 0$; the derivative where one exists and 0 elsewhere; and monotonicity from a nonnegative pointwise derivative. Definitions 28.13 and 28.22, Section 28.7.

Π^0_2 **weak excluded middle, the shift** $\neg\Pi_M \vee \neg\neg\Pi_M$ for every double sequence of bits M, where Π_M says that every row has an entry 1; the shift asks it only when every row is not not inhabited. Definition 28.25; as sentences of HAS, Definition 28.31.

Gödel's T**,** val(t) Programs built by application from K, S, 0, Succ and the recursors at every finite type, and their values. Definition 28.47.

record frame, IPC, LC A preordered set of stages with forcing, and intuitionistic and Gödel–Dummett logic. Definitions 29.1 and 29.5.

learner, certain learner A rule that names an index of a prior at every finite record, identifying a world in the limit when it settles on a correct index; and one that may stay silent and announces only correct indices. Definition 29.23.

EX, BC, BC***,** BC^k**,** EX* Criteria for learners that name codes of partial computable functions: settling on one correct code, eventually only correct codes, and these up to finitely many or k errors. Definition 29.34.

place learner, D^j**,** $C_k(\mathbf{b})$ A learner that names a place of a catalogue W at every finite record, its changes of mind counted; the derived catalogues, D^0 every place and $i \in D^{j+1}$ when $i \in D^j$ and, for every N, some place of D^j holding a world other than W_i agrees with W_i below N; and the catalogues $C_k(\mathbf{b})$ built from nested sums of tests. Definitions 29.57 and 29.63.

Σ_2**-LEM,** Σ_2**-LPO** For every binary double sequence, some row is all 0 or none is; every row has an entry 1 or some row is all 0. One principle, Proposition 29.50; Definitions 29.26 and 29.49.

LPO$_T$ LPO for the binary worlds that programs of Gödel's T compute. Definition 29.43.

Appendix O

Selected solutions

Each heading gives the chapter, the question number and the result in the text that the question concerns. Within a chapter the solutions follow the order of those results in the text, so a solution may come before one with a smaller question number. The solutions show the decisive steps and point back to their hypotheses. Try the question before reading its solution; in particular, identify the object of an induction and the direction of each map yourself.

O.1 Distinction and rigidity

Chapter 1, question 1: Proposition 1.2

Separation says that an expression with outer constructor S cannot equal the expression with outer constructor 0. This uses the difference between the two constructor forms. Injectivity compares two expressions with the same outer constructor: if $S(a) = S(b)$, their enclosed expressions must be equal, so $a = b$. The two facts concern different comparisons. One excludes an equality across constructors; the other recovers an equality from within a constructor.

Chapter 1, question 2: Theorem 1.4

For $r(e(n)) = n$, induct on the natural number n. At a successor,

$$r(e(n+1)) = r(S(e(n))) = r(e(n)) + 1 = n + 1.$$

The final equality uses the induction hypothesis. For $e(r(a)) = a$, induct on the orbit expression a. Its step is

$$e(r(S(a))) = e(r(a) + 1) = S(e(r(a))) = S(a).$$

The variables over which the two conclusions quantify determine the objects of induction. Both start cases follow by unfolding the two definitions at zero.

Chapter 2, question 1: Theorem 2.3

For a competing structure-preserving map f, the induction hypothesis is $f(a) = R_M(a)$. At the step,

$$f(S(a)) = s(f(a)) = s(R_M(a)) = R_M(S(a)).$$

The first equality uses preservation of the target step; the second uses the induction hypothesis; the third is the defining equation of R_M. None of the three faithful-generation conditions is needed. This proves uniqueness of a reading into any pointed step system, including one whose step merges distinct inputs.

Chapter 2, question 3: Lemma 2.6

Apply target induction to

$$P(y) : \quad \exists a \in \mathbb{N}_\delta \, R_M(a) = y.$$

At the target start b, use the witness $a = 0$. If a witnesses $P(y)$, then $S(a)$ witnesses $P(s(y))$, because $R_M(S(a)) = s(R_M(a)) = s(y)$. Target generation makes this property hold at every target element. Step injectivity and separation from the start are not used in this surjectivity argument.

Chapter 2, question 5: Proposition 2.8

The step is injective: distinct orbit elements have distinct successors, and $s(*) = 0_\delta$ is the successor of no orbit element. The start is a step, since $s(*) = 0_\delta$, so the second condition fails. Target induction fails for the property $y \neq *$: it holds at 0_δ and is preserved by s, which never returns $*$, yet it fails at $*$. The reading is the inclusion of the orbit, injective but not surjective. This is the first assertion of Proposition 2.8, and it shows that Lemma 2.5 needs its two conditions only at reached elements.

O.2 Arithmetic and its extensions

Chapter 3, question 1: Theorem 3.3

Addition is defined recursively in its second argument. In the commutativity step, the definition and induction hypothesis give

$$a + S(b) = S(a + b) = S(b + a).$$

The required answer is $S(b) + a$. The earlier lemma for a step in the first argument gives $S(b) + a = S(b + a)$, so it supplies the final equality in the reverse direction. Without that lemma, the recursive definition alone does not rewrite the desired first argument.

Chapter 3, question 2: Proposition 3.4

Prove right cancellation by induction on the common addend c. At $c = 0$, the hypothesis $a + 0 = b + 0$ is $a = b$. At $c = S(d)$, the hypothesis becomes $S(a + d) = S(b + d)$. Step injectivity gives $a + d = b + d$, and the induction hypothesis gives $a = b$. Left cancellation then follows by commutativity. This proof stays entirely within the constructed expressions; it does not pass through the reading r.

Chapter 3, question 6: Corollary 3.12

Let σ exchange 1 and 2 and fix every other natural number, and put $\varphi = \sigma \circ r$. Define $a \oplus b = \varphi^{-1}(\varphi(a) + \varphi(b))$ and $a \otimes b = \varphi^{-1}(\varphi(a)\varphi(b))$. Every semiring law transfers along the bijection φ. The neutral elements are $\varphi^{-1}(0) = 0$ and $\varphi^{-1}(1) = S(S(0))$. Since $\varphi(1) = 2$, we get $1 \oplus 1 = \varphi^{-1}(4)$, the tally with four steps. The hypothesis $a \oplus u = S(a)$ fails already at $a = 0$: there $0 \oplus u = u = S(S(0))$, while $S(0)$ is the tally with one step. The start is kept; the step is not.

Chapter 4, question 1: Proposition 4.2

Given $a + d = c + b$ and $c + f = e + d$, rearrange additions to obtain

$$(a + f) + d = (a + d) + f = (c + b) + f = (c + f) + b = (e + d) + b = (e + b) + d.$$

Cancellation gives $a + f = e + b$, the desired balance. All terms remain in the nonnegative carrier. Truncated subtraction discards the part below zero and cannot be treated as an additive inverse. The balance equation retains both sides until cancellation is justified.

Chapter 4, question 3: Proposition 4.8

For ratio representatives $(u, d), (v, e), (w, f)$, the two supplied cross equalities are $ue = vd$ and $vf = we$. Their consequence is

$$(uf)e = (wd)e.$$

The middle denominator e is nonzero. After the faithful integer reading, nonzero integer cancellation yields $uf = wd$; faithfulness returns this equality to the constructed integers. This is the exact point where the denominator condition is used. Allowing a zero middle denominator would remove the cancellation step.

Chapter 4, question 5: Theorem 4.13

With $\iota'(n) = 2n$, an additive g on the integers with $g(\iota'(n)) = r(n)$ must satisfy $g(2) = r(1) = 1$. Additivity gives $g(2) = g(1) + g(1)$, so $2g(1) = 1$, which has no integer solution. The carrier is the ordinary integers; the failure comes from the map $n \mapsto 2n$.

O.3 Rules and logical resources

Chapter 5, question 1: Display (5.1)

The hole formula is $1 + S(0) = S(x_0)$. The two terms are $1 + 0$ and 1. Substituting the first produces $1 + S(0) = S(1 + 0)$, supplied by the successor clause for addition. The zero clause supplies $1 + 0 = 1$. Equality substitution then fills the hole with the second term, giving $1 + S(0) = S(1)$. No induction is used.

Chapter 5, question 2: Theorem 5.5

Universal introduction lifts the old context before introducing the new variable. The truth of those lifted hypotheses under an extended assignment depends only on the old assignment, not on its new first entry. That entry may therefore be any natural number. The premise derivation establishes the body at every such entry, which is the universal conclusion.

In existential elimination, a witness supplies the new entry and makes the existential body true. The lifted old hypotheses remain true. The conclusion in that premise is also lifted, so its truth does not depend on the witness entry. It therefore descends to the original assignment as the required conclusion.

Chapter 5, question 7: Theorem 5.8

Injectivity fails: $S(0) = 1 = S(1)$, while $0 \neq 1$. Every other base rule, induction included, holds in the Boolean structure, by the third case of Theorem 5.8. A derivation from no hypotheses that avoids injectivity would therefore make $\neg(S(S(0)) = S(0))$ true there. But $S(S(0))$ and $S(0)$ both have value 1, so the formula is false. With injectivity the derivation is short: assume $S(S(0)) = S(0)$, apply injectivity to obtain $S(0) = 0$, refute that by separation, and discharge the assumption.

Chapter 5, question 5: Section 5.7

The rule at $y = a$ reads $x + S(a) = S(x + a)$, and $S(a) = a$, so $x + a = S(x + a)$: the sum must be a fixed point of S, that is, a or b. With only the new element a, every sum $x + a$ would be a, so $0 + a = a$ and the law $\forall x(0 + x = x)$ would hold. The second fixed point b allows $0 + a = b \neq a$. The remaining checks are those listed in the text.

Chapter 5, question 6: Corollary 5.9

The zero clause gives $0 + 0 = 0$. The successor clause gives $0 + S(0) = S(0 + 0)$, and substitution turns it into $0 + S(0) = S(0)$. The successor clause again gives $0 + S(S(0)) = S(0 + S(0))$, and substitution gives $0 + S(S(0)) = S(S(0))$. No induction occurs. An induction-free derivation of $\forall x(0 + x = x)$ would make the formula true in W by Theorem 5.8, but $0 + a = b \neq a$ there.

Chapter 6, question 1: Definition 6.3

The EM instance directly concludes $(0 = 0) \vee \neg(0 = 0)$ and has ledger (true, false, false; false). In the other derivation, reflexivity gives $0 = 0$ with an empty ledger, and left disjunction introduction preserves that empty ledger. Thus the displayed EM use is avoidable for this conclusion. Looking only at that proof would establish what it used, not what every proof must use.

Chapter 6, question 3: Definition 6.3

The induction formula is $\varphi(x) = \forall y(y = y)$, independent of x. It contains a quantifier, so the induction rule contributes the fourth entry. The base, step and all other rules use no EM, LPO or MP. The ledger is therefore (false, false, false; true). It is posit-free and nonempty. The formula tested for the induction entry is φ, not merely the final universally quantified conclusion.

Chapter 6, question 5: Lemma 6.8

The left side $x \cdot x$ has coefficients $(0, 0, 1)$ and the right side $y + y$ has $(2y)$, so $B = 1 + 1 + 2y = 2y + 2$. For $y = 8$, $B = 18$, and the search over $n = 0, \ldots, 18$ finds $n = 4$. For $n \geq 18$ the digit lists $(0, 0, 1)$ and $(16, 0, 0)$ differ. The formula $\exists z\,(x = z + z)$ holds at every even x and fails at every odd x, so its truth value never settles. The lemma's proof described each side by finitely many coefficients; a quantifier hides the value of z, so no such description exists.

Chapter 6, question 6: Theorem 6.10

The EM rule at $\exists x\varphi$ gives $(\exists x\varphi) \vee \neg\exists x\varphi$. In the first case, introduce the left side of the LPO conclusion. In the second, assume φ at a fresh variable; existential introduction, with that variable as the witness, gives $\exists x\varphi$, which contradicts $\neg\exists x\varphi$. Discharging the assumption and generalizing gives $\forall x\neg\varphi$, the right side. Implication introduction then adds the premise of the LPO instance, which is never used. Existential introduction occurs only in the passage from $\neg\exists x\varphi$ to $\forall x\neg\varphi$. The ledger is (true, false, false; false).

Chapter 6, question 7: Theorem 6.10

The only inductions are those in the proof of (6.9): one on the quantified formula $\forall y(x = y \vee \neg(x = y))$, and two quantifier-free ones on y that split into the zero and successor cases. For the equation $x = 0$, let β be $x = 0 \vee \neg(x = 0)$ under a quantifier whose variable does not occur in it. Assuming $\neg\beta$ gives $\neg(x = 0)$, since $x = 0$ would give β; that in turn gives β, a contradiction. So $\neg\neg\beta$ holds, and with it $\neg\neg\exists z\,\beta$. The MP rule at the quantifier-free β gives $\exists z\,\beta$, and existential elimination returns β. The ledger is (false, false, true; false).

Chapter 6, question 8: Theorem 6.11

The two results concern different sets of derivations: the proposition permits no induction, and the theorem permits induction on every formula. A reduction without induction remains a reduction with it, so the positive reductions of the proposition persist; its separations need not. Induction on quantified formulas decides equality, as in (6.9), and derives every MP instance, by Theorem 6.9. Once the restricted rule costs nothing, the reduction of EM to LPO and MP becomes a reduction of EM to LPO, and the four strengths collapse to two: the MP rule falls to the level of no rule, and EM to the level of LPO. The same observation shows that induction fails in the two-stage model, since the formula $\forall x(x = 0 \vee \neg(x = 0))$, which induction proves, fails in that model. Induction on quantifier-free formulas already proves that formula, but it does not supply the collapse. In the model of Proposition 6.14 quantifier-free induction holds, yet $\forall x\forall y(x = y \vee \neg(x = y))$ and an MP instance fail. With only that induction, MP keeps a level of its own, and the four strengths remain.

O.4 Recognition and representation

Chapter 7, question 2: Theorem 7.6

Take the supplied collision $a \sim b$ with $a < b$. Its positive difference $b - a$ is already a period at a, so it bounds the search for the least positive period. Once that period p is selected, $a \sim a + p$ supplies an upper bound a for the search for the least index. Pairwise decidability decides each candidate relation in these two bounded searches. The collision is the finite witness that prevents either search from being an unbounded existence task.

Chapter 7, question 6: Display (7.5)

Suppose (x, y) and (x', y') are both first collisions. If $y' < y$, the related pair (x', y') violates the leastness of y; if $y < y'$, the reverse holds. So $y = y'$. If $x' < x$, then $x' \sim y$ violates the second leastness condition of (x, y); if $x < x'$, the reverse holds. So $x = x'$.

For $\sim_{i,p}$ the pair $(i, i + p)$ is related. Any related pair $x < y$ has $i \leq x$ and $x + p \leq y$, so no related pair has its larger element below $i + p$, and no $x' < i$ is related to $i + p$. Hence $(i, i + p)$ is the first collision, and the event of γ sits at $2(i + p) + (i \bmod 2)$. The position determines its half y, the larger element, and y determines the smaller element as the least count related to it. Only the parity of that element remains to be recorded.

Chapter 7, question 5: Theorem 7.9

If θ has no witness, the second alternative of (7.4) never applies, so $x \sim_\theta y$ gives $x = y$. If $\sim_\theta$ is equality and $\theta(n)$ held, then $n \sim_\theta n + 1$, since $n \leq \min(n, n + 1)$, and this would give $n = n + 1$. Hence no n satisfies θ.

In the forward direction, WLPO is applied to $\beta_\sim$. In its all-zero branch a related pair $x \sim y$ must be shown equal. Decide whether $x = y$. If $x \neq y$, then $x < y$ or $y < x$, and by symmetry the smaller count is related to the larger, so the search at $\max(x, y)$ succeeds: $\beta_\sim(\max(x, y)) = 1$. So only the answer $x = y$ remains. Equality and order of two counts are decided by comparing them, a finite procedure; no principle about an unbounded search is involved.

Chapter 7, question 4: Theorem 7.10

Define $x \sim_P y$ by $x = y \vee P$. Its equivalence and addition properties follow by cases on supplied proofs of these disjunctions; defining the relation does not require deciding P.

If the catalogue says this relation is equality, then P would give $0 \sim_P 1$, hence $0 = 1$, a contradiction. This branch supplies $\neg P$. If the catalogue supplies an index and positive period, it gives a related pair i and $i + p$. These are unequal, so their relation $i = i + p \vee P$ supplies P. The two catalogue branches therefore decide the original proposition.

Chapter 7, question 7: Theorem 7.12

Adding 2 to 0 and to 3 gives 2 and 5. Both are at least 2 and both leave remainder 2 modulo 3, so $0 + 2 \sim_{2,3} 3 + 2$. But 0 and 3 are different and $0 < 2$, so they are not related. The relation is not cancellative.

For $\sim_{0,3}$, relation (7.8) gives $[a, b] \approx [c, d]$ exactly when $(a + d) \bmod 3 = (c + b) \bmod 3$. Since $I([c, d]) - I([a, b]) = (c + b) - (a + d)$, this says that 3 divides the difference of the integer readings: $\approx$ is congruence modulo 3 of the readings $I(u)$ and $I(v)$.

Chapter 7, question 11: Proposition 7.43

Each $\{n\}$ is open and closed, so $\mathrm{Dec}(X)$ and $\mathrm{A}(X)$ have the value $\top$. An open set containing ∞ contains all but finitely many natural numbers, so the value of $\mathrm{Z}(X)$, the interior of $\{\infty\}$, is empty, and $\neg\mathrm{Z}(X)$ is the whole space. The value of $\mathrm{E}(X)$ is $\mathbb{N}$. The value of $\mathrm{Ev}(X)$ is the

interior of the complement of the even numbers, which is the set of odd numbers, and $\mathrm{Od}(X)$ has the value of the even numbers. So the instances of MP, LLPO and $\mathrm{MP}^{\vee}$ at A all have the value $\mathbb{N}$, which misses ∞.

At B, $\mathrm{Dec}(Y)$ has the value $\top$, since $\{n\}$ and $\emptyset$ are open and closed. The value of $\mathrm{E}(Y)$ is the set of even numbers; its closure adds ∞, and the interior of that closure is again the set of even numbers, because every neighbourhood of ∞ contains odd numbers. So $\neg\neg\mathrm{E}(Y)$ has the value of the even numbers. The value of $\exists n\,(n \in X \wedge \neg\, n \in Y)$ is the union of the sets $\{n\} \cap \neg B_n$, which is the set of odd numbers, and its double negation is the same set. The instance of $\mathrm{W}(X)$ at B therefore has the value $\mathbb{N}$. Hence the value of $\mathrm{W}(X)$ lies inside $\mathbb{N}$, the value of $\mathrm{E}(X)$, and the instance of WMP at A is $\top$: at this sequence the hypothesis of WMP already fails at ∞.

Chapter 7, question 12: Proposition 7.46

The values of $\mathrm{Dec}(X)$ and $\mathrm{A}(X)$ are $\top$. The residue classes R_0, R_1, R_2 modulo 3 divide $\mathbb{N}$ into three disjoint sets, so each of the ultrafilters $U_{2,0}$ and $U_{2,1}$ contains exactly one of them. Some class R_i therefore belongs to neither, and its complement belongs to both, hence to F_2. The set $\{\infty\} \cup (\mathbb{N} \setminus R_i)$ is then open, contains ∞, and misses every $A_{3j+i} = \{3j + i\}$, so it lies in the value of $\mathrm{C}^3_i(X)$.

Which i it is depends on the two ultrafilters, and their construction does not say: $U_{2,0}$ contains the even numbers, which meet all three classes, and the ultrafilter chooses among them. That is no obstacle. The value of LLPO_3 is computed in classical mathematics, where it is enough that some i works at each point; the model is an outside witness that $\mathrm{LLPO}_3 \to \mathrm{LLPO}$ has no derivation, not a procedure for naming the class.

Chapter 7, question 13: Proposition 7.48

The open sets of the cone are $\emptyset$, $\{a\}$, $\{b\}$, $\{a, b\}$ and the whole space. So $\neg\{a\} = \{b\}$ and $\neg\{b\} = \{a\}$. For $n = 0$, $A_0 \cup \neg A_0 = \{a, b\}$; for $n \geq 1$, $A_n \cup \neg A_n$ is the whole space. The value of $\mathrm{Dec}(X)$ is $\{a, b\}$, that of $\mathrm{E}(X)$ is $\{a\}$, and that of $\mathrm{Z}(X)$ is $\neg A_0 = \{b\}$. The instance of LPO is $\{a, b\} \Rightarrow \{a, b\} = \top$. The instance of WEM is $\neg A_0 \cup \neg\neg A_0 = \{b\} \cup \{a\}$, which misses c.

At the focal point the set is not decidable, so LPO says nothing about it there; LPO only decides sets that are decidable. WEM speaks about every proposition, decidable or not, and it is exactly at such a point that it fails.

Chapter 8, question 1: Theorem 8.4

In the list induction step, the head of a nonempty list must be the one available mark. It is therefore the same head that expansion places in front of the recursively expanded tail. The induction hypothesis identifies the tails, completing the round trip.

If two lists have equal lengths, expanding that equality and using the round trip identifies the lists. This injectivity is used to reflect equality in the term and formula interpretation. With more than one possible mark, length would discard the head's identity, and that argument would fail.

Chapter 8, question 5: Theorem 8.8

For $x = n > 0$ and $y = a$: $S(a) = a$, so $n \cdot S(a) = n \cdot a = b$, since neither factor is 0 and one of them is a; and $n \cdot a + n = b + n = b$. For $x = y = a$: $a \cdot S(a) = a \cdot a = b$, and $a \cdot a + a = b + a = b$, because $x + a = b$ for every x.

Each numeral instance $\neg(S(S^n(0)) = S^n(0))$ is a quantifier-free sentence true in $\mathbb{N}$, so it holds in W by the first conclusion of Theorem 8.8. The universal sentence ranges over all of W, including a, where $S(a) = a$. The instances speak only about numerals, and the numerals miss a.

Chapter 8, question 6: Theorem 8.8

Every equation holds in the one-element carrier, so injectivity of the step and the four recursion equations hold. Separation fails, because the only element is zero and is also its own successor. Then $\nu(0) = \nu(1)$, so ν is not injective, and the first conclusion of the theorem fails: the quantifier-free sentence $S(0) = 0$ is true in the carrier and false in $\mathbb{N}$.

Chapter 8, question 7: Theorem 8.11

Assume $S(t) = S(u)$ as a hypothesis, apply the injectivity rule to obtain $t = u$, and discharge the hypothesis by implication introduction. No additional principle or induction occurs, so the ledger is empty. In the other direction, a use of the injectivity rule on a derivation of $S(t) = S(u)$ becomes implication elimination, applied to the axiom $S(t) = S(u) \to t = u$ and to the translated derivation of $S(t) = S(u)$.

Chapter 8, question 8: Theorem 8.11

Take the usual derivation: the base $0 + 0 = 0$ is the axiom $t + 0 = t$; the step assumes $0 + x = x$, uses the axiom $0 + S(x) = S(0 + x)$ and equality substitution, discharges the assumption and generalizes; induction on $0 + x = x$ concludes. It uses no excluded middle, and its only induction formula is quantifier-free. By the final clause of Theorem 8.11, the EM and induction entries of its translation are false, and the LPO and MP entries are false for every translation. The ledger is empty. The translation is the derivation (5.5) of Chapter 5, whose empty ledger Chapter 6 records: its conclusion contains a quantifier, but its induction formula does not.

Chapter 8, question 4: Theorem 8.13

The quotient relation is $x \sim y$ exactly when $r(x) = r(y)$. Consequently $[x] \mapsto r(x)$ is independent of the representative. If two outputs agree, the same kernel definition identifies their classes, proving injectivity. An element of the range is, by its definition, some $r(x)$; its preimage is $[x]$. A value in a larger ambient target need not have such an x, so that larger surjectivity does not follow.

O.5 Iteration and effective description

Chapter 9, question 2: Theorem 9.2

The recursor's step for predecessor is $g = \lambda x.\lambda y.x$. After applying the successor equation, the two function evaluations are

$$\mathrm{pred}(S(x)) = g(x, R(O, 0, g, x)) = (\lambda y.x)(R(O, 0, g, x)) = x.$$

The first argument of g is the preceding orbit point x. The second, which the function ignores, is the preceding recursive value. An ordinary iterator step receives only that second kind of input; the indexed recursor supplies the position explicitly.

Chapter 9, question 3: Theorem 9.6

Write a point of the two-chain model as (i, n), with start $(0, 0)$ and successor $(i, n + 1)$. The maps are $c(i, n) = (0, n)$ and $q(i, n) = (i, n)$. Both send the start to itself. For c,

$$c(S(i, n)) = (0, n + 1) = S(c(i, n));$$

for q, step preservation is immediate from its identity definition. At $(1, 0)$ their values are $(0, 0)$ and $(1, 0)$, so they differ. The recursive equations do not force equality on the chain that the designated start never reaches.

Chapter 10, question 1: Theorem 10.3

Let L be the length of the supplied tally x. Its own-budget representative belongs to F_L. Define the global output using that representative and the map for F_L.

If the same tally is supplied as an element of F_n, then $L \leq n$. Use the inclusion $F_L \hookrightarrow F_n$. Compatibility says that applying the map at F_n after this inclusion gives the same output as the map at F_L. This proves agreement with every permitted presentation. The own-budget construction gives the output; the compatibility equation proves its independence from a larger budget.

Chapter 10, question 4: Definition 10.10

The program can witness the finite-prefix assertion for requests below N, provided the supplied endpoint pairs form the required prefix. A uniform name has to halt and return the correct endpoints of one valid protocol at every request. Printing zeros afterward supplies termination, but does not by itself establish those endpoint conditions. A correct finite prefix leaves the infinitely many remaining requests as a separate obligation.

O.6 Enclosures and exact comparison

Chapter 11, question 1: Display (11.1)

If $a \leq b$, nesting gives $\ell_a \leq \ell_b \leq u_b$. If $b \leq a$, it gives $\ell_a \leq u_a \leq u_b$. Both prove $\ell_a \leq u_b$. Choosing $k = \max(a, b)$ combines the two arguments as $\ell_a \leq \ell_k \leq u_k \leq u_b$.

Chapter 11, question 2: Theorem 11.5

Overlap bounds the gap between one protocol's endpoint and the other protocol's corresponding interval. Adding the two width estimates then bounds the absolute difference of the displayed values by $2/(n+1)$. To apply the reciprocal-squeeze lemma in its stated form, request $n = 2m+1$. Then $2/(n+1) = 1/(m+1)$ for every m, so the displayed values agree. Overlap supplies the comparison; shrinking widths force its gap to vanish.

Chapter 12, question 2: Lemma 12.5

Each jump stage inspects only its own finite prefix. Either it finds a first event within that prefix or it does not; both results are decidable by finite search. This defines every stage without a decision about the whole sequence.

When a particular first event N has been supplied, 2^{N+1} is an explicitly constructed later stage. It exposes the nonzero jump at a precision fine enough for the contradiction in Lemma 12.5. The supplied N determines the later stage by a finite calculation.

Chapter 12, question 3: Theorem 12.6

For the zero test, WLPO decides whether every comparison test in the relevant binary sequence vanishes. That is enough to decide equality to zero as a proposition: zero or not zero. In the reverse direction, applying the proposed zero test to the jump construction decides whether the original binary sequence is all zero.

For trichotomy, the nonzero alternative must provide a strict sign. The proof uses LPO to obtain an actual event in the comparison sequence, hence a finite strict-separation witness. WLPO's negative answer to "all zero" does not by itself display that event. This is the additional step needed for the stronger comparison. Proposition 12.13 isolates that step. It is the implication $\neg Z(x) \to P(x) \vee N(x)$, and by Theorem 12.11 its exact price is $\mathrm{MP}_{\mathrm{bin}}$. Together with Theorem 12.6 this recovers $\mathrm{LPO} \iff \mathrm{WLPO} \wedge \mathrm{MP}_{\mathrm{bin}}$.

Chapter 12, question 5: Lemma 12.10

Assume $\neg P(x)$ and $\neg N(x)$, and fix n. The comparison $|q_n|(n+1) \le 2 \cdot 2^n$ is decidable, so it suffices to refute its failure. Suppose $2 \cdot 2^n < |q_n|(n+1)$. The sign of the integer q_n is decidable. If $q_n \ge 0$, then $|q_n| = q_n$ and n is a positive witness. If $q_n < 0$, then $|q_n| = -q_n$, so $q_n(n+1) < -2 \cdot 2^n$ and n is a negative witness. Either contradicts a hypothesis, so the bound holds at n. Decidability is used only at the single stage n: once for the zero bound and once for the sign of q_n. The proof never decides $P(x)$; it only refutes a witness at the stage under consideration, which is what the hypothesis $\neg P(x)$ provides, and no search is made.

Chapter 12, question 6: Corollary 12.12

Let x' have numerators $-q_n$. Condition (12.1) involves $|q_m 2^n - q_n 2^m|$, which negating both numerators leaves unchanged. A negative witness for x is a positive witness for x', and $x'' = x$. So stability of N for every presentation is stability of P for every presentation, and Corollary 12.12 for P gives it for N.

Chapter 12, question 7: Theorem 12.45

If $t_n = \eta(1)$, an event occurs at some $k \le n$, and the same event gives $t_{n+1} = \eta(1)$. If $t_n = \eta(0)$, then $t_n \le t_{n+1}$ because $\eta(0) \le \eta(0)$ and $\eta(0) \le \eta(1)$. Every term lies between $\eta(0)$ and $\eta(1)$, so the sequence is bounded. The limit L and the index N come from existential statements, and they are used inside a proof of one proposition: LPO's alternative for the given α. Using a witness of an existential statement to prove a proposition is ordinary existential elimination. No infinite family of selections is assembled into a sequence, and the test sequence itself is defined by bounded searches, not selected.

Chapter 12, question 8: Theorem 12.48

Cotransitivity applied to $\eta(0) < \eta(1)$ places L strictly above $\eta(0)$ or strictly below $\eta(1)$. Each case excludes one alternative of WLPO, and neither requires knowing which of $\eta(0)$ and $\eta(1)$ the point L equals. In the case $\eta(0) < L$ the argument gives only that the bits are not all zero. If every ratio below L is exceeded by a term, apply this at the ratio 0: some b_n exceeds $\eta(0)$. Then $b_n = \eta(1)$, since $b_n = \eta(0)$ would give $\eta(0) < \eta(0)$, and so $\alpha(n) = 1$. The case $L < \eta(1)$ still gives that every bit is zero, so the two cases give LPO. This is the first part of Theorem 12.49.

O.7 Compactness, algebra and computation

Chapter 13, question 1: Theorem 13.3

Let $D(s) = 1$ exactly when $|s| = 1$. Every binary sequence p has $\bar{p}(1)$ in D, so D is a decidable bar. Its complement contains the string 00 but not its initial segment 0, so the complement is not a tree. No string of length at least 1 is unseen, so the tree A of unseen strings is $\{\varnothing\}$, and it has no member of length 1. In general, suppose A has no member of length N, and let p be a binary sequence. Then $\bar{p}(N)$ is seen: some $n \le N$ has $D(\bar{p}(N)\restriction n) = 1$. Since $\bar{p}(N)\restriction n = \bar{p}(n)$, the sequence p meets D at a length at most N. The detour through A is needed because the tree form speaks only of trees. The seen strings are closed under extension, so their complement is closed under initial segments; the complement of D itself need not be.

Chapter 13, question 3: Theorem 13.6

A string of length m with numeral v is caught when some $k < m$ has $a_k < (v-1)/2^m$ and $(v+2)/2^m < b_k$. At $m = 0$ nothing is caught, since there is no $k < 0$. At $m = 1$ only $I_0 = (-1, \frac{1}{2})$ may be used, and the widened pieces $[-\frac{1}{2}, 1]$ and $[0, \frac{3}{2}]$ do not lie inside it. At $m = 2$ the intervals I_0 and $I_1 = (\frac{1}{4}, \frac{3}{4})$ may be used, and the widened pieces are $[(v-1)/4, (v+2)/4]$ for $v \le 3$. Their right ends $\frac{1}{2}, \frac{3}{4}, 1, \frac{5}{4}$ are never below $\frac{1}{2}$, which rules out I_0; for I_1 the left end must exceed $\frac{1}{4}$, which needs $v = 3$, and then the right end $\frac{5}{4}$ exceeds $\frac{3}{4}$. So nothing is caught. At $m = 3$ the intervals I_0, I_1 and $I_2 = (\frac{1}{2}, 2)$ may be used, and the widened pieces are $[(v-1)/8, (v+2)/8]$. The interval I_0 catches the pieces with $v + 2 < 4$, that is $v \le 1$. The interval I_1 would need $v - 1 > 2$ and $v + 2 < 6$, which no v satisfies. The interval I_2 catches the pieces with $v - 1 > 4$, that is $v \ge 6$. So

$$H = \{\varnothing,\ 0,\ 1,\ 00,\ 01,\ 10,\ 11,\ 010,\ 011,\ 100,\ 101\},$$

the members of length 3 being the pieces with $v = 2, 3, 4, 5$. At $m = 4$ every one of the sixteen pieces is caught, as the opening computes, so no string of length 4 lies in H.

Each piece of length 4 is caught by exactly one of I_0, I_1 and I_2: I_0 for $v \leq 5$, I_1 for $6 \leq v \leq 9$ and I_2 for $v \geq 10$. At the borders, $v = 5$ misses I_1 because its left end $\frac{4}{16}$ is not above $\frac{1}{4}$; $v = 6$ misses I_0 because its right end $\frac{8}{16}$ is not below $\frac{1}{2}$; $v = 9$ misses I_2 because its left end $\frac{8}{16}$ is not above $\frac{1}{2}$; and $v = 10$ misses I_1 because its right end $\frac{12}{16}$ is not below $\frac{3}{4}$. The proof yields the first $N = 4$ intervals; since every catching index is below 3, the first three intervals already cover $[0, 1]$.

Chapter 13, question 2: Theorem 13.7

Every binary sequence leaves T, so T cannot be infinite: weak König's lemma would give a path through it, a sequence that never leaves it. So it is false that T has a member of every length. Whether T has no member of length n is decided by inspecting 2^n strings, so what we know is $\neg\neg\exists n\, Q(n)$ for a decidable property Q. Searching $n = 0, 1, 2, \ldots$ for an empty level would stop only if $\exists n\, Q(n)$ held. Passing from the double negation to the existence statement is Markov's principle for Q: knowing that the search cannot run forever does not show that it stops.

The padded tree avoids the passage. It is infinite outright, with no case distinction on T, so weak König's lemma applies to it and gives a path p. The hypothesis on T, applied to the binary sequence p, gives an n with $\bar{p}(n) \notin T$. This existence statement is supplied by the hypothesis, not by a search. Membership of $\bar{p}(n)$ in the padded tree at $k = n$ then leaves only the second alternative: T has no member of length n.

Chapter 13, question 4: Theorem 13.18

Let D be a decidable bar and p a binary sequence. Each test $D(\bar{p}(n)) = 1$ is decided, and the bar asserts that some n passes. A search through $n = 0, 1, 2, \ldots$ therefore stops, at the least passing n, and the stopping point is unique. The search reads only $p(0), \ldots, p(h(p) - 1)$, which is the continuity of the first hit used in Theorem 13.15. Collecting these values into a map is the step at which that theorem names unique choice.

A last exit n of p requires $D(\bar{p}(m)) = 1$ for every $m \geq n$. No finite inspection of $D(\bar{p}(0)), \ldots, D(\bar{p}(M))$ establishes this, since a later value 0 can always follow. When the c-set of D is a bar there is an N with $\bar{p}(N)$ in the c-set, but membership in the c-set, $D(\bar{p}(N)t) = 1$ for every string t, is again a statement about all extensions, so a search cannot recognize such an N. That is why Lemma 13.17 proves only that exactly one last exit exists. Under FAN_c one number N serves for all sequences: every p has $\bar{p}(n)$ in the c-set for some $n \leq N$, so $D(\bar{p}(m)) = 1$ for every $m \geq N$. The last exit is then one more than the last $m < N$ with $D(\bar{p}(m)) = 0$, or 0 if there is none, found by inspecting N values. This is the map L in the proof of Theorem 13.18.

Chapter 13, question 5: Theorem 13.29

Fix the point a of the proof of Theorem 12.60 and one regular sequence naming its clamp c. The conclusion drawn from a is a proposition, so one name serves. The function $h(x) = \max\big(\min(c, x - \frac{2}{3}), \min(-c, \frac{1}{3} - x)\big)$ is built from x by translations, negations, maxima and minima. Each operation has an explicit formula on regular sequences, so a name of $-h(x)$ is computed from a name of x and the fixed name of c; this is the transformer. By Lemma 12.52, item 5, points within $1/(k+1)$ have values of h, and hence of $-h$, within $1/(k+1)$, so $\mu(k) = k$ is a modulus. With the presentation of $[0,1]$ by dyadic grids, $-h$ is a presented uniform map on a presented set. Theorem 13.29 therefore constructs its infimum with no choice principle and no omniscience principle.

Suppose the theorem were strengthened to supply, for every presented uniform map on an inhabited presented set, a member at which the infimum is attained. Applied to $-h$ it gives x in $[0,1]$ with $-h(x) \le -h(y)$, that is $h(y) \le h(x)$, for every y in $[0,1]$. Then x is a maximum point of h, and the first part of the proof of Theorem 12.60 gives $a \ge \eta(0)$ or $a \le \eta(0)$. Since a is arbitrary, this is LLPO by Corollary 12.18. The infimum costs nothing; a point that attains it costs at least LLPO.

Chapter 14, question 1: Definition 14.1

A basis selection of the single vector (x) is one bit b_0, and a bit is decided. If $b_0 = 0$, nothing is selected, and spanning says that (x) is the empty combination; so $x = 0$. If $b_0 = 1$, independence applies to the combination with coefficient 1: were $x = 0$, it would vanish and give $1 = 0$. So $x \neq 0$; this is the first statement of Lemma 14.11. Spanning gives the first alternative and independence the second, and together they give $x = 0 \vee x \neq 0$ for every point, which is WLPO by Corollary 12.18.

Chapter 14, question 2: Lemma 14.8

Taking absolute values in $|x|\,c = x$ gives $|x|\,|c| = \big||x|c\big| = |x| = |x| \cdot 1$, using $|uv| = |u|\,|v|$ and $\big||x|\big| = |x|$. Since $x \neq 0$, also $|x| \neq 0$, and Lemma 14.4 cancels $|x|$: $|c| = 1$.

The proof of Lemma 14.8 uses only that c is a point. Cotransitivity of $-1 < 1$ at c gives $-1 < c$ or $c < 1$. In the first case a negative x would be invertible and force $c = -1$, so $x \ge 0$; in the second a positive x would force $c = 1$, so $x \le 0$. No bound on c is given in advance and none is used, and the lemma does not need $x \neq 0$. The bound $|c| = 1$ is a consequence when $x \neq 0$; it is what makes c apart from 0 in Lemma 14.9.

Chapter 14, question 3: Theorem 14.16

Write $y = g(j/2^n)$. The statement $\neg(y \le 0)$ is $\neg\neg(y > 0)$. If $y < 0$, then $y > 0$ is impossible, since $0 < y < 0$ would give $0 < 0$; so $\neg(y > 0)$, which contradicts $\neg\neg(y > 0)$. Hence $\neg(y < 0)$, that is $y \ge 0$.

The relation of the proof says: $\beta = 1$ and $y \le 0$, or $\beta = 0$ and $\neg(y \le 0)$. The two conditions exclude each other, so at most one bit satisfies it, and WLPO, through the third row of Table 12.2, gives one. So exactly one bit satisfies it, and unique choice applies. The bits in the proof of

Theorem 12.54 only promise $y \le 0$ when $\beta = 1$ and $y \ge 0$ when $\beta = 0$. When $y = 0$ both promises hold, so both bits are correct and the relation need not have exactly one witness; that proof therefore collects its bits with countable choice.

Chapter 14, question 4: Definition 14.23

Suppose $a \le bl$ and $br \le a$. Then $br \le bl$. Here $b \ge 0$, because $0 \le a \le b$, and $b \ne 0$, so Lemma 14.5 gives $r \le l$, contrary to $l < r$. So $a \le bl$ and $br \le a$ cannot both hold.

With a single midpoint m in place of $l < r$ there is no contradiction to reach: $a \le bm$ and $bm \le a$ together say only that $bm = a$, and $a = bm$ makes both hold. To name a side at one point one has to compare a with bm, which is the comparison of the fourth row of Table 12.2, priced LLPO. Two different points leave room. Because positivity belongs to the point, a search through stages for a witness of $a > bl$ stays silent exactly when $a \le bl$, and one for $br > a$ exactly when $br \le a$; so the two searches cannot both stay silent. This is what $\mathrm{MP}^{\vee}_{\mathrm{seq}}$ turns into a bit in Theorem 14.28.

Chapter 15, question 1: Proposition 15.4

A sum requested at precision n asks both summands for precision $n + 2$. Induction on h: if the inner sums of depth $h - 1$ ask their leaves for $(n + 2) + 2(h - 1)$, the leaves of a sum of depth h are asked for $n + 2h$. The protocol sum of Chapter 11 turns a request n into $2n + 1$, and h nestings turn it into $2^h(n+1)-1$, again by induction, since $2\big(2^{h-1}(n+1)-1\big)+1 = 2^h(n+1)-1$. The first is linear in h, the second exponential. The difference comes from the modulus: with 2^{-n} two errors of size $2^{-(n+2)}$ and a rounding of $2^{-(n+1)}$ fit into 2^{-n}, whereas with $1/(n + 1)$ halving an error requires doubling the index.

Chapter 15, question 3: Theorem 15.11

Forty bits within 2^{-40} require $2^{40} \le 120K^4$, that is $K^4 \ge 2^{40}/120 \approx 9.16 \cdot 10^9$. Since $309^4 = 9116621361$ is smaller and $310^4 = 9235210000$ is larger, at least 310 steps are needed. The Taylor solver uses 32 steps for the oscillator at every precision, of order 61 at 40 bits. The two equations differ, but both are linear, and the mechanism is visible in the proofs: one step of a fixed-order method has an error of fixed order in the step, $h^5/120$ here, so the error over $[0, 1]$ decreases only like K^{-4}; the Taylor step has truncation error $M2^{-N}$ (Lemma 15.16(b)), which the solver drives down by raising the order N with the precision instead of shrinking the step.

Chapter 15, question 2: Definition 15.18

The field has $d = 1$, $c = 0$, no A-terms and the single B-term $(-1, 0, 0)$, so $B(u, v) = -u_0 v_0$. Definition 15.24 gives $\gamma = 0$, $\alpha = 0$ and $\beta = \lceil |-1| \rceil = 1$. With $M = 1$, $R = 0 + 0 + 1 \cdot 1 + 1 = 2$, so $\sigma = \mathrm{bl}(8) + 1 = 5$ and $S = 1 \cdot 2^5 = 32$. Then $G = \lfloor 40^{32}/2^{160} \rfloor + 1 = \lfloor (5/4)^{32} \rfloor + 1 = 1263$, and $1 + 2S(M + 2) = 193$, so $\kappa = \mathrm{bl}(1263 \cdot 193) + 2 = \mathrm{bl}(243759) + 2 = 18 + 2 = 20$, because $2^{17} \le 243759 < 2^{18}$. These are the same σ, S and G as for the oscillator, since both fields have $R = 2$; only $M + 2$ differs. The region certificate at level 0 asks that the 33 numbers $y_0^{(0)}, \dots, y_{32}^{(0)}$, computed with Taylor order and working precision 20, all have absolute value at

most $1 - 2^{-2} = 3/4$. That is a finite computation with dyadic numbers; whether it succeeds is decided by carrying it out. The classical solution $1/(2+t)$ stays between $1/3$ and $1/2$, so if the certificate holds, Theorem 15.29 identifies the certified point with $1/3$.

Chapter 15, question 4: Theorem 15.23

As a coefficient field the oscillator has $d = 2$, $c = 0$, the A-term $(1, 1)$ for coordinate 0 and $(-1, 0)$ for coordinate 1, and no B-terms. So $c_A = 2 \cdot 2 = 4$ and $c_B = 0$, and the bounds are $\gamma = 0$, $\alpha = 1$ and $\beta = 0$, as in the text. Then $2\,\mathrm{step}(N) = 2N(4 + 12) + 4 + 2N(N + 1)$, that is $\mathrm{step}(N) = 16N + 2 + N(N + 1)$. At $m = 40$ with $n_0 = 0$ and $\kappa = 21$, $N = 61$, so $\mathrm{step}(61) = 976 + 2 + 3782 = 4760$ and $\mathrm{cost}(40) = 1 + 2 + 32 \cdot 4760 = 152323$. The bound of Proposition 15.25 is $(32 \cdot (4 + 0 + 16) + 3) \cdot 62^2 = 643 \cdot 3844 = 2471692$, about sixteen times larger. The gap comes from replacing $\mathrm{step}(N)$ by $(c_A + c_B + 8d)(N + 1)^2$; both grow like m^2.

Chapter 15, question 5: Definition 15.27

Here $d = 1$ and p has the single term $(1, (3))$, so $D = 3$. The variables are $w_0 = 1$, $w_1 = x$, $w_2 = x^2$ and $w_3 = x^3$, which is $(D + 1)^1 = 4$ variables, as Theorem 15.28(a) allows. For w_a with $a > 0$ the only term is $(a \cdot 1,\ a - 1,\ 3)$, so

$$w_0' = 0, \qquad w_1' = w_0 w_3, \qquad w_2' = 2 w_1 w_3, \qquad w_3' = 3 w_2 w_3,$$

with initial values $(1, x_0, x_0^2, x_0^3)$. For x^3 the identity reads $(x^3)' = 3x^2\ p(x) = 3x^2 \cdot x^3$, which is $3 w_2 w_3$ at the monomial vector. The field has $c_B = 3 \cdot 3 = 9 \le 3 d_Q t_p = 12$.

Chapter 16, question 1: Lemma 16.5

In the context Ω take the formula $\neg \in (\mathrm{map}(\mathrm{id}))$, which says "not p" of the truth value p. With only the first half of the earlier clause, the earlier object $(\mathrm{false}, \mathrm{true})$ of Ω satisfies it: the atom fails there at the earlier stage, so the implication to $\bot$ holds vacuously. The passage sends this object to the proposition true, at which the formula fails at the later stage. So the reading is no longer a predicate. In the proof of the lemma, the case of an implication used exactly the second half of the earlier clause, which is the later clause at $h(g)$; without it that case has nothing to appeal to.

Chapter 16, question 2: Theorem 16.14

A closed term of type $\mathbb{N}$ is a numeral, an application $t\,u$, or another term, and each term has exactly one of these forms. Put $V(\bar{n}) = n$; for an application $t\,\bar{n}$ to a numeral put $V(t\,\bar{n}) = J(t)(n)$; and give every other closed term of type $\mathbb{N}$ the value 0. Let $J(t)$ be the function carried by t when that function is computable, and the zero function otherwise. Then $J(t)$ is always computable, and conditions (1) and (2) hold by construction. Condition (3) fails at the instance $h_r\,\bar{n} = \overline{r(n)}$ for every n with $r(n) = 1$: the left side has the value $J(h_r)(n) = 0$, because r is not computable, and the right side the value 1.

Chapter 16, question 4: Proposition 16.21

Suppose a tracked map $F : \Omega^{\mathbb{N}} \to \mathbb{N}^{\mathbb{N}}$ sent every classifier to its 0–1 function. The map $p \mapsto (n \mapsto p)$ from Ω to $\Omega^{\mathbb{N}}$ is tracked: the program that returns the program 0 on every input names every later object of $\Omega^{\mathbb{N}}$. Evaluation at the number 0 is tracked. Composing the three gives a tracked map $\Omega \to \mathbb{N}$ that sends the true proposition to 1 and the false one to 0, which part (c) of the proposition forbids. The proof of Theorem 16.27 meets the same obstacle: comprehension gives, for every binary matrix, the classifier "row i vanishes", and $\mathsf{WLPO}_{\mathsf{seq}}$ asks for its 0–1 function as a named sequence.

Chapter 16, question 3: Theorem 16.22

Let A and B be sentences. From a derivation of $A \vdash B$, cut $\top \wedge A \vdash A$, obtained by conjunction elimination from construction (2), with it to get $\top \wedge A \vdash B$, and apply implication introduction: $\top \vdash A \to B$. Conversely, from $\top \vdash A \to B$, cut $A \vdash \top$ with it to get $A \vdash A \to B$, and apply implication elimination with $A \vdash A$: $A \vdash B$. Only constructions common to both calculi are used, and no term or map appears, so the argument is the same in the computable calculus.

Chapter 16, question 5: Theorem 16.32

The path p is computable, since g is a finite string. By Lemma 16.29(d) it leaves T_K. The proof of that part gives a program e with $\{e\}(x) = p(e)$ for every x, halting on input 0 within some k steps, and shows that $\bar{p}(k + e + 1) \notin T_K$. So the first initial segment of p outside T_K has length at most $k + e + 1$; it exceeds N, since every initial segment of length at most N lies in T_K. The bound depends on the program e that the recursion theorem gives for this p, and so on N through p; the proof of the theorem shows that no single bound serves all computable sequences.

O.8 Records and physical construction

Chapter 17, question 1: Lemma 17.2

The collision lemma assumes one fixed reader whose entire input is the record $r(w)$. If it also receives a control setting $c(w)$, equal values of r no longer imply equal inputs to that reader. The complete record must include the setting, for example as the pair $(r(w), c(w))$. The capacity theorem then applies to this enlarged record space. A setting that carries target information cannot be omitted from the count.

Chapter 17, question 4: Lemma 17.8

For worlds with a common record, let y be the reader's common answer. The two accuracy bounds give $d(f(w), y) \le \varepsilon$ and $d(f(w'), y) \le \varepsilon$. Symmetry reverses the second distance. The triangle inequality then gives

$$d(f(w), f(w')) \le d(f(w), y) + d(y, f(w')) \le 2\varepsilon.$$

A selected family with pairwise distance strictly greater than 2ε therefore cannot contain a record collision. The non-strict bound just proved would not contradict a distance equal to 2ε; the strict margin is necessary for this particular argument.

Chapter 17, question 6: Theorem 17.15

The question Q says that $\alpha(m) = \alpha(n) = 1$ for some $m < n$. If $Q(\alpha)$ holds with witnesses $m < n$, every run that agrees with α up to $n + 1$ satisfies Q, so Q is open and confirmable by Theorem 17.13. It is not closed: the run of zeros fails Q, and its record of length n is also the record of the run with entries 1 at n and $n + 1$, which satisfies Q. So Q is not refutable.

The map $\Phi(\alpha) = (1, \alpha(0), \alpha(1), \ldots)$ has finite information, since each entry of $\Phi(\alpha)$ is an entry of α, and $Q(\Phi(\alpha))$ holds exactly when α has an entry 1. So the event test reduces to Q, and by Proposition 17.18(3) deciding Q for every run implies LPO. Conversely LPO decides Q: apply it to the binary sequence whose entry at n is 1 exactly when $\alpha(0), \ldots, \alpha(n)$ contain two entries 1. Deciding Q costs exactly LPO.

Chapter 17, question 7: Theorem 17.17

A decision for α gives either that the first entry 1 of α is at an even place, which exhibits an entry 1, or the negation of that statement. The negation is compatible with a first entry 1 at an odd place and gives no place: a search for it could fail only if α were all zero, and turning that impossibility into a place is the binary Markov principle $\mathrm{MP}_{\mathrm{bin}}$, which is what we want to prove. The shifted run moves every entry one place to the right, so its first entry 1 is at an even place exactly when that of α is at an odd place. A positive decision for the shifted run therefore exhibits an entry 1 of α as well, and if both decisions are negative, α is all zero, which contradicts the promise.

Chapter 17, question 8: Theorem 17.21

Consistency asks for $|y - 1| < 1$, $|y - 3/2| < 1/2$ and $|y - 13/8| < 1/4$, that is, $0 < y < 2$, $1 < y < 2$ and $11/8 < y < 15/8$. The consistent values form the open interval $(11/8, 15/8)$. The golden ratio $\varphi = 1.6180\ldots$ lies in it. The largest admissible δ is the distance from φ to the nearer end, $\varphi - 11/8 = 0.2430\ldots$; the other end is at distance $15/8 - \varphi = 0.2569\ldots$.

The rivals lie above φ, so they are consistent exactly when $\varphi^{-K} < 15/8 - \varphi$. Since $\varphi^{-1} = \varphi - 1$ and $\varphi^{-2} = 2 - \varphi$, the first two rivals are $2\varphi - 1 = 2.236\ldots$ and 2, both inconsistent. Next, $\varphi^{-3} = \sqrt{5} - 2 = 0.2360\ldots < 0.2569\ldots$, so $\varphi + \varphi^{-3} = 1.8541\ldots$ is consistent, and so is every later rival, because the powers φ^{-K} decrease. The least K is 3.

Chapter 18, question 1: Theorem 18.3

The identity $V^{\dagger}V = I$ gives the upper-left block of U^2. It also gives $(I - VV^{\dagger})V = 0$ and its adjoint, which make the off-diagonal blocks vanish. Finally $VV^{\dagger}$ is a projection, so the lower-right block is

$$VV^{\dagger} + (I - VV^{\dagger})^2 = VV^{\dagger} + I - VV^{\dagger} = I.$$

The complement is the part of the larger output space outside the embedded input. Including its action is what makes the construction a unitary on the whole displayed space.

Chapter 18, question 3: Lemma 18.7

For an accepted word, the exact entry discrepancy is bounded by word-evaluation error, the accepted rational discrepancy, and target-naming error. These are $e + r + e$, with $e = r/8$, giving $5r/4 \le 2r$. This proves accuracy of the word actually accepted.

To prove that the search terminates, first use density to obtain a word whose exact entries are within e of the target. Its rational discrepancy in absolute complex value is then bounded by the two evaluation errors and that true gap: $e + e + e = 3e < r/2$. The rational certificate criterion makes this candidate pass. The second argument proves that some candidate will be accepted; it does not assume that the search already found one.

Chapter 18, question 5: Theorem 18.10

Set $h = \|H\|$. Since $t \le \delta\hbar/[2(\ell h + 1)]$,

$$\frac{\ell t h}{\hbar} \le \frac{\delta}{2}\frac{\ell h}{\ell h + 1} \le \frac{\delta}{2}.$$

Also $t \le T/(\ell + 1)$ implies $\ell t \le \ell T/(\ell + 1) < T$. For each pulse, its scalar baseline contribution is $t(\hbar/t)\|G\| = \hbar\|G\|$. Summing gives $\hbar c(w)$. The amplitude scale $\hbar/t$ grows when duration shrinks; the integrated baseline does not disappear.

O.9 Conservation and the closing argument

Chapter 19, question 2: Lemma 19.2

With $D = M - P$, expand

$$(I - P)D(I - P) - PDP = D - DP - PD.$$

Substituting $D = M - P$ and using $P^2 = P$ gives $M + P - MP - PM$, the noise block. Apply the event-error bound to the two vectors $(I - P)x$ and Px. They are orthogonal and sum to x, because P is an orthogonal projection. Their squared norms therefore sum to $\|x\|^2$, leaving one factor of e in the noise estimate.

Chapter 19, question 4: Theorem 19.5

The centered total-charge vector is

$$(A - I)\psi \otimes p + \psi \otimes (R - bI)p.$$

Its cross inner product factors as $\langle (A-I)\psi, \psi\rangle\langle p, (R-bI)p\rangle$ and is zero by the source witness's centered mean. The two squared norms are $3/4$ and $\|(R - bI)p\|^2$, since both ψ and p are unit vectors. Their sum is the stated total spread.

The factorization of the cross term uses the initial product $\psi \otimes p$ between source and whole recorder. It makes no factorization assumption about the cells inside p. Internal recorder correlations remain permitted.

Chapter 20, question 1: Theorem 2.7

The target step's injectivity and its separation from the target start give injectivity of the canonical reading. Target generation gives surjectivity by the image predicate used in the solution to Chapter 2, question 3. Initiality then makes the resulting structure-preserving bijection unique. Each conclusion uses its own condition; the existence of the initial map alone supplies neither of the two bijection properties.

Chapter 20, question 3: Theorem 10.8

Faithful storage proves that decoding the stored record recovers the same program expression. Execution after recovery therefore has exactly the same behavior as execution before storage, including failure to halt. A uniform interval name has a stronger specification: for every precision request it must return a valid pair of endpoints. A program that fails to halt on one such request fails that specification even if its storage and recovery are exact.

Chapter 20, question 7: Theorem 20.39

The translation of $\forall x \neg(S(x) = 0)$ is $\forall x(\neg\neg(S(x) = 0) \to \bot)$, expressed by

$$\prod_{x : O}\Big(\big((\mathrm{Id}_O(Sx, 0) \to \mathbf{0}) \to \mathbf{0}\big) \to \mathbf{0}\Big).$$

The valuation gives the identity type the value true and $\mathbf{0}$ the value false. Then $\mathrm{Id} \to \mathbf{0}$ is false, its implication into $\mathbf{0}$ is true, the next implication into $\mathbf{0}$ is false, and the product over O, with $\nu(O)$ true, is false. Theorem 9.8 excludes a closed term. Peano arithmetic proves the sentence, so $\mathscr{E}^{-}$ does not prove the translation of every theorem of Peano arithmetic; the discriminator is needed.

O.10 The comparison cost and its forcing chain

Chapter 21, question 3: Theorem 21.8

By part 1 of the theorem, $\cos\alpha = 5\sin\alpha$ and $\cos\beta = 239\sin\beta$. Put $a = \sin\alpha$ and $b = \sin\beta$. The addition formulas give $\cos 2\alpha = \cos^2\alpha - \sin^2\alpha = 24a^2$ and $\sin 2\alpha = 2\sin\alpha\cos\alpha = 10a^2$, then $\cos 4\alpha = (24^2 - 10^2)a^4 = 476a^4$ and $\sin 4\alpha = 2 \cdot 10 \cdot 24\, a^4 = 480a^4$. With $\cos(-\beta) = \cos\beta$ and $\sin(-\beta) = -\sin\beta$,

$$\cos(4\alpha - \beta) = 476 \cdot 239\, a^4 b + 480\, a^4 b = 114244\, a^4 b,$$
$$\sin(4\alpha - \beta) = 480 \cdot 239\, a^4 b - 476\, a^4 b = 114244\, a^4 b.$$

(This is $(5 + \mathrm{i})^4(239 - \mathrm{i}) = 114244(1 + \mathrm{i})$.) So with $\theta = 4\alpha - \beta$, $\cos 2\theta = \cos^2\theta - \sin^2\theta = 0$. Part 1 gives $\frac{4}{25} \le \alpha \le \frac{1}{5}$ and $\frac{4}{1195} \le \beta \le \frac{1}{239}$, so $2\theta = 8\alpha - 2\beta$ lies between $\frac{32}{25} - \frac{2}{239} > 1$ and $\frac{8}{5} < 2$. By part 3, $2\theta = \pi_\delta/2$, that is $\pi_\delta = 4(4\alpha - \beta)$.

Chapter 21, question 1: Theorem 21.14

The cost $F(x) = \frac{1}{2}(x-1)^2$ has $F(1) = 0$ and $F(x) - (x-1)^2/2 = 0$, so it is calibrated at 1 with any modulus. At $x = y = 2$ and $z = \frac{1}{2}$ the multiplicative law would read $F(4) + F(1) = 2F(2)^2 + 4F(2)$, that is $\frac{9}{2} = \frac{1}{2} + 2 = \frac{5}{2}$, which is false. Put $C(t) = F(e^t) = \frac{1}{2}(e^t - 1)^2$ and $g = \cosh - 1$. Both are calibrated (the passage from calibration at 1 to calibration at 0 is the estimate in the proof of Theorem 21.14, part 3), so hypothesis (i) of Theorem 21.13 holds, by the triangle inequality at index $2k+1$, and hypothesis (ii) holds for g by Proposition 21.12. What fails is the duplication law for C: at $s = \log 2$, $C(2s) = F(4) = \frac{9}{2}$, while $2C(s)^2 + 4C(s) = 2F(2)^2 + 4F(2) = \frac{5}{2}$. Accordingly $C \neq g$: $C(\log 2) = \frac{1}{2}$, while $g(\log 2) = J(2) = \frac{1}{4}$. Curvature at the reference does not determine a cost; the law does.

Chapter 21, question 2: Proposition 21.16

Write $G = \cosh - 1$, which obeys the duplication law $G(2) = 2G(1)^2 + 4G(1)$, and $\lambda = \frac{2}{3}$. At $s = t = 1$ the left side of the composition law for λG is $\lambda G(2) + \lambda G(0) = \frac{2}{3}\big(2G(1)^2 + 4G(1)\big) = \frac{4}{3}G(1)^2 + \frac{8}{3}G(1)$. The right side is $2\lambda^2 G(1)^2 + 4\lambda G(1) = \frac{8}{9}G(1)^2 + \frac{8}{3}G(1)$. The difference is $\frac{4}{9}G(1)^2$, and $G(1) \geq \frac{1}{2}e^{-1} > 0$, so the law fails. With $\kappa = 3$ the product term becomes $\kappa\lambda^2 G(1)^2 = \frac{4}{3}G(1)^2$, and the two sides agree: λG obeys the law with product coefficient 3, as part 3 of the proposition says.

Chapter 21, question 4: Theorem 21.22

By part 1 there is a natural number c with $C(x) = J(x^c)$, so $C(2) = J(2^c) = \frac{9}{8}$. Put $z = 2^c \geq 1$. Then $J(z) = \frac{9}{8}$ means $z + z^{-1} = \frac{17}{4}$, that is $4z^2 - 17z + 4 = (4z-1)(z-4) = 0$, and $z \geq 1$ gives $z = 4$, so $c = 2$. By part 2 the weights are $\frac{1}{2}$ at 2 and at -2 and 0 everywhere else: the law is the fair step ± 2, and $C(x) = J(x^2)$.

Chapter 21, question 5: Theorem 21.26

$W_5 = W_4 W_3 =$ dcddcdcd dcddc, so the history begins dcddcdcddcddc. With $\varphi^{-3} = \sqrt{5} - 2 = 0.2360679\ldots$ the balances and discrepancies $D_N = N\varphi^{-3} - b_N$, to three places, are as follows; the letter in row N is posting N, made after b_N is read.

N	letter	b_N	D_N	N	letter	b_N	D_N
0	d	0	0	7	d	1	0.652
1	c	1	−0.764	8	d	2	−0.111
2	d	0	0.472	9	c	3	−0.875
3	d	1	−0.292	10	d	2	0.361
4	c	2	−1.056	11	d	3	−0.403
5	d	1	0.180	12	c	4	−1.167
6	c	2	−0.584	13		3	0.069

All values lie strictly between $-2/\varphi = -1.236\ldots$ and $2/\varphi^2 = 0.764\ldots$; the closest approaches are $D_7 = 0.652$ to the upper bound and $D_{12} = -1.167$ to the lower one. The rule of part (e) says that posting N is a debit exactly when $D_N > -2\varphi^{-3} = -0.472\ldots$. The postings 1, 4, 6, 9 and 12 have $D_N \le -0.584$ and are credits; all others have $D_N \ge -0.403$ and are debits, as the table shows. Every margin exceeds 0.06, far more than the rounding error; exactly, each comparison is the sign test of an element of $\mathbb{Z}[\varphi]$, for instance $D_{12} + 2/\varphi = (12\varphi^{-3} - 4) + (2\varphi - 2) = 26\varphi - 42$, which passes the sign test because $s = -58$, $t = 26$ and $58^2 = 3364 < 3380 = 5 \cdot 26^2$.

Chapter 21, question 6: Theorem 21.29

Write $G = \cosh - 1$. The coded cost of the constant c is $C_c(t) = G(t) + c\big(\max(0, t-1) + \max(0, -t-1)\big)$, so $C_c(0) = 0$, $C_c(2) = G(2) + c$, $C_c(3) = G(3) + 2c$, $C_c(4) = G(4) + 3c$ and $C_c(6) = G(6) + 5c$. Using the duplication law $G(2s) = 2G(s)^2 + 4G(s)$, the defect $C(s+t) + C(s-t) - 2C(s)C(t) - 2C(s) - 2C(t)$ is

$$-c\big(1 + 4G(2) + 2c\big) \text{ at } s = t = 2, \qquad -c\big(3 + 8G(3) + 8c\big) \text{ at } s = t = 3.$$

If both vanish, four times the first minus the second gives $c\big(8G(3) - 16G(2) - 1\big) = 0$. With $u = \cosh 1$, the addition formulas for cosh give $\cosh 2 = 2u^2 - 1$ and $\cosh 3 = 4u^3 - 3u$, so $8G(3) - 16G(2) - 1 = 32u^3 - 32u^2 - 24u + 23 = 23 + 8u(2u-3)(2u+1)$. Since $e \ge 1 + 1 + \frac{1}{2} + \frac{1}{6} = \frac{8}{3}$ and $e \le 3$, $u = \frac{1}{2}(e + e^{-1}) \ge \frac{1}{2}(\frac{8}{3} + \frac{1}{3}) = \frac{3}{2}$, so the factor is at least 23, hence invertible, and $c = 0$. Conversely $C_0 = \cosh - 1$ obeys the law. Part 2 of the theorem gives more: for every function H, the coded cost obeys the law exactly when $H \equiv 0$; its proof uses the forcing theorem, which reduces the law to the single equation $C_H = \cosh - 1$.

Chapter 22, question 1: Theorem 22.16

By the computation in the proof, $J(1+r^2) = r^4/(2(1+r^2))$ for every point r. Hence $J(1+r^2) = 0$ exactly when $r^4 = 0$, that is, when $r = 0$ (a point apart from 0 has a positive fourth power); so $J(1 + r^2) \ne 0$ exactly when $r \ne 0$. And $J(1 + r^2) > 0$ exactly when $r^4 > 0$, which holds exactly when $r \# 0$: a positive power is apart from 0, so its factor r is. Now assume (ii) and let $r \ne 0$. Then $J(1 + r^2) \ne 0$, so (ii) gives $J(1 + r^2) > 0$, hence $r \# 0$, that is, $r < 0$ or $r > 0$. So every point $r \ne 0$ satisfies $r < 0 \vee r > 0$. With $y = 0$, this is the row "$x \ne y \to x < y \vee y < x$" of Table 12.2, whose price is $\mathrm{MP}_{\mathrm{bin}}$. No jump point is used; the jump point is hidden inside the proof of that row.

Chapter 22, question 2: Theorem 22.20

Put $F_{-1} = 1$, so that $F_1 = F_0 + F_{-1}$. Then $\ell(0) = (0, 1) = (F_0, F_{-1})$, and if $\ell(n) = (F_n, F_{n-1})$ then $\ell(n+1) = A(F_n, F_{n-1}) = (F_n + F_{n-1}, F_n) = (F_{n+1}, F_n)$. Hence $\nu(\ell(n)) = F_n\varphi + F_{n-1}$, which is φ^n by Proposition 22.37(d) for $n \ge 1$ and equals $1 = \varphi^0$ for $n = 0$. The hypotheses of Theorem 22.20(b) for $s_* = 0$: $r(n) = \varphi^n > 0$ because $\varphi > 0$; A is a homomorphism of $\mathbb{Z} \times \mathbb{Z}$ and ν is additive; $\nu(\ell(n)) = r(n)$ was just shown, and $\ell(n+1) = A(\ell(n))$ holds by definition; the step preserves positive values because $\nu(A(a, b)) = (a + b)\varphi + a = \varphi(a\varphi + b)$ by $\varphi^2 = \varphi + 1$; and the levels of 0 are $1, \varphi, \varphi^2$ with $\varphi^2 = \varphi + 1$, so $(a, b) = (0, 1)$ posts additively, and the join ratio φ satisfies $\varphi > 1$, so $J(\varphi) > 0$ (Proposition 22.15). The theorem then returns $r(n+1) = \varphi\, r(n)$, which is visibly true in the model.

Chapter 22, question 3: Theorem 22.31

Let $x, y \geq 1$ with $J(x) = J(y)$, so that $w = (x - y)(xy - 1) = 0$. Suppose $x \# y$, say $x > y$ (the case $y > x$ is symmetric). Then $x > y \geq 1$, so $xy \geq x > 1$ and $xy - 1 > 0$. A product of two points apart from 0 is apart from 0, against $w = 0$. Hence $\neg(x \# y)$, which is $x = y$. No principle is used. On $[1, \infty)$ the branch $xy = 1$ adds nothing: $x, y \geq 1$ and $xy = 1$ force $x = y = 1$. The price of the general statement comes from pairs on opposite sides of 1, where $xy = 1$ and $x = y$ are genuinely different conclusions. In the proof of the theorem the pair $x = \exp((u - v)/2)$, $y = \exp(-(u + v)/2)$ has $x/y = \exp(u)$ and $xy = \exp(-v)$; choosing the branch $x = y$ or $xy = 1$ is choosing which of u and v vanishes, and that is the domain law, whose price is LLPO.

Chapter 22, question 5: Theorem 22.42

Fix x, a natural number $T \geq |x|$ and k, and take j for the uniform derivative 0 on $[-T, T]$: $|h(t) - h(u)| \leq |t - u|/(k + 1)$ whenever $|t|, |u| \leq T$ and $|t - u| \leq 1/(j + 1)$. With $N = (T + 1)(j + 1)$ and $t_i = ix/N$,

$$|h(x) - h(0)| \leq \sum_{i<N} |h(t_{i+1}) - h(t_i)| \leq \frac{|x|}{k + 1}.$$

This holds for every k, so $h(x) = h(0)$: h is constant. For the second part, Theorem 22.42(b) gives $g(x) = \sigma \exp(-x/\sigma)$ and $g(-x) = \sigma \exp(x/\sigma)$, so $g(x)g(-x) = \sigma^2 \exp(0) = \sigma^2$ by $\exp(a + b) = \exp(a) \exp(b)$ (Proposition 12.88).

Chapter 22, question 4: Theorem 22.44

Section 22.9 gives $3.1415925 < \pi < 3.1415927$ and $0.4812 < \log \varphi < 0.4813$, so $1.9248 < 4 \log \varphi < 1.9252$. Hence

$$\frac{\pi}{4 \log \varphi} > \frac{3.1415925}{1.9252} > 1.6318 > 1.631, \qquad \frac{\pi}{4 \log \varphi} < \frac{3.1415927}{1.9248} < 1.6322 < 1.633.$$

Each comparison is a comparison of integers after clearing denominators, for instance, after multiplying by 10^8, $314159250 > 314154136$. Since $K < 3/2$ by Theorem 22.44(b), the ratio exceeds K by more than $1.631 - 1.5 = 0.131 > 1/10$. The check's second test compares the ratio with 1, from which it differs by more than 0.63, far above the tolerance 10^{-6}.

Chapter 22, question 6: Proposition 22.49

Let w have period $p > 0$ and reach every point of $\{0, 1\}^D$. By induction on q, $w(r + qp) = w(r)$, so every value of w is one of $w(0), \ldots, w(p - 1)$. Two points of $\{0, 1\}^D$ are equal exactly when they agree in each of the D coordinates, a finite check; so for each point x the least $r < p$ with $w(r) = x$ is found by testing $r = 0, 1, \ldots, p - 1$ in turn. No choice is made: the search is bounded and each test is decided. Since $w(r_x) = x$, different points have different first visits, so $x \mapsto r_x$ is an injective map from the 2^D points to $\{0, \ldots, p - 1\}$, and $2^D \leq p$ by the count in the proof of Proposition 22.28.

For the second part, define lists G_D of points by $G_1 = (0, 1)$ and let G_{D+1} be G_D with 0 put in front of each point, followed by G_D in reverse order with 1 put in front of each point.

By induction, G_D lists each of the 2^D points once, consecutive points differ in exactly one coordinate (inside each half by induction; at the junction the two points differ only in the new first coordinate), and its last point $10\cdots0$ differs from its first point $00\cdots0$ in the first coordinate only. The sequence $w(n) = G_D(n \bmod 2^D)$ has period 2^D, reaches every point, and changes one coordinate per step. For $D = 3$ it is $000, 001, 011, 010, 110, 111, 101, 100$; the cycle in the proof of Proposition 22.49(a) is the same construction with the coordinates read in the opposite order.

Chapter 23, question 2: Lemma 23.12

With $|x| = |p| = 1$ and $\langle x, p\rangle = c$, $|2tx + kp|^2 = 4t^2 + 4tkc + k^2$. Put $B = A - m$, so $k = B - 2tc$. Then

$$4t^2 + 4tc(B - 2tc) + (B - 2tc)^2 = 4t^2 + 4tcB - 8t^2c^2 + B^2 - 4tcB + 4t^2c^2 = 4t^2(1 - c^2) + B^2.$$

Since $4Am = 4t^2(1 + c)(1 - c) = 4t^2(1 - c^2)$, this is $(A - m)^2 + 4Am = (A + m)^2 = Q^2$.

For $D = 1$, $p = (1, 0)$, $x = (0, 1)$ and $t = \frac{1}{2}$: $c = 0$, $m = 1$, $A = \frac{1}{4}$, $Q = \frac{5}{4}$ and $k = \frac{1}{4} - 0 - 1 = -\frac{3}{4}$. Hence

$$H(\tfrac{1}{2}, x) = \frac{(0, 1) - \frac{3}{4}(1, 0)}{5/4} = \Big(-\frac{3}{5}, \frac{4}{5}\Big),$$

and $\frac{9}{25} + \frac{16}{25} = 1$, so it lies on the circle. Its squared distance from p is $(\frac{8}{5})^2 + (\frac{4}{5})^2 = \frac{16}{5}$, which agrees with $4m/Q = \frac{16}{5}$ and exceeds $|x - p|^2 = 2 = 2m$. In the sup distance, $d(H(\frac{1}{2}, x), p) = \frac{8}{5} > 1 = d(x, p)$.

Chapter 23, question 4: Lemma 23.16

Near a pole $u = |x'|^2$ is small. If $u < \kappa$, then $\phi(x) = u/\kappa < 1$ and $c^2 = 1 - u > 1 - \kappa \geq 0$, so c is apart from 0, and the first coordinate $(1 - \phi)c/\sqrt{n}$ of $H(1, x)$ is apart from 0: such a point stops short of the equator. The proof never needs those points. The cycle z has its simplices r-apart from both poles, and with $\kappa = r^2$ item 4 of the proof gives $u \geq \kappa$ at every value of z; there $\phi = 1$ and $H(1, x) = (0, x')/\sqrt{u}$ lies on the equator. The cut-off is there for a different reason: it makes $n \geq \kappa/8$ on the whole sphere, so that H is one uniformly continuous homotopy of all of S^{D+1}. Then the prism of Lemma 23.11 is an operator on all maps $\Delta^k \to S^{D+1}$, defined term by term, and it respects the moves of Definition 23.4; this is what makes $P(\partial z) \sim \emptyset$ for a cycle z.

Chapter 23, question 1: Lemma 23.17

Let $f : S^1 \to S^0$ be uniformly continuous with an inverse modulus ω'. The arc $u \mapsto z(u)$, $u \in [-1, 0]$, of Lemma 23.33 runs from $z(-1) = (-1, 0)$ to $z(0) = (1, 0)$ and is 32-Lipschitz, so $s \mapsto f(z(s - 1))$ is a uniformly continuous map from $[0, 1]$ to S^0. By Lemma 23.17 it is constant, so $f(1, 0) = f(-1, 0)$. Then $d(f(1, 0), f(-1, 0)) = 0 < \omega'(1)$, and the inverse modulus gives $d((1, 0), (-1, 0)) < 1$; but that distance is 2. So no native embedding into S^0 exists.

No sign of a point is decided. For v with $v^2 = 1$ we have $(v-1)(v+1) = 0$ and $(v+1)-(v-1) = 2$, so $|v-1| + |v+1| \geq 2 > 1$, and cotransitivity gives $|v-1| > 1/2$ or $|v+1| > 1/2$. The factor that is bounded away from 0 has an inverse, so the other factor is 0: $v = 1$ or $v = -1$. This disjunction is proved for each given v; it is not a decision procedure on the line, and it is used only inside the proof of an equation. For two points v, w of S^0 with $|v - w| < 1$, the four combinations of signs leave only $v = w$, since mixed signs give $|v - w| = 2$.

Chapter 23, question 3: Lemma 23.26

Each chord lies in one chart, and its swept angle is the difference of the diamond angles of its end points in that chart. Using $\theta_j(p) = j + y'/(x' + |y'|)$ with $(x', y') = \rho^j(p)$:

- $(1, 0) \to (\frac{3}{5}, \frac{4}{5})$ in chart 0: from 0 to $\frac{4/5}{7/5} = \frac{4}{7}$; swept $\frac{4}{7}$.
- $(\frac{3}{5}, \frac{4}{5}) \to (0, 1)$ in chart 1, where $\rho(p) = (y, -x)$: from $1 - \frac{3}{7} = \frac{4}{7}$ to 1; swept $\frac{3}{7}$.
- $(0, 1) \to (-\frac{3}{5}, \frac{4}{5})$ in chart 1: from 1 to $1 + \frac{3}{7}$; swept $\frac{3}{7}$.
- $(-\frac{3}{5}, \frac{4}{5}) \to (-1, 0)$ in chart 2, where $\rho^2(p) = (-x, -y)$: from $2 - \frac{4}{7}$ to 2; swept $\frac{4}{7}$.
- $(-1, 0) \to (-\frac{3}{5}, -\frac{4}{5})$ in chart 2: from 2 to $2 + \frac{4}{7}$; swept $\frac{4}{7}$.
- $(-\frac{3}{5}, -\frac{4}{5}) \to (0, -1)$ in chart 3, where $\rho^3(p) = (-y, x)$: from $3 - \frac{3}{7}$ to 3; swept $\frac{3}{7}$.
- $(0, -1) \to (\frac{3}{5}, -\frac{4}{5})$ in chart 3: from 3 to $3 + \frac{3}{7}$; swept $\frac{3}{7}$.
- $(\frac{3}{5}, -\frac{4}{5}) \to (1, 0)$ in chart 0: from $-\frac{4}{7}$ to 0; swept $\frac{4}{7}$.

The total is $4 \cdot \frac{4}{7} + 4 \cdot \frac{3}{7} = 4$: one full turn. At the shared end points the readings of neighbouring charts agree or differ by 4, as Lemma 23.26 says; for instance $(\frac{3}{5}, \frac{4}{5})$ reads $\frac{4}{7}$ in chart 0 and in chart 1.

Chapter 23, question 5: Theorem 23.40

Since $i(ix) = (-x_0, -x_1) = -x$, the colouring satisfies $q(-x) \equiv q(ix) + 1 \equiv q(x) + 2 \pmod 4$. If $q(x)$ is 0 or 1 modulo 4, then $q(-x)$ is 2 or 3, and conversely; so $b(-x) \neq b(x)$, and b is an antipodal two-colouring. Residues of integers modulo 4 are computed, so b is a map.

For the identity, let a, b, c, d be $G(x), G(ix), G(-x), G(-ix)$. Then $q(x) = k_0(3a + 2b + c)$, and since $i(ix) = -x$ and $i(-x) = -ix$, $q(ix) = k_0(3b + 2c + d)$. Hence

$$q(ix) - q(x) - 1 = k_0(b + c + d - 3a) - 1 = k_0(a + b + c + d) - 4k_0 a - 1 = -4k_0 a,$$

using $k_0(a + b + c + d) = 1$, which is the statement that the cycle of four quarter chords at x has label 1.

Chapter 23, question 6: Theorem 23.40

Let d be a WLPO function. The sequence $\bar{0}$ of zeros is identically 0, so $d(\bar{0}) = 1$. Continuity at $\bar{0}$ gives n such that $d(\beta) = 1$ for every β agreeing with $\bar{0}$ below n. The sequence β whose only 1 is at place n agrees with $\bar{0}$ below n, so $d(\beta) = 1$; but β is not identically 0, so $d(\beta) = 0$. This is a contradiction, so continuity on Cantor space refutes the WLPO function.

Classically both principles are false. For BU_2, let $b(x) = 1$ when $x_1 > 0$, or $x_1 = 0$ and $x_0 > 0$, and $b(x) = 0$ otherwise. For a point of the circle, if $x_1 \neq 0$ exactly one of x_1 and $-x_1$ is positive, and if $x_1 = 0$ then $x_0 = \pm 1$ and exactly one of x_0 and $-x_0$ is positive; so $b(-x) \neq b(x)$ for every x. For continuity on Cantor space, excluded middle decides for each α whether it is identically 0, and a classical map d records the answer; by the first paragraph it is not continuous at $\bar{0}$.

Chapter 24, question 2: Proposition 24.3

If $D \leq D'$ and $C \leq C'$ then $2D \leq 2D'$ and $C \leq C'$, and conversely; so $(D, C) \mapsto (2D, C)$ preserves and reflects the order. It is not onto, since $(1, 0)$ is not an image, so it is not an order bijection, and the proposition does not apply to it. If $(kD, C/k) \in \mathbb{N} \times \mathbb{N}$ for all records, the record $(1, 0)$ gives $k \in \mathbb{N}$ and the record $(0, 1)$ gives $1/k \in \mathbb{N}$, so $k = 1$. Theorem 24.14(f) concerns real coherent records: on the diagonal it sends real (D, C) to $(kD, C/k)$, keeping the determinant DC and the cone. It is a symmetry of the real record cone, not of integer counts, and integer counts single out the frame in which they are counts.

Chapter 24, question 1: Theorem 24.5

The legs dc, ddc and dcd have counts $(1, 1)$, $(2, 1)$ and $(2, 1)$, so their proper times are 2, $2\sqrt{2}$ and $2\sqrt{2}$, with sum $2 + 4\sqrt{2} \approx 7.657 < 2\sqrt{15} \approx 7.746$. The squared deficit is $60 - (2 + 4\sqrt{2})^2 = 24 - 16\sqrt{2} \approx 1.373$. In Proposition 24.6 the ratios are $r_1 = 1$ and $r_2 = r_3 = 2$. The pair $(1, 2)$ gives $2 \cdot 2 \cdot 2\sqrt{2} \cdot J(1/\sqrt{2})$, and $J(1/\sqrt{2}) = J(\sqrt{2}) = \frac{1}{2}(\sqrt{2} + 1/\sqrt{2}) - 1 = \frac{3}{4}\sqrt{2} - 1$, so the term is $8\sqrt{2}(\frac{3}{4}\sqrt{2} - 1) = 12 - 8\sqrt{2}$; the pair $(1, 3)$ gives the same, and the pair $(2, 3)$ gives $J(1) = 0$. The sum is $24 - 16\sqrt{2}$, as required. In the integer form of the proof, $4(\sqrt{p_{12}} - \sqrt{p_{21}})^2 = 4(1 - \sqrt{2})^2 = 12 - 8\sqrt{2}$ with $p_{12} = 1$ and $p_{21} = 2$. The legs ddc and dcd post in the same proportion, $D_2C_3 = D_3C_2 = 2$; merging them loses no proper time, since $\tau(ddcdcd) = 2\sqrt{4 \cdot 2} = 4\sqrt{2} = 2\sqrt{2} + 2\sqrt{2}$, by Theorem 24.5(b).

Chapter 24, question 3: Theorem 24.12

For $(5, (2, -1))$: $|2| + |-1| = 3 \leq 5$ and $5 - (2 - 1) = 4$ is even, so it is reachable. Post dd to account 1 and c to account 2, then the pair dc to account 1: the records are $(3, 1)$ and $(0, 1)$, with 5 posts and potentials $(2, -1)$. For $(4, (2, -1))$: $4 - 1 = 3$ is odd, so it is not reachable; the number of posts at each account has the parity of its potential. For $(6, (3, 3))$: $6 \leq 6$ and $6 - 6 = 0$ is even; post ddd to each account. This point lies on the boundary of the taxicab cone: every post moves a potential away from 0.

Chapter 24, question 4: Theorem 24.17

$P_4(n) = n + 4n(n-1)/2 = 2n^2 - n$, so $P_4(2) = 6$, $P_4(3) = 15$, $P_4(4) = 28$ and $P_4(6) = 66$. Multiplication would require $P_4(4) = P_4(2)^2 = 36$ and $P_4(6) = P_4(2)P_4(3) = 90$; both fail. In the proof of the theorem, the condition at $2 \cdot 2$ is $k^2 = 2k$, which fails at $k = 4$ because $16 \neq 8$.

Chapter 24, question 5: Theorem 24.31

By the record law, agreement at τ_0 gives $x_j \in \mathbb{Z}$, and agreement at $\frac{8}{3}\tau_0$ gives $3 \mid 8x_j$, hence $3 \mid x_j$ because $\gcd(3, 8) = 1$; likewise $\frac{8}{5}$ and $\frac{8}{7}$ give $5 \mid x_j$ and $7 \mid x_j$, so $105 \mid x_j$. Conversely 105 times each of the four times is an integer. The other four times, 8, 4, 2 and $\frac{4}{3}$, add nothing: for $x_j \in 105\mathbb{Z}$ the products $8x_j$, $4x_j$ and $2x_j$ are integers, and $\frac{4}{3}x_j$ is an integer because $3 \mid x_j$. The identity $1 + \frac{8}{3} + \frac{8}{7} - 3 \cdot \frac{8}{5} = \frac{1}{105}$ uses only the four times, so they already generate $\frac{1}{105}\mathbb{Z}$.

Chapter 24, question 6: Theorem 24.43

The closing coder of $\alpha = (0, 1, 0, 0, \ldots)$ posts d, then dc for $\alpha(0) = 0$, cd for $\alpha(1) = 1$, dc for $\alpha(2) = 0$ and begins dc for $\alpha(3) = 0$: the first eight posts are $ddcddcd$, with balances $1, 2, 1, 0, 1, 2, 1, 2$ after one to eight posts. It closes after four posts, inside the pair coding the entry $\alpha(1) = 1$, as the proof of Theorem 24.39 predicts.

The recorder with states $\{0, 1, 2\}$ is in state 2 exactly when the last bit read is 1. On the run of zeros it stays in state 1 from the first entry on and never answers, so it does not always answer. The proof of Theorem 24.43(d), with $s = 2$, finds the states $0, 1, 1, 1$ after $0, 1, 2, 3$ entries, a first repetition at stages $i = 1 < j = 2$, and the run that copies the zeros up to place 2 and then repeats place 1: the run of zeros itself, which never answers. For a recorder that always answers this would be a contradiction; here it only shows that the hypothesis fails. On a run whose first 1 is at place p the recorder answers at stage $p + 1$, which can be arbitrarily late, so no deadline exists, consistently with the theorem.

Chapter 24, question 7: Theorem 24.53

Here $f = f_{1,2}$ in the notation of the proof of Theorem 24.53, so $Pf = f_{3/\sqrt{2},\,1/\sqrt{2}}$, with entries $3/\sqrt{2}$, $1/\sqrt{2}$, $-3/\sqrt{2}$, $-1/\sqrt{2}$ at positions $0, 2, 4, 6$. Then $\sum_t f(t)^2 = 1 + 4 + 1 + 4 = 10$ and $\sum_t (Pf)(t)^2 = \frac{9}{2} + \frac{1}{2} + \frac{9}{2} + \frac{1}{2} = 10$, while $\sum_t |f(t)| = 6$ and $\sum_t |(Pf)(t)| = 8/\sqrt{2} = 4\sqrt{2} \approx 5.66$: the magnitude reads see the phase. For g, $\|g\|^2 = 4$ and $\kappa(g, \{t\}) = g(t)^2 + g(t)^2\big(g(t+1)^2 - g(t-1)^2\big)/8$ gives $\frac{9}{8}$, $\frac{7}{8}$, 0, 0, $\frac{9}{8}$, $\frac{7}{8}$, 0, 0 at positions $0, \ldots, 7$, with total $4 = \|g\|^2$. Next $(Pg)(t) = \big(g(t) + g(t+2)\big)/\sqrt{2}$ gives $Pg = \frac{1}{\sqrt{2}}(1, 1, -1, -1, -1, -1, 1, 1)$, with $\|Pg\|^2 = 4$. Every position of Pg has squared amplitude $\frac{1}{2}$ and so do both its neighbours, so $\kappa(Pg, \{t\}) = \frac{1}{2}$ everywhere and the total is again 4, as Proposition 24.55 requires. Positions 0 and 1 of g both carry amplitude 1, yet κ reads $\frac{9}{8}$ at the first and $\frac{7}{8}$ at the second, so no single φ gives $\kappa(g, \{t\}) = \varphi(g(t))$.

O.11 Classical physics on the line

Chapter 25, question 1: Theorem 25.9

The state has $I = u^2|x|^2 = 1$ and $|v|^2 = \frac{1}{2}$, so $E = \frac{1}{4} - 1 = -\frac{3}{4}$. Further $L = x \times v = (0, -\frac{1}{2}, \frac{1}{2})$, $|L|^2 = \frac{1}{2}$, and $v \times L = (\frac{1}{2}, 0, 0)$, so $A = v \times L - m\,x/|x| = (-\frac{1}{2}, 0, 0)$ and $|A|^2 = \frac{1}{4}$. Indeed $2E|L|^2 + m^2 = -\frac{3}{4} + 1 = \frac{1}{4}$.

By Theorem 25.9, $A \cdot x + mr = |L|^2$ on the orbit. Here $A \cdot x = -|A|\,r$ at the present point, since A points away from the body, so $r(m - |A|) = |L|^2$ and $r = \frac{1}{2}/\frac{1}{2} = 1$, the largest value $|L|^2/(m - |A|)$ that the conic allows: the body is at its aphelion. The perihelion lies on the other side, at $r = |L|^2/(m + |A|) = \frac{1}{2}/\frac{3}{2} = \frac{1}{3}$. The eccentricity is $|A|/m = \frac{1}{2}$, the semi-major axis is $\frac{1}{2}(1 + \frac{1}{3}) = \frac{2}{3} = m/(-2E)$, and Kepler's third law $T^2(-2E)^3 = (2\pi_\delta)^2 m^2$ gives $T^2 \cdot \frac{27}{8} = 4\pi_\delta^2$, so $T = 2\pi_\delta(\frac{2}{3})^{3/2} = \frac{4}{9}\sqrt{6}\,\pi_\delta \approx 3.420$. Every number is computed from ratios, so nothing is decided.

Chapter 25, question 4: Theorem 25.42

With $x = m/p = 2.66 \times 10^{-8}$ the first-order term is $6\pi_\delta x \approx 5.014 \times 10^{-7}$ radian per revolution. Over 415.2 revolutions this is 2.082×10^{-4} radian, and with 1 radian $= 206265''$ it is about $42.9''$ per century.

The second-order term is $\frac{3}{2}\pi_\delta(18 + e^2)x^2 \approx 6.0 \times 10^{-14}$ radian per revolution, or about $5 \times 10^{-6}{}''$ per century, and the remainder is at most $160\pi_\delta x^3 \approx 9.5 \times 10^{-21}$ radian per revolution, below $10^{-12}{}''$ per century. The theorem therefore pins the relativistic advance of such an orbit to $42.9''$ per century with every neglected part bounded explicitly. Reading Mercury's orbit as a window orbit of the proper-time field, and m/p, e and the revolution count as measured values, are identifications and observations; the theorem supplies only the bounds. The observed advance also contains the much larger Newtonian contributions of the other planets, which the field of this chapter does not include.

Chapter 25, question 2: Theorem 25.54

For $F = x_0^2 + x_1^2$,

$$\mathscr{L}_p F = 2x_0\,x_1 + 2x_1\,(-x_0 + x_0^2) = 2x_0^2 x_1.$$

The largest exponent of one variable in a term is $E = 2$, so the grid is $\{0, 1, 2\}^2$. At the grid point $(1, 1)$ the value is $2 \neq 0$, which witnesses that F is not a first integral. For G, $\partial G/\partial x_0 = x_0 - x_0^2$ and $\partial G/\partial x_1 = x_1$, so

$$\mathscr{L}_p G = (x_0 - x_0^2)\,x_1 + x_1\,(-x_0 + x_0^2) = 0$$

as a polynomial. It vanishes on every grid point, and the theorem makes G a first integral. It is the energy $\frac{1}{2}x_1^2 + V(x_0)$ with the cubic potential $V(x_0) = \frac{1}{2}x_0^2 - \frac{1}{3}x_0^3$.

Chapter 25, question 3: Theorem 25.56

The field has one term, x^2, so $t_p = 1$, $D = 2$ and $c = 1$. Then $X = 3$, $M = 3^2 + 1 = 10$, $s = \mathrm{bl}(10) + 3 = 4 + 3 = 7$, and

$$k = \mathrm{bl}(1 \cdot 2 \cdot 1 \cdot 10 \cdot 2^7) = \mathrm{bl}(2560) = 12,$$

since $2^{11} \le 2560 < 2^{12}$. The theorem certifies the state at time 2^{-12}, where the solution is $3/(1 - 3 \cdot 2^{-12}) = 12288/4093 \approx 3.0022$. That is $1/1365$ of the way to the blow-up time $\frac{1}{3}$, a cautious but explicit start.

No passing run reaches time $\frac{1}{3}$. Such a run, of a scaled field $2^{-j}p$ to an end time a with $a2^{-j} \ge \frac{1}{3}$, gives by Theorem 25.50 a motion of p on $[0, a2^{-j}]$ from 3, and a motion on a bounded interval is bounded by a natural number B (the first step of the proof of Theorem 25.3). For $t < \frac{1}{3}$ the curve $3/(1-3s)$ is a motion on $[0, t]$, so by Theorem 25.3 the two agree there; but $3/(1-3t) > B$ once $t > \frac{1}{3} - 1/B$. So the certificate fails at every level for every such run.

Chapter 25, question 5: Theorem 25.62

Here $\alpha = J_1 - J_0 = 2$ and $\beta = J_2 - J_0 = 3$, both positive, so (b) applies with $\min(\alpha, \beta) = 2$ and $\max(\alpha, \beta) = 3$. At the start $L_1^2 + L_2^2 = \frac{2}{25}$, so along the motion $2(L_1^2 + L_2^2) \le 3 \cdot \frac{2}{25}$, that is $L_1^2 + L_2^2 \le \frac{3}{25} = 0.12$.

The energy–Casimir form keeps $2L_1^2 + 3L_2^2 = \frac{2}{25} + \frac{3}{25} = \frac{1}{5}$. On that ellipse $L_1^2 + L_2^2$ lies between $\frac{1}{15}$ (all of it in L_2) and $\frac{1}{10}$ (all of it in L_1), so the exact bound is 0.1; the theorem's 0.12 is the price of replacing the ellipse by two circles.

To keep $L_1^2 + L_2^2 \le 10^{-2}$ it suffices, by the second part of (b), that $3(L_1^2 + L_2^2) \le 2 \cdot 10^{-2}$ at the start, that is $L_1^2 + L_2^2 \le \frac{2}{3} \cdot 10^{-2}$.

For $J = (2, 1, 3)$, $\alpha = -1$ and $\beta = 1$: the minimum is negative, the inequality of (b) bounds nothing, and $Q = -L_1^2 + L_2^2$ is indefinite. Here $J_1 < J_0 < J_2$, so axis 0 is the middle axis. Euler's field is unchanged when the indices are shifted cyclically, and the shift that moves axis 0 to position 1 turns the moments into $(3, 2, 1)$; Theorem 25.64 then shows that no bound of this kind exists.

Chapter 25, question 6: Theorem 25.64

The moments $(J_1 + v^2, J_1, J_1 - u^2) = (3, 2, 1)$ give $J_1 = 2$ and $u^2 = v^2 = 1$; take $u = v = 1$ and $h = \sqrt{2}$, so that $h^2 = u^2 + v^2$. Then $C = h^2 r^2 = 2r^2 = 200$ gives $r = 10$, and $\lambda = uvhr = 10\sqrt{2} \approx 14.14$. As Proposition 25.65 says, $\lambda^2 = 200 = (J_0 - J_1)(J_1 - J_2)\,C$.

With $\tau = 1$ the start satisfies $\sqrt{L_0^2 + L_2^2} \le 2e^{-10\sqrt{2}}\sqrt{C} \approx 1.44 \times 10^{-6} \cdot \sqrt{200}$: relative to $|L|$, the body starts within about 1.4×10^{-6} of the middle axis, at $L(0) \approx (-1.44 \times 10^{-5},\ 14.142,\ 1.44 \times 10^{-5})$. At time 1 it is at $L = (-10, 0, 10)$, perpendicular to the middle axis, having turned through it in one time unit.

In Theorem 25.64(b) take $\mu = \sqrt{(J_0 - J_1)(J_1 - J_2)} = 1$. While $L_1 \ge \ell_1$, W grows at least like $e^{2\mu\ell_1 t}$. At the start $L_1 \approx \sqrt{C} = 10\sqrt{2}$, so the rate $2\mu\ell_1$ is 2λ there, and along the separatrix

$W = uvr^2 \operatorname{sech}^2\phi = 100\operatorname{sech}^2\phi$ indeed grows like $e^{2\lambda t}$ while $\phi < 0$. The separatrix does not stay in $L_1 \geq \ell_1$ for any $\ell_1 > 0$ up to time 1, since $L_1(1) = 0$; this is the escape the theorem forces.

Chapter 26, question 4: Theorem 26.6

Convexity. Lemma 26.4, item 1, at a point m in place of ℓ says $-\eta(a) \geq a + am - e^m$ for every $a \geq 0$. Let $a, b \geq 0$, let $0 \leq t \leq 1$, and put $c = ta + (1-t)b$. If $c > 0$, take $m = \log c$ and add the inequality at a with weight t to the one at b with weight $1 - t$:

$$t\big(-\eta(a)\big) + (1-t)\big(-\eta(b)\big) \geq c + cm - e^m = cm = -\eta(c).$$

Without deciding whether $c > 0$, apply this to $a + \varepsilon$ and $b + \varepsilon$ for every point $\varepsilon > 0$, where the combination is $c + \varepsilon > 0$. Both sides are continuous in ε, so Lemma 26.2, applied to their difference, gives the inequality at $\varepsilon = 0$. Hence $-\eta$ is convex on $[0, \infty)$. The other terms of $g(\ell, q) = e^\ell - q - \eta(q) - q\ell$ are affine in q, so $g(\ell, \cdot)$ is convex.

The alternative gives LPO. Suppose that for all data of Theorem 26.5, $F(q) = -y$ or $F(q) > -y$. Let a be a point and $A \geq |a|$ a natural number, and take the two-level system $n = 2$, $E_1 = E_2 = 0$, $\beta = 0$, $Z = 2$, $y = \log 2$ and $q = (\frac{1}{2} + c, \frac{1}{2} - c)$ with $c = a/(2A+1)$. By Theorem 26.5, item 2, $F(q) = -y$ exactly when $2q_1 = 2q_2 = 1$, that is $c = 0$, that is $a = 0$; by item 3, $F(q) > -y$ exactly when $2q_1 \# 1$ or $2q_2 \# 1$, that is $2c \# 0$, that is $a \# 0$. So the alternative gives $a = 0 \vee a \# 0$ for every point a. Since $a \# 0$ means $a < 0$ or $a > 0$, this is the sign trichotomy on the line, which is LPO by Corollary 12.18.

Chapter 26, question 1: Theorem 26.15

The predecessor set of a configuration j is $\{i : K_{ij} \neq 0\}$. Column 0 of K has the entries $K_{00} = \frac{1}{2}$ and $K_{20} = 1$, column 1 only $K_{01} = \frac{1}{2}$, and column 2 only $K_{12} = 1$. So the predecessor sets are $\{0, 2\}$, $\{0\}$ and $\{1\}$. Configurations 0 and 2 feed a common configuration, and nothing else is merged: the merging classes of K are $\{0, 2\}$ and $\{1\}$.

By Theorem 26.15(a), $D(qK \,\|\, p) = D(q \,\|\, p)$ exactly when q/p is constant on $\{0, 2\}$, that is $q_0/\frac{1}{2} = q_2/\frac{1}{4}$, or $q_0 = 2q_2$. The distributions with this property are

$$q = (2t,\ 1 - 3t,\ t), \qquad 0 \leq t \leq \tfrac{1}{3}.$$

The value $t = \frac{1}{3}$ gives $q_0 = (\frac{2}{3}, 0, \frac{1}{3})$, and $t = \frac{1}{4}$ gives p itself.

The rows of K^2 are $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$, $(1, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, 0)$. Column 0 of K^2 has three nonzero entries, so all three configurations feed configuration 0 and K^2 has a single merging class. K^2 is stochastic and $pK^2 = p$, so Theorem 26.15(b) applied to K^2 gives $D(qK^2 \,\|\, p) < D(q \,\|\, p)$ for every distribution $q \neq p$. The criterion asks only that the merging relation connect all configurations; the zero entries $(K^2)_{11}$, $(K^2)_{12}$ and $(K^2)_{22}$ do not matter. For q_0 the two-step loss is visible in the opening table: $q_0K^2 = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$, and D falls from 0.2877 to 0.0566.

Chapter 26, question 2: Theorem 26.16

The rows of K^4 are $(\frac{9}{16}, \frac{5}{16}, \frac{1}{8})$, $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$ and $(\frac{5}{8}, \frac{1}{8}, \frac{1}{4})$. Dividing column j by p_j gives the ratios $(K^4)_{ij}/p_j$:

$$\begin{pmatrix} \frac{9}{8} & \frac{5}{4} & \frac{1}{2} \\ \frac{1}{2} & 1 & 2 \\ \frac{5}{4} & \frac{1}{2} & 1 \end{pmatrix}.$$

The largest δ with $(K^4)_{ij} \geq \delta p_j$ for all i, j is the least ratio, $\delta = \frac{1}{2}$. With $N = 4$ and $m = 2$ the theorem gives

$$D(q_0 K^8 \,\|\, p) \leq \left(\tfrac{1}{2}\right)^2 D(q_0 \,\|\, p) = \tfrac{1}{4} \log \tfrac{4}{3} \approx 0.0719.$$

Stepping the opening table on gives $q_0 K^8 = (\frac{95}{192}, \frac{51}{192}, \frac{46}{192})$, whose ratios to p are $\frac{95}{96}$, $\frac{51}{48}$ and $\frac{46}{48}$, so

$$D(q_0 K^8 \,\|\, p) = \tfrac{95}{192} \log \tfrac{95}{96} + \tfrac{51}{192} \log \tfrac{51}{48} + \tfrac{46}{192} \log \tfrac{46}{48} \approx 0.000726.$$

The bound holds with a factor of about 100 to spare. Doeblin's condition uses only the worst entry of one window, here the entries $\frac{1}{2}$ of K^4, and treats every window as if the distribution were at its worst.

Chapter 26, question 3: Theorem 26.24

Write u for any of the six unit vectors. On $\mathbb{Z}^3$ the Metropolis tick posts $\rho/6$ along each move out of the vacuum and holds there with probability $1 - \rho = \rho^2$. From u the inward post to the vacuum has probability $\frac{1}{6}$, and the five outward posts, each $\rho/6$, lead to states of cost 2, outside S. The wall turns them into a hold, so

$$P_S(0, u) = \tfrac{\rho}{6}, \quad P_S(0, 0) = \rho^2, \quad P_S(u, 0) = \tfrac{1}{6}, \quad P_S(u, u) = \tfrac{5}{6}, \quad P_S(u, u') = 0 \ (u' \neq u).$$

Each row sums to 1. The weights are 1 at the vacuum and ρ at each u, with total $1 + 6\rho$, and $\pi_S(0) P_S(0, u) = \rho/(6(1 + 6\rho)) = \pi_S(u) P_S(u, 0)$; detailed balance holds, and summing it gives $\pi_S P_S = \pi_S$. The vacuum and every unit vector feed the vacuum, so P_S has a single merging class, and by Theorem 26.23(b) one walled tick lowers $D(q \,\|\, \pi_S)$ strictly from every $q \neq \pi_S$.

For Theorem 26.24 take $R = 1$. The holds of the Metropolis tick on $\mathbb{Z}^3$ are least at states with three nonzero coordinates, where three posts are $\frac{1}{6}$ and three are $\rho/6$, so every hold is at least $h = 1 - (1 + \rho)/2 = \rho^2/2 \approx 0.191$. Every post is at least $e = \rho/6 \approx 0.103$. So $\min(h, e) = \rho/6$ and the theorem gives the constant $(\rho/6)^2 = \rho^2/36 \approx 0.0106$ at window 2.

The true largest constant is the least ratio $P_S^2(x, y)/\pi_S(y)$. For $u \neq u'$, $P_S^2(u, u') = P_S(u, 0) P_S(0, u') = \rho/36$ and $\pi_S(u') = \rho/(1 + 6\rho)$, a ratio of $(1 + 6\rho)/36 = (6\varphi - 5)/36 \approx 0.1308$. The other ratios are larger: $P_S^2(0, 0)/\pi_S(0) = (\rho^4 + \rho/6)(1 + 6\rho) \approx 1.172$, $P_S^2(0, u)/\pi_S(u) = P_S^2(u, 0)/\pi_S(0) = (\rho^2 + \frac{5}{6})(1 + 6\rho)/6 \approx 0.954$, and $P_S^2(u, u) \geq \frac{25}{36}$. So the largest Doeblin constant at window 2 is $(6\varphi - 5)/36$, about twelve times the constant the theorem guarantees. The theorem bounds every step of a path by the worst hold or post anywhere on $\mathbb{Z}^3$, while the walled holds at the unit vectors are $\frac{5}{6}$.

Chapter 26, question 5: Proposition 26.43

At the empty record G_0 is the point mass at the vacuum, so $m_0 = 0$, $H(G_0) = 0$ and $D_0(0) = -\log \pi(0) = 9 \log \varphi$. Part (b) gives

$$D(\mathsf{P}_0 \,\|\, \Pi_c) = 9 \log \varphi + \log Z + 9 \log \varphi = 3 \log \varphi + 3 \log(1 + \varphi^{-2}),$$

since $\log Z = 3 \log(1 + \varphi^{-2}) - 15 \log \varphi$. Now $\varphi^2 = \varphi + 1$, so $\varphi + \varphi^{-1} = 2\varphi - 1 = \sqrt{5}$ and $1 + \varphi^{-2} = \sqrt{5}/\varphi$. Hence $D(\mathsf{P}_0 \,\|\, \Pi_c) = 3 \log \sqrt{5} = \frac{3}{2} \log 5 \approx 2.414$. Part (c) gives $\mathrm{TC}(\mathsf{P}_0) = H(G_0) = 0$: at the empty record the two voxels are independent, both at the vacuum. Theorem 26.41(b) gives $D(\mathsf{P}_0 \,\|\, \pi \otimes \pi) = 2D_0(0) + 0 = 18 \log \varphi \approx 8.662$, and part (d) checks: $D(\mathsf{P}_0 \,\|\, \Pi_c) - \log Z = \frac{3}{2} \log 5 + 15 \log \varphi - \left(\frac{3}{2} \log 5 - 3 \log \varphi\right) = 18 \log \varphi$.

Both Π_A and Π_c live on the anti-diagonal, with $\Pi_c(s, -s) = \pi(s)^2 / Z$, so

$$D(\Pi_A \,\|\, \Pi_c) = \sum_s \pi(s) \log \frac{\pi(s)\, Z}{\pi(s)^2} = \log Z + \sum_s \pi(s)(9 + |s|_1) \log \varphi = \log Z + 15 \log \varphi,$$

using the mean cost 6 of the T9 law from the proof of part (c). This is $3 \log(1 + \varphi^{-2}) = \frac{3}{2} \log 5 - 3 \log \varphi \approx 0.9705$, the limit in part (e). So, with (T1) and (T2), the pair does relax, to its own equilibrium Π_A; the conditioned product law is a different law, because conditioning the product law on a zero total squares the one-voxel weights.

The floor of part (d) is $-\log Z = 15 \log \varphi - 3 \log(1 + \varphi^{-2}) = 18 \log \varphi - \frac{3}{2} \log 5 \approx 6.248$. It exceeds $9 \log \varphi \approx 4.331$ by $9 \log \varphi - \frac{3}{2} \log 5 \approx 1.917$ nats. The floor of Theorem 26.41(d) came from the bound $Z \le \pi(0) = \varphi^{-9}$; part (b) computes Z exactly.

Chapter 26, question 6: Theorem 26.57

Take $D = 2$. At the origin put rate 1 on the edges to e_0 and e_1 and rate -1 on the edges from $-e_0$ and $-e_1$; the source is $\sum_i \big(j(0, i) - j(-e_i, i)\big) = 4$, and every edge leaving the box of radius 0 carries $f(0) = 1$ outward.

Fix a shell $\|x\|_\infty = s$ with $s \ge 1$. Its sites receive $1/(2s - 1)$ along each outward edge of the box of radius $s - 1$ and must send $1/(2s + 1)$ along each outward edge of the box of radius s. Consider the side $x_0 = s$, the sites (s, y) with $|y| \le s$. A site with $|y| \le s - 1$ receives $1/(2s - 1)$ from $(s - 1, y)$ and sends $1/(2s + 1)$ to $(s + 1, y)$, an excess of

$$\varepsilon_s = \frac{1}{2s - 1} - \frac{1}{2s + 1} = \frac{2}{(2s - 1)(2s + 1)}.$$

The corner (s, s) receives nothing from inside and sends $1/(2s + 1)$ through each of its two outward edges, to $(s + 1, s)$ and $(s, s + 1)$, a deficit of $2/(2s + 1)$. Route the excess along the side toward the corners: give the edge from (s, y) to $(s, y + 1)$, for $0 \le y \le s - 1$, the rate $(2y + 1)\varepsilon_s/2$, and give the edge from $(s, -y - 1)$ to $(s, -y)$ the rate $-(2y + 1)\varepsilon_s/2$. Then $(s, 0)$ sends $\varepsilon_s/2$ each way, each $(s, \pm y)$ with $1 \le y \le s - 1$ passes on $(2y - 1)\varepsilon_s/2$ and adds its own ε_s, and the corner receives $(2s - 1)\varepsilon_s/2 = 1/(2s + 1)$ from this side. Rotating the same routing to the other three sides, each corner receives $1/(2s + 1)$ from each of its two sides, which is what it sends out. Every site off the origin is balanced, every rate is rational, and every outward edge of the box of radius r carries $f(r) = 1/(2r + 1)$. On the first shell: $(1, 0)$ receives 1, sends

$\frac{1}{3}$ outward and $\frac{1}{3}$ to each of $(1, \pm 1)$, and each corner receives $\frac{1}{3}$ from two axis sites and sends $\frac{1}{3}$ out through each of its two outward edges.

A multiple cj with c an integer has rate $c/(2r+1)$ on the outward edges of the box of radius r. Once $2r+1 > |c|$ this has absolute value below 1, so it is an integer only when $c = 0$. This is the argument of Theorem 26.57(a) in two dimensions: by (26.4) every balanced shell-uniform current on $\mathbb{Z}^2$ has $4(2r+1)f(r) = \operatorname{div} j(0)$ for every r, and integer rates force the source to be 0.

Chapter 27, question 1: Theorem 27.3

For $|\varepsilon| < 1$ the matrix $1 + \varepsilon h = \operatorname{diag}(1, 1+\varepsilon, 1-\varepsilon, 1)$ has positive eigenvalues, and $J(1+y) = y^2/(2(1+y))$ gives

$$J(1+\varepsilon h) = J(1+\varepsilon) + J(1-\varepsilon) = \frac{\varepsilon^2}{2(1+\varepsilon)} + \frac{\varepsilon^2}{2(1-\varepsilon)} = \frac{\varepsilon^2}{1-\varepsilon^2}.$$

Divided by ε^2 it tends to $1 = J_2(h) = \frac{1}{2}\operatorname{tr}(h^2)$. Since $he_0 = 0$ and $\operatorname{tr} h = 0$, the strain is TT at e_0, and $\mathrm{FP}(h, e_0) = 1 \cdot 2 - 0 + 0 - 0 = 2 = |K|^2 \cdot 2J_2(h)$, as part (b) says.

Now $h' = h + E_{03} + E_{30}$ adds the gauge mode $K\xi^{\mathsf{T}} + \xi K^{\mathsf{T}}$ with $K = e_0$, $\xi = e_3$. The block of $1 + \varepsilon h'$ on the coordinates $0, 3$ is $\left(\begin{smallmatrix} 1 & \varepsilon \\ \varepsilon & 1 \end{smallmatrix}\right)$, with eigenvalues $1 \pm \varepsilon$, so the eigenvalues are $1+\varepsilon$ and $1-\varepsilon$, each twice, and $J(1+\varepsilon h') = 2\varepsilon^2/(1-\varepsilon^2)$, with long-wave limit $2 = J_2(h')$. The gauge mode added $J_2(e_0 e_3^{\mathsf{T}} + e_3 e_0^{\mathsf{T}}) = (K \cdot \xi)^2 + |K|^2|\xi|^2 = 1$, as part (c) says. For Fierz–Pauli, $\operatorname{tr}(h'^2) = 4$, $h'e_0 = e_3$ so $|h'K|^2 = 1$, $\operatorname{tr} h' = 0$ and $K^{\mathsf{T}} h' K = 0$, so $\mathrm{FP}(h', e_0) = 4 - 2 = 2$: unchanged, as part (a) requires, since $\Pi_{e_0} h' \Pi_{e_0} = \Pi_{e_0} h \Pi_{e_0}$. The ledger charges the change of coordinates; gravity does not.

Chapter 27, question 2: Theorem 27.5

The dimension is $(D+1)(D-2)/2 = 2$. The vectors orthogonal to both $\mathbf{1}$ and $m = (1, -1, 0, 0)$ are (a, a, b, c) with $2a + b + c = 0$, spanned by $u = (1, 1, -1, -1)$ and $v = (0, 0, 1, -1)$. Every combination of uu^{T}, vv^{T} and $uv^{\mathsf{T}} + vu^{\mathsf{T}}$ is symmetric and kills $\mathbf{1}$ and m; the traces are $|u|^2 = 4$, $|v|^2 = 2$ and $2\,u \cdot v = 0$. So the TT strains at m are spanned by

$$H_1 = uu^{\mathsf{T}} - 2vv^{\mathsf{T}} = \begin{pmatrix} 1 & 1 & -1 & -1 \\ 1 & 1 & -1 & -1 \\ -1 & -1 & -1 & 3 \\ -1 & -1 & 3 & -1 \end{pmatrix}, \qquad H_2 = uv^{\mathsf{T}} + vu^{\mathsf{T}} = \begin{pmatrix} 0 & 0 & 1 & -1 \\ 0 & 0 & 1 & -1 \\ 1 & 1 & -2 & 0 \\ -1 & -1 & 0 & 2 \end{pmatrix}.$$

Each has zero row sums, zero trace, and equal zeroth and first columns, so $H_i\mathbf{1} = 0 = H_i m$; they are independent. Their costs are $J_2(H_1) = 16$ and $J_2(H_2) = 8$, both positive, as part (b) says. In the proof's construction one takes $i = 0$, $j = 1$ and $R = \{2, 3\}$; then $a_k = b_k = \frac{1}{2}$ and $r_k = e_k - \frac{1}{2}(e_0 + e_1)$, and $u = -(r_2 + r_3)$, $v = r_2 - r_3$.

Chapter 27, question 3: Theorem 27.24

Both momenta have zeroth component 0, and $k_1 \cdot k_1 = 9 + 16 + (5i)^2 = 0$, $k_2 \cdot k_2 = 25 + 144 + (13i)^2 = 0$. Since $k_3 = -(k_1 + k_2)$, $\Xi = (k_1 + k_2)\zeta^{\mathsf{T}} + \zeta(k_1 + k_2)^{\mathsf{T}}$ with $\zeta = -\xi$, a gauge mode at $k_1 + k_2$.

The central inversion sends the slot ij to $(4 - j)(4 - i)$: $01 \leftrightarrow 34$, $02 \leftrightarrow 24$, $03 \leftrightarrow 14$, $12 \leftrightarrow 23$, while 04 and 13 are fixed; on slot numbers this is $(0\,9)(1\,8)(2\,6)(4\,7)$. So $000 \mapsto 999$, $444 \mapsto 777$ and $044 \mapsto 977$, which is the monomial 779. In Table 27.2 the form $128\,r$ has the coefficients 4 and 4, -32 and -32, -48 and -48 on these three pairs, and $128\,d$ has 2 and 2, -10 and -10, -24 and -24.

With V_r in place of V_d the test direction $H' = \Xi$ gives $-\frac{1}{4}\mathrm{FP}_1(k_1 + k_2; H_2, \Xi) = 0$ by gauge invariance and $V_r(\eta, \eta, \Xi; k_1, k_2, k_3) = 0$ by part (b), so the equation reads $0 = 0$. The test is a necessary condition for a second-order field: it can exclude one, as it does for J's extra vertex, but passing it constructs nothing. Regge's vertex passes it, so this test leaves Regge's second-order field possible.

Chapter 27, question 4: Theorem 27.26

At $\kappa = 1$, $\det G = 1 - 4\kappa = -3$. The Heron values are $4(1-2) = -4$ on 012, 123, 234; $8(1-3) = -16$ on 013, 023, 124, 134; $12(1-4) = -36$ on 014, 034; and $16(1-4) = -48$ on 024. For 012 directly: its edges have 1, 1 and 2 steps, with squared lengths 0, 0 and $2 - 4 = -2$, and Heron's expression is $-(-2)^2 = -4$. The diagonal of G^{-1} is $(2, 2, 2, (3\kappa - 1)/(4\kappa - 1)) = (2, 2, 2, \frac{2}{3})$, with off-diagonal entries -1. The vertices off 012 are $l = 3$, $m = 4$, and $W_{ij} = (G^{-1})_{ij}$ for $i, j \geq 1$, so

$$W_{33}W_{44} - W_{34}^2 = 2 \cdot \tfrac{2}{3} - 1 = \tfrac{1}{3} = \frac{-4}{4 \cdot (-3)} = \frac{Q_{012}}{4(1 - 4\kappa)}.$$

Chapter 27, question 5: Theorem 27.40

By part (c) the squared Bloch length is $3/(4\kappa - 1) = 3/4$, so the Bloch vector of a posting record has length $\sqrt{3}/2$: the record is mixed, as $\kappa > 1$ requires. A sharp test $(1, \vec{m})$ passes $(1, \vec{p})$ with probability P, $2P - 1 = \vec{m} \cdot \vec{p} \leq \sqrt{3}/2$, so the largest probability is $(2 + \sqrt{3})/4 \approx 0.933$, attained by $\vec{m}$ along $\vec{p}$. Then $\varepsilon = (2 - \sqrt{3})/4$, $1 - 2\varepsilon = \sqrt{3}/2$, and the bound of part (c) reads $\kappa \leq \frac{1}{4} + 3/(4 \cdot \frac{3}{4}) = \frac{5}{4}$, with equality. Distinct posting records have pairing $(2\kappa - 1)/(4\kappa - 1) = \frac{3}{8}$. By part (d) the depolarizing strength satisfies $r^2(2\kappa - 1) = 1$, so $r^2 = \frac{2}{3}$ and $r = \sqrt{6}/3 \approx 0.816$; a posting off the posting plane then has a record of trace $2\kappa/(2\kappa - 1) = \frac{5}{3}$.

Chapter 27, question 6: Theorem 27.44

Write an assignment as (r_0, r_1, r_2) with one-bit records; the law posts a debit when $r_0 + r_1 + r_2$ is even. For the partner $y = 0$ take $(0, 0, 0)$ and $(0, 1, 0)$; for $y = 1$ take $(0, 0, 0)$ and $(0, 0, 1)$; for $y = 2$ take $(0, 0, 0)$ and $(0, 1, 0)$. In each pair the two assignments agree at the site 0 and at y, and their sums are 0 and 1, so one posts a debit and the other a credit. No partner determines the post at 0, so the law is not pair-reading there. Each post is still a single debit or credit on one account, and its cost on the ledger is that of any unit post, whatever decided it.

O.12 The library, learning and open problems

Chapter 28, question 1: Theorem 28.9

In the proof of item 4, $u(x) = 1$ exactly when $\neg(x > 0)$. Since $u(x)$ is a bit, $u(x) = 0$ exactly when $\neg(u(x) = 1)$, that is, when $\neg\neg(x > 0)$. The relation $x \leq 0$ is $\neg(0 < x)$, so $\neg\neg(x > 0)$ is $\neg(x \leq 0)$, and $S(x) = 1$ exactly when $u(x) = 0$. In the same way $S(x) = -1$ exactly when $u(x) = 1$ and $u(-x) = 0$, which gives $\neg\neg(x < 0)$.

Now assume MP. If $|S(y)| > 0$, then $S(y) \neq 0$, and since the three cases of the construction are decided, $S(y) = 1$ or $S(y) = -1$. In the first case $\neg\neg(y > 0)$, in the second $\neg\neg(y < 0)$. MP in the form $\neg\neg(x > 0) \to x > 0$ (Corollary 12.18), applied to y or to $-y$, gives $y > 0$ or $y < 0$, that is, $y \# 0$. For $y \# 0$ we have $|S(y) - S(0)| = 1$, so S jumps at 0, and the jump carries a test. Part 2 of Theorem 28.8 gives the LPO function. So the WLPO function together with MP gives the LPO function.

Without MP the step from $\neg\neg(y > 0)$ to $y > 0$ is missing. The value $S(y) = 1$ records only that y is not ≤ 0. Corollary 12.18 prices the passage from that to positivity at MP, so the jump of S need not carry a test, and only part 1 of the rule applies. That part gives the WLPO function, which is the price of S.

Chapter 28, question 2: Theorem 28.45

The strict slacks are $a - 0$ and $b - a$. Expand:

$$(b-a)^2 + 3a(b-a) + 3a^2 = b^2 - 2ab + a^2 + 3ab - 3a^2 + 3a^2 = b^2 + ab + a^2,$$

and $(b-a)(b^2 + ab + a^2) = b^3 - a^3$. So, with $k_1 = 1$ and

$$\begin{aligned} k_2 = (b-a)\cdot\big((b-a)(b-a) + (a-0)(b-a) + (a-0)(b-a) + (a-0)(b-a) \\ + (a-0)(a-0) + (a-0)(a-0) + (a-0)(a-0)\big), \end{aligned}$$

the identity $k_1 \cdot (b\cdot b\cdot b - a\cdot a\cdot a) = k_2$ holds at every point, by the ring laws (Proposition 12.19). The expression k_2 is built from the strict slacks by sums and products, so it is a cone expression, and $k_1 = 1$ is one too. Part 1 of Theorem 28.45 gives $a\cdot a\cdot a < b\cdot b\cdot b$ at every point satisfying $0 < a$ and $a < b$.

Density applies to closed conclusions only. Part 1 of Theorem 28.42, with the strict atoms $0 < a$ and $a < b$ as hypotheses, would move the closed atom $a\cdot a\cdot a \leq b\cdot b\cdot b$, which holds at all ratios satisfying them, but not the strict inequality. A strict conclusion need not survive the limit (Proposition 28.43, item 1).

Chapter 28, question 3: Theorem 28.50

Here $\|d_n\| + 1 = 10n + 16$. For $n = 6$ this is $76 \geq 64 = 2^6$, and for $n = 7$ it is $86 < 128 = 2^7$, so the least n is 7. There $\|d_7\| = 85$, while $\|t_{d_7}\| \geq 4^8 = 65{,}536$.

For given C and k the proof puts $a = C\cdot 16^k$, $j = k+a+4$ and $n = 2^j - 1$. Since $10n+16 \leq 16(n+1)$, $C(\|d_n\|+1)^k \leq a(n+1)^k = a\,2^{jk}$. For $j \geq 4$, $j^2 \leq 2^j$: this holds at $j = 4$, and $(j+1)^2 = j^2 + 2j + 1 \leq$

$2j^2$ for $j \geq 3$. Moreover $j^2 = jk + ja + 4j \geq jk + a + 16$, so $a + jk \leq j^2 - 16 < 2^j - 1 = n$. Since $a < 2^a$ for every a,

$$C(\|d_n\| + 1)^k \leq a\, 2^{jk} < 2^{a+jk} \leq 2^n \leq \|t_{d_n}\|.$$

Chapter 28, question 4: Theorem 28.52

Suppose $\|F(d)\|^q \leq C(\|d\| + 1)^p$ for every d with $\mathrm{sh}(d) \leq 3$, where $2p < 5q$. Every formula concluded in B_K has shape at most 3, so B_K qualifies. For $K \geq 1$, $\|B_K\| + 1 = 14K^2 + 28K + 16 \leq 16(K+1)^2 \leq 64K^2$, so the reported count $5K^5 \leq 6\,\|F(B_K)\|$ gives

$$\Big(\frac{5K^5}{6}\Big)^q \leq \|F(B_K)\|^q \leq C \cdot 64^p K^{2p},$$

and $K^{5q-2p} \leq C \cdot 64^p (6/5)^q$ for every $K \geq 1$. Since $5q - 2p \geq 1$, this fails for large K.

For part 3 the family is useless: B_K keeps K hypotheses open, so $\mathrm{cx}(B_K) = K$, and for $K > c$ it leaves the class of part 3. Its growth comes from exactly the long hypothesis lists that part 3 excludes; there the lower bound comes from the size of the matrix instead.

Chapter 28, question 5: Theorem 28.53

If $x = t(x) + t(x)$, then $2t(x) = x$; if $x = t(x) + t(x) + 1$, then $2t(x) = x - 1$. Either way $2t(x) \leq x \leq 2t(x) + 1$, so $x/2 - 1 < t(x) \leq x/2$, and $t(x)$ is the one integer in that interval, $\lfloor x/2 \rfloor$.

The proof of the theorem uses the derivation h, the specification of the compiler in Theorem 28.51 (the matrix holds at $\mathrm{val}(t)(x)$ for every x), the arithmetic just given, and item 4 of Theorem 28.49 for the orbit. The specification already determines the value, because the matrix has exactly one witness for each x. The inside of the program, its size and its evaluation do not affect the value; they affect only what the value costs to compute.

Chapter 28, question 6: Theorem 28.56

Let φ preserve 0, 1, sums and products, and reason classically. For every real s, $\varphi(s^2) = \varphi(s)^2 \geq 0$, and every nonnegative real is a square, so φ maps nonnegative numbers to nonnegative numbers. If $x \leq y$, then $\varphi(y) - \varphi(x) = \varphi(y - x) \geq 0$, so φ is monotone. From $\varphi(1) = 1$ and additivity, $\varphi(n) = n$ for every integer n, and $\varphi(u/d) \cdot d = \varphi(u) = u$ gives $\varphi(q) = q$ for every rational q. If $\varphi(x) < x$, take a rational q with $\varphi(x) < q < x$; monotonicity gives $q = \varphi(q) \leq \varphi(x)$, a contradiction. In the same way $\varphi(x) > x$ is impossible, so $\varphi(x) = x$.

To deduce item 2, let D and D' have the properties of item 1. If $D(x) = D(y)$, then neither $x < y$ nor $y < x$, so $x \leq y \leq x$ and $x = y$ (Proposition 12.19, item 2). So D is injective, and it is onto, so classically it has an inverse D^{-1}, which also preserves 0, 1, sums and products. Then $D' \circ D^{-1}$ preserves them, so it is the identity, and $D' = D$.

For Proposition 28.57 at $n = 2$, expansion along the first column gives $\det M = M_{00} \det M^{(0,0)} - M_{10} \det M^{(1,0)} = M_{00}M_{11} - M_{10}M_{01}$. In the permutation sum, the identity contributes $M_{00}M_{11}$. The exchange $\pi(0) = 1$, $\pi(1) = 0$ has sign -1 and contributes $-M_{\pi(0)0}M_{\pi(1)1} = -M_{10}M_{01}$. The two agree.

Chapter 29, question 1: Theorem 29.4

In $H(\alpha)$ the atom p_0 is forced at stage n exactly when $\alpha(k) = 1$ for some $k \le n$, so here exactly at the stages $n \ge 3$. The formula $\neg p_0$ is forced at n only if no stage $u \ge n$ forces p_0; since stage $\max(n, 3)$ forces p_0, $\neg p_0$ is forced at no stage. Consequently $\neg\neg p_0$, which asks that no later stage force $\neg p_0$, is forced at every stage. At stage 0, p_0 is not forced (the record has not yet seen the event) and $\neg p_0$ is not forced (stage 3 refutes it), so em $= p_0 \vee \neg p_0$ fails there; wem $= \neg p_0 \vee \neg\neg p_0$ holds through its second disjunct. What makes wem true at stage 0 is the fact that α is not all zero, which the record at stage 0 does not show. Asking for wem at stage 0 in every history therefore asks to decide, for every α, whether it is all zero, and that is WLPO, as part 2 of the theorem states.

Chapter 29, question 2: Theorem 29.8

The law gives $\frac{1}{3}$ to each of 100, 010, 001; it is exchangeable. Its first two records have the law $P_2(00) = \frac{1}{3}$ (from 001), $P_2(10) = \frac{1}{3}$, $P_2(01) = \frac{1}{3}$ and $P_2(11) = 0$. Every record has one entry 1, so the coin mixture is the single coin of bias $\frac{1}{3}$: $Q_2(00) = \frac{4}{9}$, $Q_2(10) = Q_2(01) = \frac{2}{9}$, $Q_2(11) = \frac{1}{9}$. The sum of the absolute differences is $\frac{1}{9} + \frac{1}{9} + \frac{1}{9} + \frac{1}{9} = \frac{4}{9}$, and the total variation distance is $\frac{2}{9}$. The theorem's bound is $2(1 - (3)_2/3^2) = 2(1 - \frac{6}{9}) = \frac{2}{3}$, and $m(m-1)/n = \frac{2}{3}$ as well; indeed $\frac{4}{9} \le \frac{2}{3}$. Sampling two of three records without replacement can never show 11, while the coin shows it with probability $\frac{1}{9}$: this is the whole discrepancy, spread over the four records.

Chapter 29, question 3: Theorem 29.15

The recognition history begins dcddcdcddcddcdcddcdcd, the word W_6 of Definition 21.24, so the golden record begins

$$0\,1\,0\,0\,1\,0\,1\,0\,0\,1\,0\,0\,1\,0\,1\,0\,0\,1\,0\,1\,0.$$

Its windows of length 3 are 001, 010, 100 and 101: four, which is 3 + 1, as Theorem 29.15 requires; 000 and 011 never occur, and 110, 111 would violate balance. The windows of length 2 are 00, 01 and 10. Of these, 10 is right special, since both 100 and 101 occur, while 00 continues only to 001 and 01 only to 010. So $p(3) = p(2) + 1$, as in the proof of Theorem 29.14(2).

Chapter 29, question 4: Theorem 29.31

Write e_x for the law that is 1 exactly at x. Every point x splits H, into $H_{x,1} = \{e_x\}$, of dimension 0, and the other three laws; so $\mathrm{ldim}(H) = 1 + 0 = 1$. On the target e_3 with the points 0, 1, 2, 3: at 0 the part with label 1 is $\{e_0\}$, of rank 1, and the part with label 0 has three laws and dimension 1, rank 2; the learner predicts 0, correctly. At 1 the same comparison gives 0, correctly. At 2 the two parts are $\{e_2\}$ and $\{e_3\}$, both of rank 1, so the learner predicts 1 and errs; only e_3 remains, and the prediction at 3 is right. One mistake, equal to the dimension. The halving learner also predicts 0, 0, 1, 1 here and errs once, but its guarantee from Theorem 29.29(1) is only $\log_2 4 = 2$; the dimension gives the exact worst case, which by part 2 of Theorem 29.31 no learner can improve.

Chapter 29, question 5: Theorem 29.39

For the records 1 and 4, $S = 5$ and $T = 1 + \frac{1}{4} = \frac{5}{4}$, so $m_*^2 = 4$ and $m_* = 2$, with $\tau = m_* T = \frac{5}{2}$. The least cost is $C(2) = \tau - 2 = \frac{1}{2}$, and directly $J(\frac{1}{2}) + J(2) = \frac{1}{4} + \frac{1}{4} = \frac{1}{2}$. The learner uses $f_0 = 1$ for the first record and the centre $f_1 = 1$ of $\{1\}$ for the second, paying $J(1) + J(4) = 0 + \frac{9}{8}$; its regret is $\frac{9}{8} - \frac{1}{2} = \frac{5}{8}$. The identity of part 4 reads

$$\frac{9}{8} = C_2(f_2) + f_1 T_1 J(f_0/f_1) + f_2 T_2 J(f_1/f_2) = \frac{1}{2} + 1 \cdot 1 \cdot J(1) + 2 \cdot \frac{5}{4} \cdot J(\tfrac{1}{2}) = \frac{1}{2} + 0 + \frac{5}{8},$$

with $f_2 = 2$: the regret is the J-cost of the one change of frame, from 1 to 2, weighted by $\tau = \frac{5}{2}$.

Chapter 29, question 6: Theorem 29.47

For one world ω with its entry 1 at m, the learner of part 3 stays silent below $m + 1$ and then commits by the entry at m; it is correct on both worlds because ω is decided. A single learner for all of them fails by part 1: it commits on the zero world at some stage N to a program z, the world whose only entry 1 is at N has the same record of length N, so the learner commits to z on it too, and z computes the zero world. The same argument shows that the catalogue of the zero world and these worlds has no locking function: if g were one and the zero world had index i_0, the world with its only entry 1 at $g(i_0)$ would agree with the zero world below $g(i_0)$ without being equal to it. By Theorem 29.48(3) these two facts are the same fact; by part 4, the catalogue is nevertheless learned in the limit with one change of mind, at no price.

Chapter 30, question 1: Lemma 30.3

Here $\sqrt{5} - 2 \approx 0.23607$. For $k = 1, 2$ the nearest integer is $m = 0$, and $6k|k(\sqrt{5} - 2)|$ equals $6\sqrt{5} - 12 \approx 1.416$ and $24\sqrt{5} - 48 \approx 5.67$; the first is at least 1 because $6\sqrt{5} \geq 13$, that is $180 \geq 169$. For $k = 3, 4, 5$ the nearest integer is $m = 1$, and the distances are $7 - 3\sqrt{5} \approx 0.2918$, $9 - 4\sqrt{5} \approx 0.0557$ and $5\sqrt{5} - 11 \approx 0.1803$, giving 5.25, 1.337 and 5.41. The case $k = 4$ comes closest: $24(9 - 4\sqrt{5}) = 216 - 96\sqrt{5} \geq 1$ because $215^2 = 46225 \geq 46080 = 96^2 \cdot 5$. The proof of the lemma explains it: with $M = m + 2k = 9$, $5k^2 - M^2 = 80 - 81 = -1$, so $|4\sqrt{5} - 9| = 1/(4\sqrt{5} + 9)$, as small as the lemma allows up to the factor $6|k|/(4\sqrt{5} + 9) \approx 1.34$. The denominators $1, 4, 17, 72, \ldots$ of the convergents of $[0; 4, 4, 4, \ldots]$ are where such near equalities occur.

Chapter 30, question 2: Theorem 30.9

Here $i = 2$, $p = 4$, $j = 5$, $q = 6$, so $\gcd(4, 6) = 2$ and the join is $\sim_{2,2}$: counts at least 2 are identified when they have the same parity. Directly, $4M \equiv 2 \pmod 6$ has the solution $M = 2$, and for $t \geq 2$

$$t \sim_{2,4} t + 28 \sim_{5,6} t + 22 \sim_{2,4} t + 2.$$

Since $2 < 5$ and $4 \nmid 6$, the criterion fails. Take $a = 4$ and $b = 2$, related by the join. A count n with $n \sim_{5,6} 2$ must be 2 itself, because 2 is below the index 5; and $2 \sim_{2,4} 4$ would need $4 \mid 2$. So no common count exists.

Chapter 30, question 3: Theorem 30.13

The number $\sqrt{3}-1 \approx 0.732$ is a root of t^2+2t-2, whose other root $-1-\sqrt{3} \approx -2.732$ lies outside $[-1,1]$; so it is a rate. The recipe of the proof, with $a=1$, $b=2$, $c=-2$, gives $CD=1$, $DC=3$, $q=-6$, $DD=13$, $CC=7$, the join $\mathsf{d} \mapsto \mathsf{d}^{13}\mathsf{c}$, $\mathsf{c} \mapsto \mathsf{d}^{3}\mathsf{c}^{7}$; indeed $(1+t)^2-6(1-t^2)-3(1-t)^2 = 4(t^2+2t-2)$. A smaller join with the same CD, DC and $CC-DD$ is $\mathsf{d} \mapsto \mathsf{d}^{6}\mathsf{c}$, $\mathsf{c} \mapsto \mathsf{ddd}$, primitive at the second power: its Perron root is $3+2\sqrt{3}$, its Perron vector $(3, 2\sqrt{3}-3)$, so $\beta = 3+2\sqrt{3}$ and the rate is $(2+2\sqrt{3})/(4+2\sqrt{3}) = \sqrt{3}-1$. The number $\sqrt{3}/3$ is a root of $3t^2-1$; every integer quadratic with this root is a rational multiple of it, and the other root $-\sqrt{3}/3$ lies in $[-1,1]$. So $\sqrt{3}/3$ is not a rate.

Chapter 30, question 4: Theorem 30.14

Both joins have incidence counts $2,1,1,2$, Perron vector $(1,1)$ and rate 0, so the discrepancy is the balance. For the first, $\sigma^2(\mathsf{d}) = \mathsf{dcd\,cdc\,dcd}$, whose prefix balances for $m = 0,\dots,8$ are $0,1,0,1,0,1,0,1,0$, while the letter at position m is d for even m and c for odd m; with $\pi(\mathsf{d})=0$, $\pi(\mathsf{c})=1$, the coboundary asks exactly $\pi(\text{letter } m)-\pi(\mathsf{d})$, which is 0 or 1 as it should be. The word $\sigma^2(\mathsf{c}) = \mathsf{cdc\,dcd\,cdc}$ has prefix balances $0,-1,0,-1,\dots$ and letters $\mathsf{c},\mathsf{d},\mathsf{c},\dots$, and $\pi(\text{letter } m)-\pi(\mathsf{c})$ is 0 or -1 accordingly. For the second join, $\sigma^2(\mathsf{d}) = \mathsf{ddc\,ddc\,ccd}$; at $m=1$ the prefix d has balance 1, and the letter at position 1 is d, so a coboundary would need $1 = \pi(\mathsf{d})-\pi(\mathsf{d}) = 0$. None exists, and by the theorem the books are not balanced.

Chapter 30, question 5: Theorem 30.24

On the triad $(0,1,7)$ the cycle $e^{2\pi B/3}$ sends $e_0 \mapsto e_1 \mapsto e_7 \mapsto e_0$. So one braid token of angle $2\pi/3$ moves 7 to 0, and one of angle $-2\pi/3$, the inverse cycle, moves 0 to 7; each drives $2\pi/3$, which is optimal by the theorem. A token of angle $\pi/2$ on this triad has diagonal entries $(1+2\cos\frac{\pi}{2})/3 = \frac{1}{3}$ at the labels $0,1,7$ and 1 elsewhere. A certain change out of a label needs the diagonal entry there to vanish, since the column is a unit vector with an entry of modulus 1 elsewhere; so the token moves no label with certainty, in line with Theorem 30.22(b).

Chapter 30, question 6: Theorem 30.35

In the coordinates $(i,j,7)$ and with $c = 1/\sqrt{3}$, $A = \begin{pmatrix} 0 & -c\theta & c\theta \\ c\theta & 0 & -c\theta \\ -c\theta & c\theta & -\mathrm{i}\varepsilon \end{pmatrix}$. Write $\omega = (\omega_1,\omega_2,\omega_3)$. The first row gives $c\theta(\omega_3-\omega_2) = c\theta(-3x^2-\mathrm{i}\sqrt{3}\theta x) = -\sqrt{3}\theta x^2-\mathrm{i}\theta^2 x$, and $-\mathrm{i}x\,\omega_1 = -\mathrm{i}\theta^2 x-\sqrt{3}\theta x^2$. The second row gives $c\theta(\omega_1-\omega_3) = c\theta(3x^2-\mathrm{i}\sqrt{3}\theta x) = \sqrt{3}\theta x^2-\mathrm{i}\theta^2 x$, and $-\mathrm{i}x\,\omega_2 = -\mathrm{i}\theta^2 x+\sqrt{3}\theta x^2$. The third row gives $c\theta(\omega_2-\omega_1)-\mathrm{i}\varepsilon\omega_3 = 2\mathrm{i}\theta^2 x-\mathrm{i}\varepsilon(\theta^2-3x^2)$, while $-\mathrm{i}x\,\omega_3 = -\mathrm{i}\theta^2 x+3\mathrm{i}x^3$; they agree exactly when $3x^3-3\varepsilon x^2-3\theta^2 x+\varepsilon\theta^2 = 0$, that is $p(x)=0$.

Appendix P

Finding an argument

This guide follows the questions answered by the main proofs. Each entry points to the conclusion and to the earlier result on which it depends. It is a route back into the argument, with the hypotheses kept in view.

P.1 What determines arithmetic?

Theorem 1.4 identifies the finite orbit expressions with their natural-number readings in both directions. The initial-map theorem, Theorem 2.3, then constructs a unique reading into any pointed step system. To make that reading bijective, use the injectivity and generation conditions of Definition 2.4; the conclusion is Theorem 2.7. Proposition 2.8 shows that these conditions are also necessary for a bijective reading.

The arithmetic operations are developed in Chapter 3. Their order of proof matters: the preparation lemmas support addition's laws, and those laws support multiplication. For the passage to signed differences and ratios, start with the two equivalence relations in Chapter 4. The well-definedness arguments explain why an operation gives one answer despite a change of representatives. Theorem 3.10 and Corollary 3.12 show that the operations are forced once adding one is the step, and Proposition 3.11 gives the unique map into every commutative semiring. Section 4.9 proves that each extension is the unique solution of its task: Theorem 4.13, Corollary 4.14 and Theorem 4.15, with the forced order in Proposition 4.16. Theorem 12.38 does the same for the line built from ratios, with countable choice.

P.2 What does a proof use?

The rules are collected in Appendix D; their interpretation and soundness are in Theorem 5.5. For the additional rules, Theorem 6.6 states the surrounding principles that validate the recorded uses. Chapter 6 also separates a proof's actual ledger from a claim of necessary resources. Section 5.7 shows what separation, injectivity and induction each supply, using Theorem 5.8. With induction on every formula, the exact price of each additional rule is given by Theorems 6.9, 6.10 and 6.11; Proposition 6.13 gives the prices without induction, and Proposition 6.14 with induction on quantifier-free formulas only. Corollary 6.15 replaces the assumptions of Theorem 6.6 by the least ones: an MP entry needs no principle, and the derivations with an EM or LPO entry need, taken together, exactly the metatheoretic LPO for the predicates that formulas of the language define, which for these predicates is the same as excluded middle. Theorem 8.11 identifies the rules, with excluded middle and without LPO and MP, with Peano arithmetic, and Corollary 8.12 identifies the posit-free derivations with Heyting arithmetic, up to how the injectivity of the successor is written.

The constructive recognition catalogue begins with a decidable relation and an exhibited collision: Theorem 7.6. Its priced formulations and their reverse implications appear in

Theorems 7.7, 7.9 and 7.10, and Section 7.9 collects them. Theorem 7.11 carries the prices to readers, and Corollary 7.13 carries all six prices to signed records, with the parity question asked of the period. Theorem 7.38 shows that the six prices are different: Section 7.12 builds the four models of intuitionistic second-order arithmetic that separate them, with Lemma 7.21 turning each model into a failure of derivability. Section 7.13 goes between them: Theorem 7.45 splits Markov's principle into two halves, Proposition 7.46, with Lemma 7.41, gives a strictly descending chain of prices below LLPO, Theorem 7.47 two further intermediate prices, and Corollary 7.49 shows that the six prices are not all the prices. Theorem 8.6 shows that the two arithmetic presentations satisfy the same formulas, Theorem 8.8 what a one-way translation keeps, and Proposition 8.9 that no other quantifier prefix is kept. For a general reader, the quotient is identified with its range in Theorem 8.13.

P.3 Which constructions give stronger eliminations?

Begin with the exact language in Section 9.2. The separation results culminate in Theorem 9.10; the model argument they use is completed in Section 9.8. In particular, the countermodels must preserve substitution and conversion, and the separating families must be expressible. Those checks make the displayed models evidence about the specified language. That the strongest fragment proves the translation of every theorem of Peano arithmetic is the first assertion of Theorem 20.39; the second gives the converse, through the compiled programs of Section 20.3.

P.4 Does a richer language prove more about numbers?

Theorem 8.11 identifies Peano arithmetic with the derivations whose ledger records neither LPO nor MP. The language of functions of Section 20.3.2 is read through compiled programs. Follow the argument in four stages.

Computation inside arithmetic. Theorem 20.3 describes computations by an arithmetic formula and derives its functionality and closure laws; Theorem 20.5 derives the two facts about the record test, and Lemma 20.10 turns them into the law every compiled application uses. The routine cases are in Appendix K.

Reading formulas. Hereditary equality and its symmetry and transitivity are Proposition 20.11; the reading is exact by Theorem 20.12. Typed terms return related values, Theorem 20.15, through Lemmas 20.13 and 20.14.

Substitution and the rules. Substitution is Theorem 20.18, built on Lemma 20.16 and Theorem 20.17. The nineteen rules are assembled in Theorem 20.26, with conversion in Theorem 20.22, extensionality in Theorem 20.24 and induction in Theorem 20.25.

Back to arithmetic. Theorem 20.31 recovers a negative sentence from its reading, Theorem 20.32 gives conservativity, and Theorem 20.39 compares $\mathscr{E}^+$ with Peano arithmetic, using Lemma 20.33, Theorem 20.36 and Theorem 20.38. Consistency, Gödel's second incompleteness theorem, a universe, bounded arithmetic and finite set theory follow in Section 20.3.11, and Löb's theorem and the tower of consistency statements in Section 20.3.12. Section 20.4 converts classical proofs shape by shape, for the shapes of the book's arithmetic language:

Theorem 20.57 translates derivations, Theorems 20.59 and 20.63 and Corollary 20.65 give the free shapes, and Theorem 20.66 with Table 20.4 collects the prices.

P.5 When does finite information give one uniform procedure?

Theorem 10.3 assembles compatible finite-stage maps. Faithful program storage is Theorem 10.8. Neither result by itself supplies termination at every precision. Theorems 10.12 and 11.11 state the stronger naming property and the boundary between it and separate finite-prefix descriptions.

For interval protocols, existence of a displayed classical value and its uniqueness are established in Chapter 11. Equality of those values agrees with observational equality in Theorem 11.5. The exact logical costs of zero testing, trichotomy, the weaker sign decision and the sign of a nonzero quantity are Theorems 12.6, 12.7, 12.8 and 12.11. Theorem 12.17 and Corollary 12.18 carry them to the line built from ratios. Table 12.3 prices that line's completeness; the results from Theorem 12.25 to Proposition 12.62 prove its rows, in both directions wherever a row names a price, and Theorems 12.72, 12.75 and 12.77 price weak König's lemma, the pigeonhole principle and Ramsey's theorem for pairs. Theorem 12.22 shows that the countable choice those prices use decides none of the omniscience principles, and Theorem 12.63 that excluded middle, without unique choice, cannot replace it. Table 13.1 prices compactness: Heine–Borel for $[0,1]$ and for presented sets, and positive bounds and infima of presented maps, are each equivalent to the decidable fan theorem with no choice principle (Theorems 13.6, 13.25 and 13.28, Corollary 13.30). Table 14.1 prices linear algebra on the line (Theorems 14.13, 14.16 and 14.28), and Section 12.10 the calculus on the line (Table 12.4). Keep the chosen representation and the stated comparison relation attached to each result.

Certified computation turns precision into a count. A certified real has the modulus of Definition 15.1, and Proposition 15.4 keeps precision additive. The solution value of a quadratic field, and through its quadratization that of a polynomial field, is a certified real by Theorem 15.22, from the region certificate through Theorems 15.20 and 15.21; its arithmetic is counted in Theorem 15.23 and its operands in Proposition 15.26. Theorem 15.29 identifies the point with the classical solution under classical hypotheses, and Theorem 15.33 proves a bound $K(m+1)^{\lambda}$ for one fixed binary machine, with one exponent λ for all problems; its stage programs are constructed in Appendix I.

P.6 What can a calculus of δ's objects derive?

Chapter 16 writes statements about points, functions and compact sets as sentences of one calculus. Theorem 16.8 shows that every derivation holds at both stages of every carrier, and Theorem 16.11 that every derivation of the second-order system of Section 7.10 translates into it. Theorem 16.14 explains why the full calculus has no recursive reading, and Proposition 16.15 shows that it derives every true sentence built from equations over constant carriers, LPO and $\mathrm{WLPO}_{\mathrm{seq}}$ among them. Definitions 16.18 and 16.20 give the computable calculus and its model, Theorem 16.22 shows the model sound, and Theorem 16.25 compiles the second-order system into the computable calculus. In that calculus LPO decides each question without collecting

the answers (Theorem 16.27), and the fan theorems, weak König's lemma, and Heine–Borel, positive bounds and infima and Heine–Cantor for presented sets, written with equations, are not derivable, even from LPO and with excluded middle as a base rule (Theorems 16.32 to 16.36).

P.7 What can a physical record preserve?

The collision lemma leads to exact capacity in Theorem 17.4. Adaptive tests are handled by constructing their full transcripts before applying the same argument; the bound is Theorem 17.7. Approximate targets require the strict separation margin in Theorem 17.9. Theorem 17.13 says which questions a finite record confirms or refutes; Theorems 17.15 and 17.17 and Proposition 17.18 say what records cannot settle and what that costs, Theorem 17.20 treats revisable verdicts, and Theorem 17.21 shows that an exact value can be refuted but never confirmed.

For finite instruments, Theorem 18.3 constructs the whole-space unitary. The naming equivalence is Theorem 18.9, and the supplied-control physical construction is Theorem 18.11. Appendix A gives the finite-control argument. The construction retains the mark, returned state and any finite reference.

The conserving-recorder restriction has different apparatus conditions. Theorem 19.5 combines the noise estimate, the explicit source witness and the recorder spread bound. Its derived count uses the finite identity proved in Appendix B. Chapter 20 brings these conclusions together while retaining the conditions of each.

P.8 What does a comparison cost?

Chapter 21 starts from an arbitrary function on the line. Theorem 21.14 shows that the composition law and the calibration of Definition 21.10 leave exactly one cost, $\cosh t - 1$ in logarithmic form and J of Definition 21.11 for ratios. Its proof combines Proposition 21.12, the duplication argument of Theorem 21.13 and the logarithm of Proposition 21.5, and uses no omniscience and no choice. The functions it needs come first: Theorem 21.8 proves that the sine's period is $2\pi_\delta$. Proposition 21.20 restricts the forcing theorem to the golden orbit, and Theorems 21.22 and 21.23 characterize J, in classical mathematics, as the cost of one fair binary distinction. Theorem 21.25 identifies the ledger with $\mathbb{Z}[\varphi]$, ordered by the sign test of Lemma 21.19; Theorem 21.26 reads its history as a sigma-delta encoder of φ^{-3}; and Theorem 21.27 shows that balances and rates are δ's integers and ratios.

Whether a given cost obeys the law is a decision with a price. Under the reading of maps of Section 21.1 it is computed in Theorems 21.29, 21.30, 21.31 and 21.32, and under unique choice in Corollary 21.33; Table 21.1 collects the answers. Theorem 21.37 and Corollary 21.38 show, in classical mathematics, that a comparison which changes a record with certainty costs $J \geq \frac{1}{4}$, less a drift from the holding of the register, when the reference action is one cycle.

P.9 What does the forcing chain of Recognition Science cost?

Chapter 22 restates each step of the chain on $\mathbb{R}_\delta$ (Section 22.1) and prices it in the sense of Definition 22.1. Records compare for free and points do not, Proposition 22.2. The cost enters through a meter: Theorem 22.5 shows that every meter reads a ratio, and the native reporting theorem, Theorem 22.11, turns the apparatus law into J. Theorem 22.12 replaces continuity by reciprocity and order, and Theorem 22.14 shows that, given the WLPO function, ratio reports alone do not force J. That a ratio other than 1 has positive cost is exactly MP (Theorem 22.16). Golden scaling is free (Theorem 22.20), and Theorem 22.24 prices three readings of the first costly join: free for apart parts, MP for distinct parts and $\mathrm{SE}_{\mathbb{Z}}$ for an integer pairing. The second rung carries the prices of Theorems 22.31, 22.32 and 22.33; the constants are Section 22.9, with the units test in Theorem 22.44. Theorem 22.45 proves the restated numbered chain free, step by step, and Section 22.11 with Table 22.1 sorts all 130 rows: 119 free, ten with an exact price, one bracketed and none open.

P.10 Why three dimensions?

Theorem 23.8 says that a natively embedded circle can be linked in the native D-sphere exactly when $D = 3$, with no omniscience and no choice. That D is the dimension of space, and that a kept pair of records is a linked curve, are Recognition Science's readings in its forcing chain (Chapter 22); the theorem proves the topology, not the readings. Its proof, in Section 23.9, has two halves. For $D = 3$, Theorem 23.34 shows that the equatorial circle is linked: the loop of Lemma 23.33 sweeps four quarter turns, and the linking value of Definition 23.31 is a cocycle (Lemma 23.32). For $D \neq 3$, Proposition 23.23, through Lemmas 23.20, 23.21 and 23.22, shows that a linked circle needs a 3-cycle of the sphere that bounds nothing, and the suspension ladder, Proposition 23.19, shows that every 3-cycle bounds when $D = 2$ or $D \geq 4$; Proposition 23.24 settles dimensions 0 and 1. The tools that work in every dimension are Lemmas 23.9 to 23.14. Theorem 23.38 computes the first homology of the circle as a relation, free, and Theorem 23.40 with Theorem 22.65 prices its data form at exactly the WLPO function.

P.11 What does one account's ledger contain?

Chapter 24 reads the counts of a double-entry account. Theorem 24.2 shows that one account's records fill a light cone, Theorem 24.4 reads J as velocity and the Lorentz factor, and Theorem 24.5 proves proper time superadditive: for words w_1, w_2 whose counts are all positive, $\tau(w_1 w_2)^2$ exceeds $(\tau(w_1) + \tau(w_2))^2$ by $2\tau(w_1)\tau(w_2)$ times a value of J; Proposition 24.6 extends this to many legs. Theorems 24.8 and 24.10 follow the recognition history. Several accounts reach only the taxicab cone (Theorem 24.12). The cone of one time and three space dimensions is the record cone of a coherent binary distinction (Theorem 24.14), whose coherent changes give the Lorentz group (Theorem 24.15); Theorems 24.17, 24.19, 24.20 and 24.22 say where the distinction is carried. Theorem 24.25 identifies the comparison cost of a history with its proper-time deficit. The clock's resolution, its self-recognition band and the action floor of a native step are Theorems 24.29, 24.31 and 24.34. Questions about an unending balance

history are priced in Theorems 24.39, 24.41 and 24.43, on the record questions of Section 17.7. Readings of counts as time and position are identifications throughout.

P.12 What does classical physics cost on the line?

Chapter 25 moves mechanics onto $\mathbb{R}_\delta$. A motion is determined by its initial state (Theorem 25.3). For Kepler's problem, Theorem 25.9 gives the integrals and the conic, Theorem 25.10 solves Kepler's equation with no choice, and Theorems 25.20 and 25.21 show that every bound non-radial motion returns, free. The perihelion direction lies between LLPO and LLPO with countable choice: a perihelion direction for every planar state implies LLPO, and LLPO with countable choice provides it (Theorem 25.13). N bodies keep ten integrals (Theorem 25.25). The relativistic orbit runs from the orbit equation (Theorems 25.35 and 25.37) to the motion in proper time: Theorems 25.42 and 25.43 give the perihelion advance to second order, and Theorems 25.46 and 25.47 the periods in proper time and for a far observer. Certified runs are motions (Theorem 25.50), and Theorem 25.59 gives one conversion certificate for a whole polynomial theory. For the rigid body, Theorem 25.62 proves rotation about an extreme axis stable, and Theorem 25.63 prices the decision of which axis that is at exactly LPO.

Chapter 26 begins with entropy on the line: Theorem 26.5 is the Gibbs principle, Theorem 26.6 prices its decisions, and Theorem 26.7 is the H-theorem. Relative entropy never rises under a stochastic step (Theorem 26.10), and Theorems 26.11 and 26.12 say where and when it falls. Its theorems on voxel ticks are proved for every voxel tick with the properties they state. For Recognition Science's tick the chapter takes five numerical properties of its kernel, (T1)–(T5), as stated inputs that it does not prove, and each result names the ones it uses. From (T1)–(T4), Theorem 26.23 with Proposition 26.25 gives strict decrease on inward-closed sets, Corollary 26.29 a rate from a point start, Corollary 26.37 the pace, and Theorem 26.42 the spine's sharp cutoff; the sharper bounds on the pace and the cutoff hold under hypothesis (R), about the output of a finite computation, which the chapter states and does not prove. Theorem 26.31 is a second law with a rate that is free on the line. The lattice fields are the results from Theorem 26.46 to Theorem 26.50, and Theorem 26.52 prices every sign law.

P.13 What does the cost say about gravity?

Chapter 27 compares J with linearized gravity. On transverse-traceless strains the Fierz–Pauli form is the dispersion $|K|^2$ times twice J's long-wave form (Theorem 27.3), the calibration of J fixes the factor (Theorem 27.4), and such strains exist exactly in three or more space dimensions (Theorem 27.5). The identity holds over every commutative ring (Theorem 27.6), hence on $\mathbb{R}_\delta$, where Theorem 27.8 prices the decisions about a wave. J allows every completion (Theorem 27.10), and locality selects Fierz–Pauli (Theorems 27.11 and 27.12). Curvature and lattice deficits see exactly the non-gauge part (Theorems 27.15 and 27.20), and no nonzero local invariant form is nonnegative (Theorem 27.18). At third order J's cubic vertex breaks gauge invariance, so on the Euclidean Kuhn lattice the second-order equation for a static field built from two harmonic modes has no solution, and β_{PN} does not exist for J's cost (Theorem 27.24). Theorems 27.26, 27.27, 27.28 and 27.29 give Regge's table at every background $\kappa \notin \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$, with a plane-wave form whose only pole is the degenerate background $\kappa = \frac{1}{4}$, and its Hessian,

with true second derivatives, at every Euclidean background $\kappa < \frac{1}{4}$; Theorem 27.30 runs the near-flat chain on $\mathbb{R}_\delta$. The background $\kappa = 1$ is equivalent to a definite history record and is not derived (Theorem 27.41, with Theorems 27.39 and 27.42), and the locality clause is a named premise (Theorems 27.44 and 27.47).

P.14 What do a library's conventions cost?

Chapter 28 prices the conventions of a classical library, stored as data. Theorem 28.3 prices decisions on the line stored as maps. The convention rule, Theorem 28.8, bounds the price of a value set at an excluded point from below, and Theorem 28.9 with Table 28.1 prices eighteen conventions, $0^{-1} = 0$ at the LPO function among them. Choosing representatives costs exactly the WLPO function (Theorem 28.11); the classical linear order costs the WLPO function and the ordered field the LPO function (Theorems 28.14 and 28.15), and Theorem 28.19 prices the complete ordered field. The derivative convention costs exactly MP with a differentiability decision (Theorem 28.24), Theorem 28.26 isolates the Π^0_2 gap above the WLPO function, and monotonicity from a pointwise derivative holds at the WLPO function (Theorem 28.29). The separating models are Theorem 28.32, over HAS, and Theorem 28.39, in a calculus of streams. Theorems 28.42 and 28.45 move whole areas of the library. Section 28.11 compiles classical proofs to programs of Gödel's T (Theorem 28.49), with a compiler of polynomial degree five (Theorem 28.51).

P.15 What does learning cost?

Chapter 29 starts with the logic of records: Theorem 29.2 gives the laws of three shapes of time, Theorem 29.4 prices them at a history's start, and Theorem 29.6 shows that the record tree has intuitionistic logic and one history Gödel–Dummett logic. Chance comes from exchangeable records (Theorems 29.8 and 29.9), and deciding a fixed chance costs WLPO (Theorem 29.11). Brouwer's theorem on a triangle is free approximately (Theorem 29.21) and costs LLPO exactly, given countable choice (Theorem 29.22). Learning a pair of worlds costs $\mathrm{MP}_{\mathrm{bin}}$ or LPO (Theorem 29.24), and Theorem 29.27 prices revisable verdicts. Mistakes, dimensions and samples are counted from Theorem 29.29 to Theorem 29.32, and Theorem 29.35 turns a learner of the zero world and its flags into LPO. On the programs of Gödel's T, learning costs exactly LPO_T (Theorem 29.45), and Theorem 29.48 says which catalogues are learned. Over every system of programs, Theorem 29.51 prices the selection method at Σ_2-LPO, Theorem 29.53 separates decision tables from propositions by unique choice, and Theorem 29.58 reads revision bounds off derived catalogues.

P.16 Which conjectures are settled, and which stay open?

Chapter 30 is proved in classical mathematics throughout. Two golden probes fix a calibration with exponent exactly 2 (Theorem 30.4), and Theorems 30.5 and 30.7 lead to the simultaneous approximation constant. Theorems 30.9 and 30.11 treat two recognizers and the memory that recognition needs. Self-similar ledgers have the rates of Theorem 30.13, keep balanced books exactly as Theorem 30.14 says, and fluctuate as Theorems 30.15 and 30.18 describe. On the native register at zero holding, three golden comparisons change a record with certainty

and two never do, when the reference action is one cycle (Theorem 30.21); on a register of one channel, a certain change costs exactly a third of a turn (Theorem 30.24); and on two or more channels, where entangling tokens are available, a certain change costs exactly a quarter turn per changed channel exactly when every changed channel moves to its low-bit partner (Theorem 30.26). Table 30.1 collects these prices with the floors under holding, and Section 30.5 states every open problem exactly.

P.17 Headline results and what their proofs cite

The table lists, for each headline result, the numbered results that its statement and proof cite, in the order of citation, and, where they hold parts of the argument, the chapters, sections and tables that its proof cites. Following an entry back to its own row, where it has one, retraces the argument.

Result	Its statement and proof cite
Theorem 2.7	Lemma 2.5, Lemma 2.6, Theorem 2.3
Theorem 4.15	Proposition 3.11, Corollary 4.14
Theorem 6.11	Section 20.3.3, Section 20.3.4, Theorem 6.9, Theorem 6.10, Theorem E.9, Lemma E.6, Lemma E.7, Lemma E.11, Lemma E.8
Theorem 7.33	Proposition 7.25, Proposition 7.27, Proposition 7.32, Proposition 7.30
Theorem 7.38	Lemma 7.21, Theorem 7.33, Corollary 7.34
Theorem 7.45	Proposition 7.35, Lemma 7.41, Proposition 7.43, Theorem 7.42, Proposition 7.44, Corollary 7.36
Theorem 8.11	Theorem 6.5
Theorem 12.22	Proposition 10.6, Section F.1
Theorem 12.38	Appendix C, Section F.2, Proposition 12.19, Corollary 4.14, Lemma F.3, Lemma F.5, Lemma F.6, Lemma F.1, Lemma 12.32, Lemma F.2, Theorem 12.33
Theorem 12.63	Theorem 12.22, Lemma F.7, Theorem 12.33, Corollary 12.35, Theorem 12.56, Theorem 12.58
Theorem 12.66	Lemma 7.21
Theorem 12.87	Theorem 12.60, Theorem 12.54, Corollary 12.18, Lemma 12.81, Proposition 12.82
Theorem 13.6	Theorem 13.3, Lemma 12.52, Proposition 12.62
Theorem 13.25	Theorem 13.6, Lemma 13.24, Lemma 12.52, Lemma 13.21
Theorem 13.28	Lemma 13.26, Theorem 13.25, Lemma 13.24, Theorem 13.20
Theorem 14.13	Lemma 14.12, Lemma 14.11
Theorem 14.16	Theorem 14.15, Theorem 14.13, Theorem 14.14, Proposition 12.19, Theorem 12.54
Theorem 14.28	Lemma 14.8, Theorem 14.19, Theorem 14.27, Lemma 14.21, Corollary 12.18
Theorem 15.22	Theorem 15.21, Lemma 15.3
Theorem 15.33	Theorem I.209, Appendix I, Corollary I.59, Lemma 15.36, Lemma I.19, Lemma 15.35, Theorem 15.20, Proposition I.32, Theorem 15.22, Lemma H.5, Lemma I.205, Lemma 15.34
Theorem 16.8	Lemma 16.5
Theorem 16.11	Section J.1, Lemma 16.12, Section J.2

Result	Its statement and proof cite
Proposition 16.15	Section J.3, Remark 16.7, Lemma F.11, Theorem 16.27, Proposition 13.4, Theorem 12.72, Theorem 13.25, Theorem 13.28, Corollary 13.30, Theorem 13.32, Theorem 16.8

Appendix Q

The price table of the mathematics physics uses

This appendix lists, one statement to a row, what the mathematics that physics uses costs on the line $\mathbb{R}_\delta$. Each row reads one statement of classical analysis, algebra, topology or probability on $\mathbb{R}_\delta$ exactly as its statement says; where the reading narrows the classical statement (to an interval, to a dimension, to a uniform derivative, to the value half of an eigenvalue theorem, to a finite probability space), the statement says so. Each row gives its number, its title and statement, the physics that relies on it ("Used for"), and its price, followed by "exact" or, for an open row, by the bounds that are proved; where this book proves the row, a reference follows. Section 28.12 of Chapter 28 explains what the table shows.

How to read a price

free
: No omniscience principle, and no choice beyond the *free allowance*: countable choice at pairs of ratios. If for every natural number n some pair of ratios (p, q) has a property $R(n, p, q)$, the allowance gives a sequence of pairs (p_n, q_n) with $R(n, p_n, q_n)$ for every n. It makes every located cut the cut of a point (Theorem 12.33) and so every Cauchy sequence of points converge (Corollary 12.35). A natural number, a yes-or-no answer and a finite table can each be written as a pair of ratios, so the allowance also chooses one natural number or one answer for every n, whether or not the answer is unique: for a unique bit b it chooses the pair (b, b). It chooses a regular sequence for every point of a sequence of points, by choosing the rational approximations, and so collects points that are each determined uniquely into a sequence. The free rows whose proofs form a limit point say so after their price.

LPO, WLPO, LLPO, MP
: The omniscience principles of Chapter 12; MP is Markov's principle, written $\mathrm{MP}_{\mathrm{bin}}$ in Corollary 12.18.

EM, WEM
: Excluded middle, $P \vee \neg P$, and weak excluded middle, $\neg P \vee \neg\neg P$, for every proposition P.

MP$^\vee$
: The disjunctive Markov principle: if two Σ^0_1 statements are not both false, one of them is not false. Markov's principle gives it.

LPO function, WLPO function
: LPO or WLPO given as one map that decides every binary sequence (Definition 21.1).

FAN
: The decidable fan theorem of Definition 13.2. The *full fan theorem*, named in some bounds, is the fan theorem for bars given by arbitrary properties.

BD-N
: Ishihara's boundedness principle [60]: every countable set of natural numbers that is pseudobounded is bounded. A set S of natural numbers is *pseudobounded* when every sequence $s_0, s_1, \ldots$ of members of S has $s_n < n$ for all large n.

AC_ω
: Countable choice at every type: if for every n some object x has $R(n, x)$, there is a sequence (x_n) with $R(n, x_n)$ for every n. A price that names AC_ω means that the proof uses countable choice (an upper bound), for instance to pick a member of a set for every n, and that the table has not shown the free allowance to suffice; the choice is not shown to be needed.

exact
: Both directions hold: the statement implies the principles named with no choice principle, and the principles named, with the free allowance and with AC_ω where the price names it, imply the statement. This is exactness in the table's sense; "costs exactly" in Section 21.1 allows no choice in either direction. A row with a reference is proved in this book at the result it names; most rows without one are not proved in this book. For a row priced AC_ω alone, "exact" asserts nothing on the lower side: no principle is shown to be needed.

open
: No exact price among the letters above; the bounds that are proved follow the price, with any exact equivalence to a principle that is not one of the letters, which the row then defines.

The table has 1467 rows, one for each statement: 1166 are free, 279 have an exact price, and 22 are open.

Q.1 Conventions at excluded points

1. Total inverse with $0^{-1} = 0$, apartness guard. A total inverse function on the line that sends 0 to 0 and inverts every point apart from 0, that is, at a known positive distance from 0. *Used for:* dividing by distances, masses or times; the value at 0 is never used physically. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.9(1).

2. Total inverse with $0^{-1} = 0$, nonzero guard. A total inverse function on the line that sends 0 to 0 and inverts every point that is not equal to 0. *Used for:* dividing by distances, masses or times; the value at 0 is never used physically. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.9(1).

3. Division by zero convention, $a/0 = 0$. A total division on the line with $a/0 = 0$ for every a, and $(a/b)\cdot b = a$ whenever b is apart from 0. *Used for:* ratios such as speed as distance over time and density as mass over volume. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.9(1).

4. Negative powers with zero sent to zero. For each whole number $n \geq 1$, a total function on the line that sends 0 to 0 and every point x apart from 0 to $1/x^n$. *Used for:* inverse-power laws such as $1/r^2$ for gravity and the Coulomb force. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.9(1).

5. Logarithm convention, $\log 0 = 0$. A total logarithm on the line with $\log 0 = 0$ and $\exp(\log x) = |x|$ at every point x apart from 0. *Used for:* entropy $S = k \log W$, decibel scales and logarithmic potentials. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.9(2).

6. Zero to a real power, with $0^0 = 1$. A total function on the line giving 0 to the power y: the value 1 at $y = 0$ and the value 0 at every y not equal to 0. *Used for:* power laws evaluated at zero, and the term $0^0 = 1$ in power series. *Price:* **WLPO function**; exact (equivalent to WLPO as a function). Proved in Theorem 28.9(3).

7. Whole-number powers of any base. A power function on the line defined at every base x and whole number n, with $x^0 = 1$ and $x^{n+1} = x^n \cdot x$; no point

is excluded. *Used for:* polynomial laws such as kinetic energy $\frac{1}{2}mv^2$ and spring energy $\frac{1}{2}kx^2$. *Price:* **free**; exact. Proved in Theorem 28.9(5).

8. Square root with $\sqrt{x} = 0$ for $x \le 0$. A total function on the line that is never negative, squares to x at every $x \ge 0$, and equals 0 at every $x \le 0$. *Used for:* lengths of vectors, speeds from kinetic energies, standard deviations. *Price:* **free**; exact. Proved in Theorem 28.9(5).

9. Sign function with sign 0 = 0. A total function on the line equal to 1 at every positive point, −1 at every negative point and 0 at 0. *Used for:* direction of friction and drag forces opposing the velocity. *Price:* **WLPO function**; exact (equivalent to WLPO as a function). Proved in Theorem 28.9(4).

10. Derivative convention: zero where none exists. An operator on functions of the line that returns the derivative of f at x where one exists and returns 0 where f has no derivative at x. *Used for:* writing force as minus the slope of a potential, even at kinks. *Price:* **open**; at least the LPO function; at most MP together with the WEM function; exactly MP together with a differentiability decision, one map that decides, for every function f on the line and every point x, whether it is impossible that f has no derivative at x (a principle that is not one of the letters). Proved in Theorem 28.24.

11. Truncated subtraction of whole numbers. A subtraction on whole numbers with $(a - b) + b = a$ when $b \le a$, and $a - b = 0$ when $a \le b$. *Used for:* lowering occupation numbers of quantum states, which stop at zero. *Price:* **free**; exact. Proved in Theorem 28.9(5).

12. Integer to whole number, negatives sent to zero. A map from the integers to the whole numbers that keeps every integer $z \ge 0$ and sends every $z \le 0$ to 0. *Used for:* clamping counts at zero, such as particle numbers that cannot go negative. *Price:* **free**; exact. Proved in Theorem 28.9(5).

13. Floor function on the line. A function that assigns to every point x of the line an integer m with $m \le x < m + 1$. *Used for:* finding which lattice cell or histogram bin holds a position or reading. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.3(3).

14. Decidable equality of points, as stored data. A stored procedure that decides, for any two points of the line, whether they are equal. *Used for:* branching on whether two energy levels are equal, as in degenerate perturbation theory. *Price:* **WLPO function**; exact (equivalent to WLPO as a function). Proved in Theorem 28.3(2).

15. Decidable $\le$ between points, as stored data. A stored procedure that decides, for any two points x and y of the line, whether $x \le y$. *Used for:* piecewise laws, such as a potential given by one formula for $x \le a$. *Price:* **WLPO function**; exact (equivalent to WLPO as a function). Proved in Theorem 28.3(2).

16. Decidable < between points, as stored data. A stored procedure that decides, for any two points x and y of the line, whether $x < y$. *Used for:* threshold tests, such as whether an energy lies below a barrier. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.3(3).

17. Maximum and absolute value on the line. The maximum of two points of the line lies above both and below every common upper bound; $|x|$ is the maximum of x and $-x$. *Used for:* absolute errors, magnitudes, and ramp functions such as $\max(0, x)$. *Price:* **free**; exact.

Q.2 Limits, continuity and derivatives

18. Taylor's remainder bound. Let f be continuous on [0, 1], with derivatives of orders 1 to n that are continuous on [0, 1], and with an (n+1)-th derivative at every point strictly inside (0, 1) that is at most C in absolute value. Then for every x in [0, 1] the error of the Taylor polynomial of degree n at 0 is at most $C\,x^{n+1}/n!$. This is weaker than the classical Lagrange bound, which has $(n + 1)!$ in place of $n!$. *Used for:* Error bars for expansions in a small parameter: small angles, perturbation series, linearized equations of motion and lattice expansions, with an error of order x^{n+1}. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

19. Lagrange remainder at a point of the closed interval. Let f be a real function on [0, 1] whose derivatives up to order n + 1 exist uniformly on [0, 1]. Then the difference between f(1) and the value at 1 of its degree-n Taylor polynomial at 0 equals the (n + 1)-th derivative of f at some point ξ of the closed interval [0, 1] (an end point allowed) divided by the factorial $(n + 1)!$. *Used for:* The mean-value form of an expansion error when only some point of the closed interval is needed for the next derivative, as in worst-case bounds that take the largest value of that derivative. *Price:* **LLPO + $\mathbf{AC}_{\omega}$**; exact (the upper bound uses countable choice, not shown to be needed).

20. Rolle's theorem with an interior point. Let f be uniformly continuous on [0, 1], with a derivative

f′(x) at every point x strictly inside (0, 1). If f(0) = f(1), there is a point c strictly inside (0, 1), at a known positive distance from both ends, where f′(c) = 0. *Used for:* Finding an instant at which a quantity that ends where it started has zero rate of change, such as the turning point of a thrown body or an extremum of energy along a path; it is also the step behind the mean value theorem. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

21. Mean value theorem with an interior point. Let f be uniformly continuous on [0, 1], with a derivative f′(x) at every point x strictly inside (0, 1). Then there is a point c strictly inside (0, 1), at a known positive distance from both ends, where f′(c) = f(1) − f(0). *Used for:* Saying that the average velocity over a time interval equals the instantaneous velocity at some instant inside it, as in estimates of how far a moving body travels. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

22. Cauchy's mean value theorem. Let f and g be uniformly continuous on [0, 1], with derivatives f′(x) and g′(x) at every point x strictly inside (0, 1). Then there is a point c strictly inside (0, 1), at a known positive distance from both ends, where (g(1) − g(0))·f′(c) = (f(1) − f(0))·g′(c). *Used for:* Comparing two quantities that change together, such as two coordinates of a moving body traced against time; it is the classical proof of the rule for limits of ratios of vanishing quantities and of the Lagrange error formula for Taylor expansions. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

23. Taylor's theorem with Lagrange remainder. Let $f_0 = f, f_1, \ldots, f_{n+1}$ be real functions such that $f_0, \ldots, f_n$ are uniformly continuous on [0, 1] and, for each $i \le n$, $f_{i+1}(x)$ is the derivative of f_i at every point x strictly inside (0, 1). Then f(1) minus the value at 1 of the degree-n Taylor polynomial of f at 0, built from $f_0(0), \ldots, f_n(0)$, equals $f_{n+1}(\xi)/(n+1)!$ at some point ξ strictly inside (0, 1), at a known positive distance from both ends. *Used for:* The exact form of the error of a truncated expansion, with the next derivative taken at an unknown interior point: small-oscillation approximations of a potential near its minimum, perturbation series and finite-difference formulas of numerical simulation. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

24. Inverse function theorem in one variable. Let f be a real function with a strict derivative d at the point a (for every accuracy there is a ball around a on which |f(x) − f(y) − d·(x − y)| is at most that accuracy times |x − y|), and let d not be 0. Then f is one-to-one on some ball around a, the image of every small enough ball around a contains a ball around f(a), and every function g with g(f(x)) = x on some ball around a has the strict derivative 1/d at f(a). *Used for:* Inverting a response curve: solving an equation of state for pressure given volume or the reverse, Legendre transforms, and changes of variable that swap which quantity is the independent one. *Price:* **MP**; exact (limit points use the completeness of the line: countable choice of rational pairs).

25. Inverse function theorem with a known reciprocal slope. Let f be a real function with a strict derivative d at the point a (for every accuracy there is a ball around a on which |f(x) − f(y) − d·(x − y)| is at most that accuracy times |x − y|), and let d have a reciprocal e, d·e = 1. Then f is one-to-one on some ball around a, the image of every small enough ball around a contains a ball around f(a), and every function g with g(f(x)) = x on some ball around a has the strict derivative e at f(a). *Used for:* inverting a response curve, Legendre transforms and changes of variable when the slope is known to be bounded away from zero. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

26. Local left inverses are strictly differentiable. Let f be a real function with a strict derivative d at the point a, with d not equal to 0. Then every function g with g(f(x)) = x for all x in some ball around a has the strict derivative 1/d at f(a): for every accuracy there is a ball around f(a) on which |g(u) − g(v) − (u − v)/d| is at most that accuracy times |u − v|. *Used for:* Differentiating an inverted calibration or equation of state, for example the rate of change of temperature with respect to entropy once entropy as a function of temperature is known. *Price:* **MP**; exact (limit points use the completeness of the line: countable choice of rational pairs).

27. Derivative of an inverse function. Let g be a real function continuous at a, let f have the derivative d at g(a) with d not equal to 0, and let f(g(y)) = y for every y near a. Then g has the derivative 1/d at a. *Used for:* The derivative of any inverse function: temperature as a function of energy from energy as a function of temperature, response functions and the derivatives of inverse trigonometric and logarithmic functions. *Price:* **MP**; exact.

28. Derivative of an inverse with a known reciprocal. Let g be a real function continuous at a, let f have the derivative d at g(a), let d have a reciprocal e (d·e = 1), and let f(g(y)) = y for every y near a. Then g has the derivative e at a. *Used for:* derivative of an inverse function when the slope is known to be bounded away from zero: inverted calibrations and equations of state. *Price:* **free**; exact.

29. Implicit function theorem for a nonzero partial derivative. Let φ(x, y) be a real function of two real variables with a strict derivative at (a, b), with partial derivative p in x and d in y, and let d not be 0. Then there are intervals around a and around b such that for every x in the first there is exactly one y in the second with φ(x, y) = φ(a, b), and every function ψ that picks that y for each x has the strict derivative −p/d at a. *Used for:* Solving a constraint for one variable: an equation of state F(p, V, T) = 0 solved for V, constraint surfaces and stationarity conditions in mechanics. *Price:* **MP**; exact (limit points use the completeness of the line: countable choice of rational pairs).

30. Implicit function theorem for an invertible partial derivative. Let φ(x, y) be a real function of two real variables with a strict derivative at (a, b), with partial derivative p in x and d in y, and let d have a reciprocal e, d·e = 1. Then there are intervals around a and around b such that for every x in the first there is exactly one y in the second with φ(x, y) = φ(a, b), and every function ψ that picks that y for each x has the strict derivative −p·e at a. *Used for:* solving a constraint for one variable when its partial derivative is known to be bounded away from zero: equations of state, constraint surfaces, stationarity conditions. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

31. L'Hôpital's rule with a positive denominator slope. Let f and g be real functions on [0, 1] with derivatives f′ and g′ uniform on the closed interval [0, 1], with f(0) = g(0) = 0 and g′(x) positive, at a known positive distance from 0, for every x in (0, 1]. If f′(x)/g′(x) tends to a number l as x decreases to 0, then f(x)/g(x) tends to l as x decreases to 0. *Used for:* Limits of ratios of two vanishing quantities when it is known that the denominator's rate keeps one sign, as in small-angle and small-coupling limits of response functions. *Price:* **free**; exact.

32. L'Hôpital's rule at zero from the right. Let f and g be real functions on [0, 1] with derivatives f′ and g′ uniform on the closed interval [0, 1], with f(0) = g(0) = 0 and g′(x) not equal to 0 for every x in (0, 1]. If f′(x)/g′(x) tends to a number l as x decreases to 0, then f(x)/g(x) tends to l as x decreases to 0. *Used for:* Evaluating limits of ratios in which numerator and denominator both vanish, such as sin(x)/x near 0 or (1 − cos(x))/x^2, which appear in small-angle and small-amplitude approximations, in low-frequency and low-temperature limits of response functions, and at removable singularities of physical formulas. *Price:* $\mathbf{MP}^{\vee}$ **+** $\mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

33. Convexity from a nondecreasing derivative. If f is continuous on [0, 1], differentiable at every point strictly inside (0, 1), and its derivative is nondecreasing there, then f(a x + b y) is at most a f(x) + b f(y) whenever x and y lie in [0, 1], a and b are nonnegative and a + b = 1. *Used for:* Showing that a free energy is convex or an entropy concave (thermodynamic stability) and setting up Legendre transforms. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

34. Convexity from a nonnegative second derivative. If f is continuous on [0, 1], differentiable at every point strictly inside (0, 1), and its derivative is itself differentiable at every point strictly inside with nonnegative derivative there, then f(a x + b y) is at most a f(x) + b f(y) whenever x and y lie in [0, 1], a and b are nonnegative and a + b = 1. *Used for:* Thermodynamic stability (positive heat capacity and positive compressibility mean a convex energy) and convex potentials in variational problems. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

35. Limit of a quotient of sequences. If the sequences x(n) and y(n) tend to a and b and b is not 0, then x(n)/y(n) tends to a/b. *Used for:* Every measured ratio taken to a limit: susceptibilities, rates per unit time and normalised probabilities. *Price:* **MP**; exact.

36. Limit of the inverses of a sequence. If the sequence y(n) tends to b and b is not 0, then 1/y(n) tends to 1/b. *Used for:* Reciprocals of converging quantities: effective masses, resistances and normalisation factors. *Price:* **MP**; exact.

37. Alternating series test. If a_0, a_1, a_2, … is a sequence of real numbers that never increases and tends to 0, the alternating series $a_0 - a_1 + a_2 - a_3 + \dots$ converges. *Used for:* Alternating perturbation and virial series; the error of a partial sum is at most the first omitted term. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

38. Alternating series have Cauchy partial sums. If a_0, a_1, a_2, … is a sequence of real numbers that never increases and tends to 0, the partial sums of the alternating series $a_0 - a_1 + a_2 - a_3 + \dots$ form a Cauchy sequence. *Used for:* Controlling an alternating series without knowing its limit in advance: numerical summation of alternating expansions. *Price:* **free**; exact.

39. Even alternating partial sums lie below the sum. If a_0, a_1, a_2, … is a sequence of real numbers that never increases and the alternating series $a_0 - a_1 + a_2 - a_3 + \dots$ converges to L, then every partial sum with an even number of terms is at most L. *Used for:* One-sided error bars for alternating series: a

computed partial sum bounds the true value from one side. *Price:* **free**; exact.

40. Odd alternating partial sums lie above the sum. If a_0, a_1, a_2, ... is a sequence of real numbers that never increases and the alternating series $a_0 - a_1 + a_2 - a_3 + \ldots$ converges to L, then every partial sum with an odd number of terms is at least L. *Used for:* One-sided error bars for alternating series: a computed partial sum bounds the true value from the other side. *Price:* **free**; exact.

41. Alternating series test for nondecreasing terms. If a_0, a_1, a_2, ... is a sequence of real numbers that never decreases and tends to 0, the alternating series $a_0 - a_1 + a_2 - a_3 + \ldots$ converges. *Used for:* Alternating series whose terms approach zero from below, such as expansions with a negative leading sign. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

42. Cauchy partial sums for nondecreasing alternating terms. If a_0, a_1, a_2, ... is a sequence of real numbers that never decreases and tends to 0, the partial sums of the alternating series $a_0 - a_1 + a_2 - a_3 + \ldots$ form a Cauchy sequence. *Used for:* alternating series whose terms rise to zero, used without knowing the limit in advance. *Price:* **free**; exact.

43. Even partial sums lie above the sum, nondecreasing terms. If a_0, a_1, a_2, ... is a sequence of real numbers that never decreases and the alternating series $a_0 - a_1 + a_2 - a_3 + \ldots$ converges to L, then every partial sum with an even number of terms is at least L. *Used for:* one-sided error bars of alternating series. *Price:* **free**; exact.

44. Odd partial sums lie below the sum, nondecreasing terms. If a_0, a_1, a_2, ... is a sequence of real numbers that never decreases and the alternating series $a_0 - a_1 + a_2 - a_3 + \ldots$ converges to L, then every partial sum with an odd number of terms is at most L. *Used for:* one-sided error bars of alternating series. *Price:* **free**; exact.

45. Cauchy condensation test. Let f(0), f(1), f(2), ... be nonnegative real numbers that never increase from f(1) on. Then the series of the f(n) converges exactly when the series of the numbers $2^k \cdot f(2^k)$ converges. *Used for:* Convergence of sums such as the sum of $1/n^p$ over interaction terms, density-of-states sums and lattice sums. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

46. Polynomial times geometric decay tends to zero. For every natural number k and every real r with $|r| < 1$, the numbers $n^k \cdot r^n$ tend to 0 as n grows. *Used for:* Boltzmann weights beat any polynomial density of states; moments of geometric distributions such as Bose and Planck weights are finite. *Price:* **free**; exact.

47. Polynomial times nonnegative geometric decay tends to zero. For every natural number k and every real r with $0 \le r < 1$, the numbers $n^k \cdot r^n$ tend to 0 as n grows. *Used for:* Boltzmann weights beat any polynomial density of states; moments of geometric (Bose, Planck) distributions are finite. *Price:* **free**; exact.

48. Linear times geometric decay tends to zero. For every real r with $|r| < 1$, the numbers $n \cdot r^n$ tend to 0 as n grows. *Used for:* the mean occupation of a geometric (Bose, Planck) distribution is finite; Boltzmann weights beat a linearly growing density of states. *Price:* **free**; exact.

49. Linear times nonnegative geometric decay tends to zero. For every real r with $0 \le r < 1$, the numbers $n \cdot r^n$ tend to 0 as n grows. *Used for:* the mean occupation of a geometric (Bose, Planck) distribution is finite; Boltzmann weights beat a linearly growing density of states. *Price:* **free**; exact.

50. Dirichlet's test for series. Let f(0), f(1), f(2), ... be real numbers that never increase and tend to 0, and let z(0), z(1), z(2), ... be real numbers whose partial sums $z(0) + \ldots + z(n-1)$ are all at most b in absolute value. Then the partial sums of the series $f(0) \cdot z(0) + f(1) \cdot z(1) + f(2) \cdot z(2) + \ldots$ form a Cauchy sequence. *Used for:* real oscillating terms with slowly decreasing amplitudes: conditionally convergent lattice sums, Fourier cosine and sine series at a point, Abel summation. *Price:* **free**; exact.

51. Dirichlet's test for nondecreasing factors. Let f(0), f(1), f(2), ... be real numbers that never decrease and tend to 0, and let z(0), z(1), z(2), ... be real numbers whose partial sums $z(0) + \ldots + z(n-1)$ are all at most b in absolute value. Then the partial sums of the series $f(0) \cdot z(0) + f(1) \cdot z(1) + f(2) \cdot z(2) + \ldots$ form a Cauchy sequence. *Used for:* real oscillating terms with slowly varying amplitudes: conditionally convergent lattice sums, Abel summation. *Price:* **free**; exact.

52. Cauchy product of absolutely convergent series with known sums. If the series a(0) + a(1) + ... and b(0) + b(1) + ... both converge absolutely, with sums s and t, then the series with terms $c(n) = a(0)\,b(n) + a(1)\,b(n-1) + \ldots + a(n)\,b(0)$ converges to s t. *Used for:* Multiplying generating functions and partition functions of independent subsystems; convolving independent probability weights. *Price:* **free**; exact.

53. Sum of the Cauchy product of absolutely convergent series. If the series of the numbers |a(n)| and of the numbers |b(n)| converge, then the series of the real numbers a(n) and b(n) converge, to s and t, and their Cauchy product, whose n-th term is

a(0)·b(n) + a(1)·b(n − 1) + … + a(n)·b(0), converges to s·t. *Used for:* multiplying generating functions and partition functions of independent subsystems; convolving independent weights. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

54. Cauchy product converges absolutely. If the series a(0) + a(1) + … and b(0) + b(1) + … both converge absolutely, then the series with terms c(n) = a(0) b(n) + a(1) b(n−1) + … + a(n) b(0) converges absolutely. *Used for:* The product series can be summed in any order: composing independent weights without worrying about the order of the terms. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

55. Rearranging an unconditionally convergent series keeps its sum. Let σ be a one-to-one correspondence of the indices 0, 1, 2, … with themselves. A series of real numbers f(0), f(1), f(2), … has the unconditional sum s (the sums over finite sets of indices tend to s as the sets grow) exactly when the rearranged series f(σ(0)), f(σ(1)), f(σ(2)), … has the unconditional sum s. *Used for:* a lattice sum, once its sites are listed, has one value whether it is summed shell by shell or cube by cube. *Price:* **free**; exact.

56. Rearranging preserves unconditional summability. Let σ be a one-to-one correspondence of the indices 0, 1, 2, … with themselves. A series of real numbers f(0), f(1), f(2), … has an unconditional sum (the sums over finite sets of indices tend to some number as the sets grow) exactly when the rearranged series f(σ(0)), f(σ(1)), f(σ(2)), … has one. *Used for:* a lattice sum, once its sites are listed, that converges unconditionally in one order converges in every order. *Price:* **free**; exact.

57. Schlömilch condensation test. Let f(0), f(1), f(2), … be nonnegative real numbers that never increase from f(1) on, and let u(0) < u(1) < u(2) < … be positive whole numbers whose gaps grow at most by a fixed whole factor C ≥ 1: u(n + 2) − u(n + 1) ≤ C·(u(n + 1) − u(n)) for every n. Then the series of the f(n) converges exactly when the series of the numbers (u(k + 1) − u(k))·f(u(k)) converges. *Used for:* Convergence tests for sums over sparse shells, such as squares or powers, in lattice sums and density-of-states sums. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

58. Interior extremum of a function returning to its start. Let f be uniformly continuous on [0, 1] (one accuracy rate for all points of the interval) with f(0) = f(1). Then at some point c strictly inside (0, 1), at a known positive distance from both ends, f takes its minimum or its maximum over [0, 1]. *Used for:* Variational principles: an extremum strictly inside for a quantity that returns to its starting value, such as the energy along a closed path. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

59. Interior local extremum of a function returning to its start. Let f be uniformly continuous on [0, 1] (one accuracy rate for all points of the interval) with f(0) = f(1). Then at some point c strictly inside (0, 1), at a known positive distance from both ends, f has a local minimum or a local maximum: on some interval around c, f is never below f(c), or never above f(c). *Used for:* Equilibrium points of an energy that returns to its starting value: a stable or unstable equilibrium lies strictly inside. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

60. Uniform limits of continuous functions are continuous. Let f_0, f_1, f_2, … be real functions on the line that converge uniformly to f (for every accuracy there is an index beyond which every f_n is within that accuracy of f at every point), and suppose that beyond every index some f_n is continuous. Then f is continuous. *Used for:* Continuity of limits of approximations: perturbative and lattice approximants that converge uniformly keep the continuity of the exact quantity. *Price:* **free**; exact.

61. Uniform limits of uniformly continuous functions are uniformly continuous. Let f_0, f_1, f_2, … be real functions on the line that converge uniformly to f (for every accuracy there is an index beyond which every f_n is within that accuracy of f at every point), and suppose that beyond every index some f_n is uniformly continuous. Then f is uniformly continuous. *Used for:* continuity of limits of approximations: perturbative and lattice approximants converging uniformly. *Price:* **free**; exact.

62. Uniform limits keep uniform continuity on the unit interval. Let f_0, f_1, f_2, … be real functions that converge uniformly to f on [0, 1] (for every accuracy there is an index beyond which every f_n is within that accuracy of f at every point of [0, 1]), and suppose that beyond every index some f_n is uniformly continuous on [0, 1]. Then f is uniformly continuous on [0, 1]. *Used for:* continuity of limits of approximations on a bounded parameter range: perturbative and lattice approximants converging uniformly. *Price:* **free**; exact.

63. Weierstrass M-test for series of functions. Let g_0, g_1, g_2, … be real functions on the line with $|g_n(x)| \le M_n$ for every n and x, where the series $M_0 + M_1 + M_2 + \dots$ converges. Then the series $g_0(x) + g_1(x) + g_2(x) + \dots$ converges at every x, and uniformly: for every accuracy there is a number of terms beyond which every partial sum is within that accuracy of the

sum, at every x. *Used for:* Power series, Fourier series and lattice series of fields that converge uniformly, so that their sums can be differentiated and integrated term by term. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

64. Comparison test with absolute values. If a(0), a(1), a(2), ... are real numbers with $|a(n)| \le b(n)$ for every n, and the series b(0) + b(1) + b(2) + ... converges, then the series a(0) + a(1) + a(2) + ... converges. *Used for:* Comparing a physical series with a known one: bounding the terms of an expansion by a convergent series proves that the expansion has a sum. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

65. Continuity of the sum of a dominated series. Let g_0, g_1, g_2, ... be continuous real functions on the line with $|g_n(x)| \le M_n$ for every n and x, where the series $M_0 + M_1 + M_2 + \dots$ converges. Then the series $g_0(x) + g_1(x) + g_2(x) + \dots$ converges at every x, and its sum depends continuously on x. *Used for:* Continuity of sums over modes: partition functions and mode sums that depend on temperature or field, with terms bounded by a convergent series. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

66. Derivative of a difference. If f has derivative a at x and g has derivative b at x, then f − g has derivative a − b at x. *Used for:* Linearity of every rate computation: the rate of change of a difference of two quantities is the difference of their rates. *Price:* **free**; exact.

67. Derivative of a constant multiple. If f has derivative a at x and c is a constant, then c f has derivative c a at x. *Used for:* Linearity of every rate computation: scaling a quantity by a fixed charge, mass or conversion factor scales its rate. *Price:* **free**; exact.

68. Derivative of a finite sum. If each of f(0), ..., f(n−1) has a derivative at x, then the sum f(0) + ... + f(n−1) has at x the derivative equal to the sum of the derivatives. *Used for:* Differentiating mode sums and finite expansions term by term, as in the force on a particle from a finite sum of potentials. *Price:* **free**; exact.

69. Limit of a difference. If x(n) tends to L and y(n) tends to M, then x(n) − y(n) tends to L − M. *Used for:* Taking differences of converging quantities to a limit: energy differences, transition frequencies and the subtraction of a reference value in regularized calculations. *Price:* **free**; exact.

70. Limit of a negative. If x(n) tends to L, then −x(n) tends to −L. *Used for:* Reversing signs inside limits: charges and currents of opposite sign and potentials written with a minus sign. *Price:* **free**; exact.

71. Limit of a power. If x(n) tends to L, then $x(n)^k$ tends to L^k for every natural number k. *Used for:* Powers of converging quantities: kinetic energy from a converging velocity, intensities from converging amplitudes and the polynomial terms of series expansions. *Price:* **free**; exact.

72. Limit of an absolute value. If x(n) tends to L, then |x(n)| tends to |L|. *Used for:* Magnitudes of converging quantities: sizes of errors, speeds from velocities and distances in convergence estimates. *Price:* **free**; exact.

73. Limit of a maximum. If x(n) tends to L and y(n) tends to M, then the larger of x(n) and y(n) tends to the larger of L and M. *Used for:* Ramp and threshold quantities taken to a limit, such as max(0, x) in rectifiers and occupation cutoffs, and worst-case bounds built from two estimates. *Price:* **free**; exact.

74. Limit of a minimum. If x(n) tends to L and y(n) tends to M, then the smaller of x(n) and y(n) tends to the smaller of L and M. *Used for:* Clipped quantities and best-case bounds taken to a limit: saturation cutoffs and the smaller of two error estimates. *Price:* **free**; exact.

75. Continuous function of a convergent sequence. If x(n) tends to L and the function g is continuous at L, then g(x(n)) tends to g(L). *Used for:* Applying physical laws to converging inputs: the energy, pressure or force computed from a converging state variable converges to its value at the limiting state. *Price:* **free**; exact.

76. Sequences equal from some point share limits. If two sequences agree from some index on and one of them tends to L, then the other tends to L too. *Used for:* Ignoring transients: the first steps of an iteration, the warm-up of a simulation or finitely many corrected terms do not change a limit. *Price:* **free**; exact.

77. Limit of a constant sequence. A sequence whose terms all equal c tends to c. *Used for:* The base case of every limit argument: a fixed physical constant, or a quantity that has settled, stays at its value. *Price:* **free**; exact.

78. Limit of a constant plus a sequence. If x(n) tends to L, then c + x(n) tends to c + L for every fixed number c. *Used for:* Shifting a converging quantity by a fixed offset: zero-point energies, reference potentials and background subtraction. *Price:* **free**; exact.

79. Limit of a sequence plus a constant. If x(n) tends to L, then x(n) + c tends to L + c for every fixed number c. *Used for:* Adding a fixed offset to a converging quantity: a rest energy plus a converging

kinetic energy, or a converging correction added to a known value. *Price:* **free**; exact.

80. Limit of a sequence times a constant. If x(n) tends to L, then x(n) times c tends to L times c for every fixed number c. *Used for:* Unit conversions and fixed couplings applied to converging quantities: multiplying by a charge, a mass or a conversion factor. *Price:* **free**; exact.

81. Limit of a sequence divided by a constant. If x(n) tends to L and the fixed number y has a reciprocal, then x(n) / y tends to L / y. *Used for:* Normalizing converging quantities: dividing by a volume, a particle number or a reference scale. *Price:* **free**; exact.

82. Limits keep an inequality. If x(n) tends to L, y(n) tends to M, and x(n) ≤ y(n) from some index on, then L ≤ M. *Used for:* Bounds survive limits: comparing a converging quantity with a known bound, energy inequalities and monotone approximations in variational methods. *Price:* **free**; exact.

83. A lower bound passes to the limit. If x(n) tends to a and b ≤ x(n) from some index on, then b ≤ a. *Used for:* Positivity of limits: a limit of nonnegative energies, probabilities or densities is nonnegative. *Price:* **free**; exact.

84. An upper bound passes to the limit. If x(n) tends to a and x(n) ≤ b from some index on, then a ≤ b. *Used for:* Upper bounds of limits: probabilities stay at most 1, speeds stay at most the speed of light and efficiencies stay below their bound in the limit. *Price:* **free**; exact.

85. Powers of a number above 1 grow without bound. If r > 1, then r^n exceeds any given number once n is large enough. *Used for:* Exponential growth: chain reactions, populations, unstable modes and amplification factors grow without bound. *Price:* **free**; exact.

86. The counting numbers grow without bound. The numbers 0, 1, 2, 3, ... exceed any given real number from some point on. *Used for:* Every limit of large size or many steps: thermodynamic limits, large particle numbers and long times. *Price:* **free**; exact.

87. Unbounded plus convergent is unbounded. If u(n) grows without bound and v(n) tends to a limit C, then u(n) + v(n) grows without bound. *Used for:* A diverging leading term dominates a converging correction: energies that grow without bound while their corrections settle. *Price:* **free**; exact.

88. Unbounded plus a constant is unbounded. If u(n) grows without bound, then u(n) + c grows without bound for every fixed number c. *Used for:* A fixed offset cannot stop a divergence: shifted energies and potentials measured from a reference constant. *Price:* **free**; exact.

89. Product of unbounded sequences is unbounded. If u(n) and v(n) both grow without bound, then u(n) times v(n) grows without bound. *Used for:* Divergence of products: a total energy that grows with both size and density, or an area that grows with two lengths. *Price:* **free**; exact.

90. Reciprocal of an unbounded sequence tends to zero. If u(n) grows without bound and w(n) is the reciprocal of u(n) from some index on, then w(n) tends to 0. *Used for:* Quantities that vanish as a scale diverges: 1/N corrections in large systems, 1/T at high temperature and inverse distances far from a source. *Price:* **free**; exact.

91. Reciprocal 1/r tends to zero. For every tolerance there is a point beyond which, for every number r larger than that point, the reciprocal 1/r is within the tolerance of 0. *Used for:* Fields and potentials that vanish at infinity: Coulomb and gravitational potentials proportional to 1/r, and boundary conditions at infinity in scattering. *Price:* **free**; exact.

92. Sum of two convergent series. If one series sums to a and another sums to b, regardless of the order of their terms, then the series of termwise sums sums to a + b. *Used for:* Linearity of mode sums and partition functions: the contributions of independent sources or modes add. *Price:* **free**; exact.

93. Difference of two convergent series. If one series sums to a and another sums to b, regardless of the order of their terms, then the series of termwise differences sums to a − b. *Used for:* Subtracting a reference series: counterterms, vacuum subtraction and differences of spectral sums. *Price:* **free**; exact.

94. Negative of a convergent series. If a series sums to a regardless of the order of its terms, then the series of the negated terms sums to −a. *Used for:* Reversing signs in sums: opposite charges in lattice sums and sign-reversed contributions in mode sums. *Price:* **free**; exact.

95. Constant times a convergent series. If the terms f(i) sum to a regardless of their order, then the terms c times f(i) sum to c times a for every fixed number c. *Used for:* Pulling a constant out of a sum: a coupling constant, a charge or a unit factor that multiplies every mode. *Price:* **free**; exact.

96. Convergent series times a constant. If the terms f(i) sum to a regardless of their order, then the terms f(i) times c sum to a times c for every fixed number c. *Used for:* Factoring a common constant out of a sum: normalization constants and conversion factors in mode sums. *Price:* **free**; exact.

97. The sum of a series is unique. A series cannot sum to two different values when the sum does not depend on the order of its terms. *Used for:* A computed partition function, energy sum or expectation value is a single definite number. *Price:* **free**; exact.

98. Termwise smaller series have smaller sums. If f(i) ≤ g(i) for every i, the terms f(i) sum to a and the terms g(i) sum to b, both regardless of order, then a ≤ b. *Used for:* Comparing sums: bounding a partition function by a simpler one and estimating spectral sums by comparison. *Price:* **free**; exact.

99. The zero series sums to zero. The series whose terms are all 0 sums to 0. *Used for:* The base case of every sum: vanishing contributions add nothing to an energy or a partition function. *Price:* **free**; exact.

100. Differentiating a series term by term, continuously differentiable terms (variant). Let g_0, g_1, g_2, ... be real functions on [0, 1], each g_n with a derivative g_n' that is uniform on the closed interval [0, 1] (one accuracy rate for all points, end points included), and let $|g_n'(x)| \le u(n)$ on [0, 1] for numbers u(n) whose series converges. If the series $g_0(y) + g_1(y) + g_2(y) + \ldots$ converges at one point y of [0, 1], then at every point x of [0, 1] the series of the values $g_n(x)$ and the series of the derivatives $g_n'(x)$ both converge, and the sum of the first series has the sum of the second as its derivative, uniformly on [0, 1]. *Used for:* Differentiating Fourier series, power series and eigenfunction expansions term by term, for example to get velocities, fields or currents from a series solution of the wave or heat equation. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

101. Taylor's theorem with the Peano remainder. Let $F_0 = f, F_1, \ldots, F_n$ be real functions on [0, 1] such that, for each $i < n$, F_{i+1} is the derivative of F_i uniformly on the closed interval [0, 1] (one accuracy rate for all points, end points included), and F_n is uniformly continuous on [0, 1]. Then near 0 the difference between f(x) and its Taylor polynomial of degree n at 0, built from $F_0(0), \ldots, F_n(0)$, is small compared with x^n: for every tolerance $c > 0$ there is a distance $d > 0$ such that this difference is at most $c \cdot x^n$ in absolute value for every x in [0, 1] with $x \le d$. *Used for:* Justifying small-oscillation, harmonic and linear-response approximations: replacing a potential or a response by its Taylor polynomial near an equilibrium point leaves an error that vanishes faster than the last power kept. *Price:* **free**; exact.

102. Compound growth exceeds every bound. If $r > 0$, then $(1 + r)^n$ exceeds any given number once n is large enough. *Used for:* Growth quoted as a fixed fractional increase per step: a gain of r per pass in a laser cavity or an excess of r neutrons per generation in a chain reaction grows without limit. *Price:* **free**; exact.

103. Geometric decay stays positive. If $0 < r < 1$, then r^n tends to 0 while every r^n stays strictly positive. *Used for:* Remaining fractions after repeated attenuation: the share of nuclei left after n half-lives or of light left after n absorbing layers shrinks toward zero without ever reaching it. *Price:* **free**; exact.

104. Powers of a number smaller than 1 in size vanish. If r is a real number with $|r| < 1$, then r^n tends to 0, also when r is negative. *Used for:* Damped responses that flip sign at every step: echoes inverted at each reflection, overshooting relaxation in feedback loops and iterations whose error alternates in sign. *Price:* **free**; exact.

105. Exponentials beat polynomials. If $r > 1$ and k is a whole number, then n^k / r^n tends to 0. *Used for:* Exponential suppression outweighs polynomial growth: Boltzmann factors beat polynomially growing numbers of states at high energy, and an exponentially converging method beats any polynomial error growth. *Price:* **free**; exact.

106. A constant over a power of n tends to zero. For every number r and every whole number k of at least 1, r / n^k tends to 0 as n grows. *Used for:* Power-law corrections that disappear in large systems: $1/N$ and $1/N^2$ finite-size corrections and discretization errors that fall like a power of the number of grid points. *Price:* **free**; exact.

107. Factorials beat exponentials. For every number c, $c^n / n!$ tends to 0 as n grows. *Used for:* High-order terms of factorial series vanish: the probability of very many events in a Poisson process and the late terms of the series for time evolution and Boltzmann factors. *Price:* **free**; exact.

108. n factorial is small next to n to the n. The ratio $n! / n^n$ tends to 0 as n grows. *Used for:* Counting in statistical mechanics: the number of orderings of n particles is negligible next to the number of ways to place n particles in n cells, the comparison behind Stirling-type entropy estimates. *Price:* **free**; exact.

109. Growth by a fixed factor is unbounded. If $v(0) > 0$, $c > 1$ and $v(n+1)$ is at least c times v(n) for every n, then v(n) exceeds any given number for large n. *Used for:* Instability criteria: a perturbation amplified at least by a fixed factor each period, as in parametric resonance or an unstable mode of a numerical scheme, grows without limit. *Price:* **free**; exact.

110. Discrete Gronwall bound from above. If c is at least 0 and $u(k+1)$ is at most $c\ u(k)$ for every k below n, then u(n) is at most $c^n\ u(0)$. *Used for:* Error growth in step-by-step methods: if each time step multiplies the error by at most c, the error after n

steps is at most c^n times the initial error. *Price:* **free**; exact.

111. Discrete Gronwall bound from below. If c is at least 0 and c u(k) is at most u(k+1) for every k below n, then c^n u(0) is at most u(n). *Used for:* Guaranteed amplification: a signal or population multiplied by at least c in every step is at least c^n times its initial size after n steps. *Price:* **free**; exact.

112. Fibonacci ratios approach the golden ratio. The golden ratio, the positive number φ with $\varphi^2 = \varphi + 1$, exists, and the ratio F(n+1)/F(n) of consecutive Fibonacci numbers tends to it. *Used for:* The golden ratio in physics: self-similar scaling, quasicrystal tilings, the most irrational winding number in the stability of orbits. *Price:* **free**; exact.

113. Inverse Fibonacci ratios approach one over φ. The ratio F(n)/F(n+1) of consecutive Fibonacci numbers tends to φ − 1, which equals 1/φ, where φ is the golden ratio. *Used for:* Rational approximations of the golden mean: the fractions F(n)/F(n+1) approach the golden-mean rotation number of the last invariant orbit to break in a perturbed system. *Price:* **free**; exact.

114. A damped linear recursion settles. If $0 \le a < 1$ and u(n+1) = a u(n) + b, then u(n) tends to b / (1 − a), whatever the starting value. *Used for:* Steady states of linear relaxation: repeated dilution and refilling, a capacitor charged in steps, and any first-order discrete process with constant input. *Price:* **free**; exact.

115. Error bound for geometrically converging iterations. If the consecutive terms of a sequence u of real numbers satisfy $|u(n) - u(n+1)| \le C\, r^n$ with $0 \le r < 1$ and the sequence tends to a, then $|u(n) - a| \le C\, r^n / (1 - r)$. *Used for:* Stopping rules for iterative solvers: fixed-point and self-consistent-field iterations estimate their remaining error from the size of the current step. *Price:* **free**; exact.

116. Truncation error of a geometrically bounded series. If real numbers f(n) satisfy $|f(n)| \le C\, r^n$ with $0 \le r < 1$ and the series of the f(n) sums to a, then the sum of the first n terms differs from a by at most $C\, r^n / (1 - r)$. *Used for:* Truncating perturbation and multipole expansions: deciding how many terms to keep for a required accuracy when the terms fall off geometrically. *Price:* **free**; exact.

117. Summable steps make a Cauchy sequence. If a sequence u of real numbers satisfies $|u(n) - u(n+1)| \le d(n)$ for every n and the numbers d(n) have a finite sum, then the terms of u get arbitrarily close to one another. *Used for:* Convergence of paths with finite total length: an iteration or sampled trajectory whose step lengths add up to a finite total cannot keep wandering. *Price:* **free**; exact.

118. Geometric series with ratio smaller than 1 in size. If $|r| < 1$, then $1 + r + r^2 + r^3 + \ldots$ sums to 1 / (1 − r), in any order of the terms, also for negative r. *Used for:* Sums of multiple reflections with sign changes: image charges between two plates, transmission through a cavity with a phase flip at each pass, and alternating feedback sums. *Price:* **free**; exact.

119. The sum of n times r to the n. If r is a real number with $|r| < 1$, then the sum over n of $n\, r^n$ equals $r / (1 - r)^2$, in any order of the terms. *Used for:* Mean occupation numbers: the average number of quanta in a thermal harmonic oscillator (the Planck distribution) and the mean of a geometric distribution. *Price:* **free**; exact.

120. The exponential series converges. For every number x, the terms $x^n / n!$ for n = 0, 1, 2, ... have a finite sum, regardless of the order of the terms. *Used for:* Convergence checks for series with factorial denominators, such as the Poisson distribution and the Taylor series of the exponential, made before the exponential function itself is constructed. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

121. A sum is the limit of its partial sums. If a series of real numbers sums to a regardless of the order of its terms, then the sums of its first n terms tend to a. *Used for:* Computing sums by truncation: partition functions, lattice sums and mode sums evaluated by adding terms in order until the result settles. *Price:* **free**; exact.

122. Ratio test for divergence. If $r > 1$, the real terms of a series do not all vanish from some index on, and from some index on each term is at least r times the previous one in size, then the series has no finite sum. *Used for:* Recognizing divergent expansions: perturbation series whose terms grow geometrically, and partition functions of systems whose number of states grows exponentially with energy above a limiting temperature. *Price:* **free**; exact.

123. Ratio test with limit above 1. If the ratio of the sizes of consecutive terms of a series of real numbers tends to a limit $l > 1$, then the series has no finite sum. *Used for:* Limits of power-series methods: a perturbative or virial expansion diverges beyond the point where the ratio of successive terms exceeds 1. *Price:* **free**; exact.

124. Bounded series of nonnegative terms converge. If every term f(n) is nonnegative and every partial sum $f(0) + \ldots + f(n-1)$ is at most a fixed number c, then the series has a finite sum, independent of the order of its terms. *Used for:* Normalizable probabilities and bounded totals: nonnegative probabilities that never add up to more than 1, or

nonnegative contributions bounded by a conserved total, have a definite sum. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

125. Bounded finite sums give a convergent series. If real numbers f(0), f(1), f(2), ... are all nonnegative and their sum over every finite set of indices is at most a fixed number c, then the series has a finite sum. *Used for:* Sums over states with no natural ordering: occupation sums and lattice sums of nonnegative terms converge as soon as every finite collection of states contributes at most a fixed amount. *Price:* **LPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

126. A dominated series has a smaller sum. If real numbers f(i) and g(i), indexed by the whole numbers i, satisfy $|f(i)| \le g(i)$ for every i, the f(i) sum to a and the g(i) sum to b, then $|a| \le b$. *Used for:* Bounding a sum by a majorant: estimating the size of a perturbation series or of a Green's function expansion by a simpler series of positive terms. *Price:* **free**; exact.

127. Derivatives take every intermediate value (Darboux). Let f be uniformly continuous on [0, 1] (one accuracy rate for all points of the interval), with a derivative f′(x) at every point x of [0, 1] (one-sided at the two ends). If $f'(0) < m < f'(1)$, then $f'(c) = m$ at some point c strictly between 0 and 1, even when the derivative f′ is not continuous. *Used for:* Rates of change cannot jump over values: a velocity, slope or force that is the derivative of a position, height or potential passes through every value between two of its values, so a force that pulls one way at one end of a path and the other way at the other end balances exactly at some point in between. *Price:* **LLPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

128. Darboux's theorem for a decreasing change of rate. Let f be uniformly continuous on [0, 1] (one accuracy rate for all points of the interval), with a derivative f′(x) at every point x of [0, 1] (one-sided at the two ends). If $f'(1) < m < f'(0)$, then $f'(c) = m$ at some point c strictly between 0 and 1, even when f′ is not continuous. *Used for:* A rate that starts above a value and ends below it must equal that value somewhere in between: a body whose velocity falls from above a given velocity to below it has exactly that velocity at some instant, whether or not its acceleration is well behaved. *Price:* **LLPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

129. Derivatives reach every value between their end values. Let f be uniformly continuous on [0, 1] (one accuracy rate for all points of the interval), with a derivative f′(x) at every point x of [0, 1] (one-sided at the two ends). If $f'(0) \le m \le f'(1)$, then $f'(c) = m$ at some point c of [0, 1]. *Used for:* Guaranteeing an exact match of a rate with a target value when the rates at the two ends bracket the target, for example a point where a force exactly balances a given load or where a growth rate equals a given rate, with the match allowed at an end of the interval. *Price:* **LLPO + AC**$_\omega$; exact (the upper bound uses countable choice, not shown to be needed).

130. Differentiating a series term by term. Take a series of real functions g(0), g(1), g(2), ... on [0, 1], each continuous on [0, 1] and differentiable at every point strictly inside, with |derivative of the n-th term| at most u(n) there and the sum of the u(n) finite. If the series converges at one point of [0, 1], it converges at every point of [0, 1], the series of derivatives converges at every point strictly inside, and the sum is differentiable at every point strictly inside, with derivative equal to the sum of the derivatives. *Used for:* Differentiating Fourier series, power series and eigenfunction expansions term by term, for example to get velocities, fields or currents from a series solution of the wave or heat equation. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of representatives).

131. First derivative test for a minimum. If a function f is continuous at b and differentiable on intervals (a, b) and (b, c) on either side of b, with $f' \le 0$ on (a, b) and $f' \ge 0$ on (b, c), then f has a local minimum at b. *Used for:* Locating a stable equilibrium from the direction of the force alone: a force that points back toward b from both sides marks a minimum of potential energy, including flat minima such as a potential proportional to x^4, where the curvature vanishes and a second-derivative check says nothing. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

132. First derivative test for a maximum. If a function f is continuous at b and differentiable on intervals (a, b) and (b, c) on either side of b, with $f' \ge 0$ on (a, b) and $f' \le 0$ on (b, c), then f has a local maximum at b. *Used for:* Finding peaks where a quantity stops rising and starts falling, such as the highest point of a projectile's path or the peak of a resonance curve, even when the peak is flat and the second derivative is zero. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

133. First derivative test for a minimum, local form. If a function f is continuous at b, differentiable at the points near b other than b, with $f' \le 0$ at all points in some interval just left of b and $f' \ge 0$ at all points in some interval just right of b, then f has a local minimum at b. *Used for:* Classifying an

equilibrium by checking the sign of the force only very close to it on each side: a restoring force from both sides, however weak, makes the point a minimum of the potential energy. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

134. First derivative test for a maximum, local form. If a function f is continuous at b, differentiable at the points near b other than b, with $f' \geq 0$ at all points in some interval just left of b and $f' \leq 0$ at all points in some interval just right of b, then f has a local maximum at b. *Used for:* Recognising a point of unstable balance from the local sign of the force: a force pushing away from the point on both sides makes it a maximum of the potential energy, so the system leaves it under any small disturbance. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

135. Second derivative test for a minimum. If a function f is continuous at a point x_0 and differentiable at every point near x_0, x_0 included, with derivative f', where $f'(x_0) = 0$ and f' has a positive derivative $f''(x_0) > 0$ at x_0, then f has a local minimum at x_0: $f(x_0) \leq f(y)$ for every y close enough to x_0. *Used for:* Deciding that an equilibrium is stable: where the force vanishes and the potential energy curves upward, the system rests at a minimum of energy, which is the starting point of the small-oscillation (harmonic) approximation for molecules, crystal lattices and orbits. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

136. Second derivative test for a maximum. If a function f is continuous at a point x_0 and differentiable at every point near x_0, x_0 included, with derivative f', where $f'(x_0) = 0$ and f' has a negative derivative $f''(x_0) < 0$ at x_0, then f has a local maximum at x_0: $f(y) \leq f(x_0)$ for every y close enough to x_0. *Used for:* Recognising unstable equilibria and barrier tops: where the force vanishes and the potential energy curves downward, as at the top of an activation barrier in a chemical reaction or an inverted pendulum, the system sits at a maximum of energy and small pushes grow. *Price:* **free**; exact (the upper bound chooses representatives of a sequence of points, which the free allowance contains).

137. A derivative that misses a value stays on one side. If a function f has a derivative $f'(x)$ at every point x of the interval $[0, 1]$ (one-sided at the two ends) and $f'(x)$ is not equal to m for every x in $[0, 1]$, then either $f'(x) < m$ for every x in $[0, 1]$, or $f'(x) > m$ for every x in $[0, 1]$, even when f' is not continuous. *Used for:* A rate that never takes a value cannot cross it: a velocity that is never zero never changes direction, and a growth rate, slope or force that never equals a given threshold stays on one side of it all along. *Price:* $\mathbf{MP} + \mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

138. L'Hôpital's rule at infinity. If f(x) and g(x) both tend to 0 as x grows without bound, f and g are differentiable for all large x, $g'(x)$ is never 0 there, and $f'(x)/g'(x)$ tends to a finite limit l as x grows, then $f(x)/g(x)$ also tends to l as x grows. Nothing else is assumed about f and g. *Used for:* Comparing two quantities that both vanish at large argument: the relative decay of fields and potentials at large distance (a screened potential against a Coulomb tail), ratios of correlation functions at large separation, the leading behaviour of response functions at high frequency, and ratios of quantities that vanish as the temperature or the energy grows without bound. *Price:* $\mathbf{MP}^{\vee} + \mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

139. L'Hôpital's rule approaching a point from below. If f(x) and g(x) both tend to 0 as x increases to a point b, f and g are differentiable at every point of an interval just below b, $g'(x)$ is never 0 there, and $f'(x)/g'(x)$ tends to a finite limit l as x increases to b, then $f(x)/g(x)$ also tends to l as x increases to b. Nothing else is assumed about f and g at b. *Used for:* Limits of ratios at the upper end of a physical range approached from below, where numerator and denominator vanish together: quantities followed as a temperature rises to a critical temperature, as a speed rises toward the speed of light, or as a coupling or an energy rises to a threshold value. *Price:* $\mathbf{MP}^{\vee} + \mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

140. L'Hôpital's rule at minus infinity. If f(x) and g(x) both tend to 0 as x decreases without bound, f and g are differentiable for all sufficiently negative x, $g'(x)$ is never 0 there, and $f'(x)/g'(x)$ tends to a finite limit l as x decreases without bound, then $f(x)/g(x)$ also tends to l as x decreases without bound. Nothing else is assumed about f and g. *Used for:* Ratios of quantities that vanish in the far past or at large negative argument: the early-time behaviour of signals that switch on smoothly from zero, and the comparison of two decaying solutions deep on the forbidden side of a potential barrier. *Price:* $\mathbf{MP}^{\vee} + \mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

141. L'Hôpital's rule from both sides. If f(x) and g(x) both tend to 0 as x approaches a point a from either side, f and g are differentiable at every point near a other than a itself, $g'(x)$ is never 0 at those points, and $f'(x)/g'(x)$ tends to a finite limit l as x approaches a, then $f(x)/g(x)$ also tends to l as x

approaches a from either side. Nothing is assumed about f and g at a itself. *Used for:* Removing apparent singularities of physical formulas at a point where numerator and denominator vanish together, such as sin(x)/x at x = 0, the response of a driven oscillator exactly at resonance, or a formula with a factor (E − E0) in numerator and denominator, approached from both sides of the special value. *Price:* $\mathbf{MP}^{\vee}$ + $\mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

142. Convexity means increasing chord slopes. A function f on the interval [0, 1] is convex (the chord between any two points of its graph lies on or above the graph) exactly when, for any three points x < y < z of [0, 1], the slope of the chord from x to y, (f(y) − f(x))/(y − x), is at most the slope of the chord from y to z, (f(z) − f(y))/(z − y). *Used for:* Testing convexity from three values at a time: checking that a free energy, an energy as a function of volume or entropy, or a potential is convex (the condition for thermodynamic and mechanical stability) from tabulated or measured points, by comparing successive chord slopes; the basis of convex interpolation and of the stability tests on a grid. *Price:* **free**; exact.

143. Secant slopes of a convex function increase. If f is convex on the interval [0, 1] and a is a point of [0, 1], then the slope of the chord from a to x, (f(x) − f(a))/(x − a), increases as x increases through the points of [0, 1] different from a. *Used for:* Bounding a convex function by chords through a fixed point: estimating the change of a convex free energy or potential from a reference state, the monotone growth of average rates such as the mean cost per unit change from a fixed starting point, and the slope comparisons behind Legendre transforms. *Price:* **free**; exact.

144. Concavity means decreasing chord slopes. A function f on the interval [0, 1] is concave (the chord between any two points of its graph lies on or below the graph) exactly when, for any three points x < y < z of [0, 1], the slope of the chord from y to z, (f(z) − f(y))/(z − y), is at most the slope of the chord from x to y, (f(y) − f(x))/(y − x). *Used for:* Testing concavity from three values at a time: checking that an entropy as a function of energy is concave (positive heat capacity, thermal stability), that a utility or a production curve shows diminishing returns, from successive chord slopes of measured or tabulated values. *Price:* **free**; exact.

145. Secant slopes of a concave function decrease. If f is concave on the interval [0, 1] and a is a point of [0, 1], then the slope of the chord from a to x, (f(x) − f(a))/(x − a), decreases as x increases through the points of [0, 1] different from a. *Used for:* Bounding a concave function by chords through a fixed point: average gains such as entropy gained per unit of energy added from a reference state shrink as more is added, giving upper and lower estimates of concave entropies and of diminishing returns. *Price:* **free**; exact.

146. A convex function lies above its tangent line. If f is convex on the interval [0, 1], x < y are points of [0, 1] and f has derivative f′(x) at x, then f′(x) is at most the chord slope (f(y) − f(x))/(y − x); equivalently f(y) is at least f(x) + f′(x)(y − x), so the graph lies above the tangent line at x. *Used for:* Tangent-line lower bounds: the supporting-line inequality behind Legendre transforms and convex duality (a convex free energy is the upper envelope of its tangent lines), and linearized estimates that are guaranteed to underestimate a convex energy, free energy or cost. *Price:* **free**; exact.

147. A convex function lies above its tangent, right end. If f is convex on the interval [0, 1], x < y are points of [0, 1] and f has derivative f′(y) at y, then the chord slope (f(y) − f(x))/(y − x) is at most f′(y); equivalently f(x) is at least f(y) + f′(y)(x − y). *Used for:* Tangent-line lower bounds taken at the far end of an interval: bounding a convex energy, free energy or cost on the left of a point by its tangent line at that point, as in backward error estimates and in comparing a convex potential with its linearization. *Price:* **free**; exact.

148. Tangent below a convex function, derivative taken inside the interval. If f is convex on the closed interval [0, 1], x < y are points of [0, 1] and f has derivative f′(x) at x computed only from points of [0, 1], then f′(x) is at most the chord slope (f(y) − f(x))/(y − x). *Used for:* Tangent-line bounds at the edge of a domain, where the function is only defined on one side: a convex free energy or potential at the boundary of its allowed range (zero density, a wall, a maximal filling) is still bounded below by its one-sided tangent. *Price:* **free**; exact.

149. Chord slope below the right-end derivative, inside the interval. If f is convex on the closed interval [0, 1], x < y are points of [0, 1] and f has derivative f′(y) at y computed only from points of [0, 1], then the chord slope (f(y) − f(x))/(y − x) is at most f′(y). *Used for:* Bounding a convex quantity near the upper edge of its allowed range by its one-sided tangent there, for example a convex energy at full filling or at the largest allowed volume. *Price:* **free**; exact.

150. A convex function's right derivative is below the chord slope. If f is convex on the interval [0, 1], x < y are points of [0, 1] and f has a right derivative d at x (computed from points to the right of x only), then d is at most the chord slope (f(y) − f(x))/(y − x). *Used for:* Convex functions with kinks: at a first-order phase transition a free energy has

different left and right derivatives (two values of density, magnetization or entropy); the right derivative still bounds the free energy from below on the right, which fixes the coexisting phases and the latent heat. *Price:* **free**; exact.

151. A convex function's left derivative is above the chord slope. If f is convex on the interval [0, 1], $x < y$ are points of [0, 1] and f has a left derivative d at y (computed from points to the left of y only), then the chord slope $(f(y) - f(x))/(y - x)$ is at most d. *Used for:* Convex functions with kinks: at a phase transition the left derivative of a free energy bounds it from below on the left, the companion of the right-derivative bound that brackets the jump of density or entropy across the transition. *Price:* **free**; exact.

152. The derivative of a convex function increases. If f is convex on the interval [0, 1] and has a derivative $f'(x)$ at every point x of [0, 1], then $f'(x) \le f'(y)$ whenever $x \le y$ are points of [0, 1]. *Used for:* Monotone response from convexity: the temperature, the chemical potential or minus the pressure, obtained as the derivative of a convex energy or free energy, increases with its conjugate variable (positive compressibility and heat capacity), which makes Legendre transforms one to one and equations of state invertible. *Price:* **free**; exact.

153. The derivative of a convex function increases, edges included. If f is convex on the closed interval [0, 1] and has a derivative $f'(x)$ at every point x of [0, 1], computed only from points of [0, 1] (so one-sided at the two end points), then $f'(x) \le f'(y)$ whenever $x \le y$ are points of [0, 1]. *Used for:* Monotone response up to the boundary of the allowed range: a convex energy or free energy defined only on a closed range (densities between zero and full packing, fractions between 0 and 1) still has an increasing derivative, so its conjugate variable is ordered on the whole range. *Price:* **free**; exact.

154. Convex functions of one variable are continuous inside (variant). If f is convex on the closed interval [0, 1], then f is continuous at every point strictly between 0 and 1. *Used for:* Continuity of thermodynamic potentials for free: a free energy, entropy or energy known only to be convex or concave in one variable is automatically continuous away from the edges of its range, so it can be evaluated through limits and approximated from measured values; phase transitions show up as kinks, never as jumps, inside the range. *Price:* **free**; exact.

155. L'Hôpital's rule with continuity at the endpoint. If f and g are continuous on the interval [0, 1) with $f(0) = g(0) = 0$, differentiable at every point strictly between 0 and 1 with $g'(x)$ never 0 there, and $f'(x)/g'(x)$ tends to a limit l as x decreases to 0, then $f(x)/g(x)$ also tends to l as x decreases to 0. *Used for:* Limits of ratios of quantities that start from zero together at the beginning of a process, such as the ratio of two displacements, charges or populations that both begin at zero at time a, read off from the ratio of their initial rates of change. *Price:* $\mathbf{MP}^{\vee}$ + $\mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

156. L'Hôpital's rule from below with continuity at the endpoint. If f and g are continuous on the interval (0, 1] with $f(1) = g(1) = 0$, differentiable at every point strictly between 0 and 1 with $g'(x)$ never 0 there, and $f'(x)/g'(x)$ tends to a limit l as x increases to 1, then $f(x)/g(x)$ also tends to l as x increases to 1. *Used for:* Limits of ratios of two quantities that reach zero together at the end of a process, such as two signals or reserves that run out together at the final time b, compared through the ratio of their final rates of change. *Price:* $\mathbf{MP}^{\vee}$ + $\mathbf{AC}_{\omega}$; exact (the upper bound uses countable choice, not shown to be needed).

Q.3 Exponential, logarithm, trigonometric and complex functions

157. Exponential is at least one plus x. For every real number x, $x + 1 \le e^x$. *Used for:* Gibbs' inequality, non-negativity of relative entropy, the Gibbs variational principle. *Price:* **free**; exact.

158. Logarithm is at most x minus one. For every $x > 0$, $\ln x \le x - 1$. *Used for:* Upper bounds on the information $-\ln p$ of an outcome and on free-energy differences. *Price:* **free**; exact.

159. Logarithm is at least one minus 1/x. For every $x > 0$, $1 - 1/x \le \ln x$. *Used for:* Lower bounds on the information of an outcome and entropy estimates. *Price:* **free**; exact.

160. Derivative of the logarithm is 1/x. At every $x > 0$ the natural logarithm has derivative 1/x, uniformly for pairs of nearby points (strict differentiability). *Used for:* Entropy from heat taken in at a given temperature, and the chemical potential of a dilute solute from its concentration. *Price:* **free**; exact.

161. Strict Gibbs inequality for the exponential. If $x \neq 0$ then $x + 1 < e^x$. *Used for:* Strict positivity of

relative entropy and of the free energy of a state out of equilibrium. *Price:* **MP**; exact.

162. Strict Gibbs inequality for the logarithm. If $x > 0$ and $x \neq 1$ then $\ln x < x - 1$. *Used for:* The relative entropy of two distinct probability laws is strictly positive. *Price:* **MP**; exact.

163. Exponential of the logarithm of a nonzero number. If $x \neq 0$ there is a number L with $e^L = |x|$ (so L is the logarithm of $|x|$). *Used for:* Logarithms of magnitudes: ln of a wave amplitude in the WKB method, ln of a Jacobian determinant, decibels. *Price:* **MP**; exact.

164. Exponential decay beats every power. For every natural number n, $x^n e^{-x}$ tends to 0 as x grows without bound. *Used for:* Every moment of a Boltzmann or Planck weight is finite. *Price:* **free**; exact.

165. Error bound for the exponential series. If $|x| \leq 1$ and $n \geq 1$, the error of the n-term partial sum of the series for e^x is at most $|x|^n \cdot (n + 1)/(n! \cdot n)$. *Used for:* Error bounds for every numerical value of the exponential. *Price:* **free**; exact.

166. Mercator series for the logarithm. If $|x| < 1$, the series $x + x^2/2 + x^3/3 + \dots$ converges unconditionally to $-\ln(1 - x)$. *Used for:* Free energies of Bose and two-level systems, $-\ln(1 - e^{-\beta\varepsilon})$, mixing entropies, virial expansions. *Price:* **free**; exact.

167. Derivative of the sine. The sine has derivative the cosine at every point. *Used for:* Harmonic oscillator and wave equation. *Price:* **free**; exact.

168. Derivative of the cosine. The cosine has derivative minus the sine at every point. *Used for:* Harmonic oscillator and wave equation. *Price:* **free**; exact.

169. Sine is continuous. The sine function is continuous. *Used for:* Continuous phase observables. *Price:* **free**; exact.

170. Cosine is continuous. The cosine function is continuous. *Used for:* Continuous phase observables. *Price:* **free**; exact.

171. Pythagorean identity for sine and cosine. For every x, $\cos^2 x + \sin^2 x = 1$. *Used for:* Energy conservation of an oscillator and normalisation of qubit probabilities. *Price:* **free**; exact.

172. Sine addition formula. $\sin(x + y) = \sin x \cos y + \cos x \sin y$. *Used for:* Composing rotations, adding phases, interference. *Price:* **free**; exact.

173. Cosine addition formula. $\cos(x + y) = \cos x \cos y - \sin x \sin y$. *Used for:* Composing rotations, adding phases, beats. *Price:* **free**; exact.

174. Cosine is at most one. For every x, $\cos x \leq 1$. *Used for:* Amplitude bounds and probabilities $\cos^2(\theta/2)$ staying in $[0, 1]$. *Price:* **free**; exact.

175. Cosine is at least minus one. For every x, $-1 \leq \cos x$. *Used for:* Amplitude bounds. *Price:* **free**; exact.

176. Sine is at most one. For every x, $\sin x \leq 1$. *Used for:* Amplitude bounds. *Price:* **free**; exact.

177. Sine is at least minus one. For every x, $-1 \leq \sin x$. *Used for:* Amplitude bounds. *Price:* **free**; exact.

178. Cosine of a quarter turn is zero. $\cos(\pi/2) = 0$. *Used for:* The quarter-period phase lag between displacement and velocity of an oscillator. *Price:* **free**; exact.

179. Sine of a half turn is zero. $\sin \pi = 0$. *Used for:* Nodes of a string fixed at both ends, which quantise its modes. *Price:* **free**; exact.

180. Cosine of a half turn is minus one. $\cos \pi = -1$. *Used for:* Phase reversal and destructive interference. *Price:* **free**; exact.

181. Sine of a full turn is zero. $\sin(2\pi) = 0$. *Used for:* Closed orbits and periodic phase. *Price:* **free**; exact.

182. Cosine of a full turn is one. $\cos(2\pi) = 1$. *Used for:* Closed orbits and periodic phase. *Price:* **free**; exact.

183. Cosine has period 2π. For every x, $\cos(x + 2\pi) = \cos x$. *Used for:* Closed orbits, phase wrap in Bragg scattering, single-valued $e^{im\varphi}$. *Price:* **free**; exact.

184. Sine has period 2π. For every x, $\sin(x + 2\pi) = \sin x$. *Used for:* Closed orbits, phase wrap in Bragg scattering, single-valued $e^{im\varphi}$. *Price:* **free**; exact.

185. Small-angle bound for the cosine. If $|x| \leq 1$ then $|\cos x - (1 - x^2/2)| \leq |x|^4 \cdot 5/96$. *Used for:* Long-wave expansion of lattice links: $1 - \cos k = k^2/2 + O(k^4)$. *Price:* **free**; exact.

186. Small-angle bound for the sine. If $|x| \leq 1$ then $|\sin x - (x - x^3/6)| \leq |x|^4 \cdot 5/96$. *Used for:* Anharmonic correction of the pendulum and small-angle expansions. *Price:* **free**; exact.

187. Sine is below its argument. If $x > 0$ then $\sin x < x$. *Used for:* A chord is shorter than its arc; small-angle bounds. *Price:* **free**; exact.

188. Sine is at most its argument. If $x \geq 0$ then $\sin x \leq x$. *Used for:* Small-angle bound on a restoring force. *Price:* **free**; exact.

189. Cosine lower bound $1 - x^2/2$. For every x, $1 - x^2/2 \leq \cos x$. *Used for:* The bound $1 - \cos k \leq k^2/2$ on the symbol of a lattice Laplacian. *Price:* **free**; exact.

190. Sine is positive between 0 and π. If $0 < x < \pi$ then $\sin x > 0$. *Used for:* The first standing-wave mode is positive; a rotating qubit's probability before the half turn. *Price:* **free**; exact.

191. Jordan's inequality for the sine. If $0 \leq x \leq \pi/2$ then $(2/\pi)\, x \leq \sin x$. *Used for:* Jordan's lemma for contour and Fourier integrals; transition amplitudes up to a quarter turn. *Price:* **free**; exact.

192. Power series of the cosine. For every x, the series $\Sigma\ (-1)^n\ x^{2n}/(2n)!$ converges unconditionally to cos x. *Used for:* Small-angle expansions and every phase factor. *Price:* **free**; exact.

193. Power series of the sine. For every x, the series $\Sigma\ (-1)^n\ x^{2n+1}/(2n+1)!$ converges unconditionally to sin x. *Used for:* Small-angle expansions and every phase factor. *Price:* **free**; exact.

194. π is greater than 3. $3 < \pi$. *Used for:* Numerical values of constants that contain π, and solid angles. *Price:* **free**; exact.

195. π is less than 4. $\pi < 4$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

196. π is at most 4. $\pi \le 4$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

197. π is greater than 3.14. $3.14 < \pi$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

198. π is less than 3.15. $\pi < 3.15$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

199. π is greater than 3.1415. $3.1415 < \pi$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

200. π is less than 3.1416. $\pi < 3.1416$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

201. π is greater than 3.141592. $3.141592 < \pi$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

202. π is less than 3.141593. $\pi < 3.141593$. *Used for:* Numerical values of constants that contain π. *Price:* **free**; exact.

203. Hyperbolic Pythagorean identity. For every x, $\cosh^2 x = \sinh^2 x + 1$. *Used for:* Lorentz boosts: $\gamma^2 - (\gamma\beta)^2 = 1$. *Price:* **free**; exact.

204. Addition formula for the hyperbolic cosine. $\cosh(x + y) = \cosh x \cosh y + \sinh x \sinh y$. *Used for:* Rapidities add when relativistic velocities compose. *Price:* **free**; exact.

205. Addition formula for the hyperbolic sine. $\sinh(x + y) = \sinh x \cosh y + \cosh x \sinh y$. *Used for:* Rapidities add when relativistic velocities compose. *Price:* **free**; exact.

206. Hyperbolic cosine is positive. For every x, $\cosh x > 0$. *Used for:* $\gamma \ge 1$ and positive weights in the recognition cost. *Price:* **free**; exact.

207. Hyperbolic cosine is at least one. For every x, $\cosh x \ge 1$. *Used for:* $\gamma \ge 1$, and the recognition cost $\cosh t - 1$ is never negative. *Price:* **free**; exact.

208. Derivative of the hyperbolic sine. The hyperbolic sine has derivative the hyperbolic cosine at every point. *Used for:* The boost generator and the slope of the recognition cost. *Price:* **free**; exact.

209. Derivative of the hyperbolic cosine. The hyperbolic cosine has derivative the hyperbolic sine at every point. *Used for:* The boost generator and the slope of the recognition cost. *Price:* **free**; exact.

210. Hyperbolic tangent is below one. For every x, $\tanh x < 1$. *Used for:* $\beta = \tanh(\text{rapidity}) < 1$, so speeds stay below c; the magnetisation of a paramagnet stays below saturation. *Price:* **free**; exact.

211. Hyperbolic cosine is bounded by a Gaussian. For every x, $\cosh x \le e^{x^2/2}$. *Used for:* Hoeffding's lemma: concentration bounds for sums of ± 1 spins. *Price:* **free**; exact.

212. Strict Gibbs inequality, order-defined strictness. If $x \ne 0$ then $x + 1 < e^x$, where $a < b$ means $a \le b$ and not $b \le a$. *Used for:* Strict positivity of relative entropy, read with the strictness a partial order defines. *Price:* **free**; exact.

213. Strict Gibbs inequality for the logarithm, order-defined strictness. If $x > 0$ and $x \ne 1$ then $\ln x < x - 1$, where the conclusion $a < b$ means $a \le b$ and not $b \le a$. *Used for:* The relative entropy of two distinct probability laws is strictly positive, read with the strictness a partial order defines. *Price:* **free**; exact.

214. Polar form with a principal angle (away from zero). For every complex number z with $|z| > 0$ there are a number $r \ge 0$ with $r^2 = (\text{Re } z)^2 + (\text{Im } z)^2$ and an angle θ with $-\pi < \theta \le \pi$ such that $r \cos\theta = \text{Re } z$ and $r \sin\theta = \text{Im } z$, that is, $z = r(\cos\theta + i \sin\theta)$. *Used for:* The phase of a wave function or of any complex amplitude, the phase angle of an impedance, the direction of a vector in a plane, each read in the window from $-\pi$ to π. *Price:* **LPO**; exact.

215. Polar form with a principal angle (every point). For every complex number z, zero included, there are a number $r \ge 0$ with $r^2 = (\text{Re } z)^2 + (\text{Im } z)^2$ and an angle θ with $-\pi < \theta \le \pi$ such that $r \cos\theta = \text{Re } z$ and $r \sin\theta = \text{Im } z$, that is, $z = r(\cos\theta + i \sin\theta)$. *Used for:* The phase of a wave function or of any complex amplitude, the phase angle of an impedance, the direction of a vector in a plane, each read in the window from $-\pi$ to π at every point, zero included. *Price:* **LPO**; exact.

216. Every nonzero complex number is an exponential. For every complex number $z \ne 0$ there is a complex number w with $\exp(w) = z$: every nonzero complex number is a value of the exponential. *Used for:* Writing a complex amplitude as the exponential of a log-amplitude plus i times a phase (WKB, eikonal and scattering phases); logarithms of impedances and propagators. *Price:* **MP**; exact.

217. Every complex number away from zero is an exponential. For every complex number z with $|z| > 0$ there is a complex number w with $\exp(w) = z$. *Used for:* Writing a complex amplitude known to stay away from zero as the exponential of a log-amplitude plus i times a phase; logarithms of impedances and propagators. *Price:* **free**; exact.

218. Principal complex logarithm. For every complex number $z \neq 0$ there is a complex number w with $\exp(w) = z$ and $-\pi < \operatorname{Im} w \leq \pi$. *Used for:* The principal branch of the logarithm of an amplitude, $\log \psi = \log |\psi| + i \arg \psi$: scattering phase shifts read in one window, logarithms of impedances on the principal sheet. *Price:* **LPO**; exact.

219. Principal logarithm away from zero. For every complex number z with $|z| > 0$ there is a complex number w with $\exp(w) = z$ and $-\pi < \operatorname{Im} w \leq \pi$. *Used for:* The principal branch of the logarithm of an amplitude known to stay away from zero, $\log \psi = \log |\psi| + i \arg \psi$: scattering phase shifts read in one window, logarithms of impedances on the principal sheet. *Price:* **LPO**; exact.

220. Every number between −1 and 1 is a cosine. For every real number c with $-1 \leq c \leq 1$ there is an angle θ with $0 \leq \theta \leq \pi$ and $\cos \theta = c$. *Used for:* The angle between two vectors from their dot product; scattering, bond and dihedral angles. *Price:* **free**; exact.

221. Complex exponential turns sums into products. For all complex numbers z and w, $\exp(z + w) = \exp(z) \cdot \exp(w)$. *Used for:* Composing time evolutions, so that the phases of successive steps add; the shift rule of the Fourier transform. *Price:* **free**; exact.

222. Complex exponential of zero is one. The complex exponential of 0 is 1: $\exp(0) = 1$. *Used for:* Evolution over zero time is the identity. *Price:* **free**; exact.

223. Real part of a phase factor is the cosine. For every real number x, the real part of $\exp(i\,x)$ is $\cos x$. *Used for:* Phasors in AC circuits and optics; interference fringes. *Price:* **free**; exact.

224. Imaginary part of a phase factor is the sine. For every real number x, the imaginary part of $\exp(i\,x)$ is $\sin x$. *Used for:* Phasors in AC circuits and optics; the quadrature component of a wave. *Price:* **free**; exact.

225. Real part of the complex exponential. For every complex number z, the real part of $\exp(z)$ is $\exp(\operatorname{Re} z) \cdot \cos(\operatorname{Im} z)$. *Used for:* Damped oscillations $e^{-\gamma t} \cos(\omega t)$. *Price:* **free**; exact.

226. Imaginary part of the complex exponential. For every complex number z, the imaginary part of $\exp(z)$ is $\exp(\operatorname{Re} z) \cdot \sin(\operatorname{Im} z)$. *Used for:* Damped oscillations $e^{-\gamma t} \sin(\omega t)$. *Price:* **free**; exact.

227. Exponential of the negative is the inverse. For every complex number z, $\exp(z) \cdot \exp(-z) = 1$, and $\exp(-z)$ is the only complex number w with $\exp(z) \cdot w = 1$. *Used for:* Time reversal; the inverse of a phase factor or of a growth factor. *Price:* **free**; exact.

228. Exponential of n times z is the n-th power. For every complex number z and every natural number n, $\exp(n\,z) = \exp(z)^n$. *Used for:* Floquet and Bloch factors over n periods or n lattice cells. *Price:* **free**; exact.

229. Euler's formula for complex angles. For every complex number x, $\exp(i\,x) = \cos x + i \sin x$, where the complex cosine and sine are $\cos x = (\exp(i\,x) + \exp(-i\,x))/2$ and $\sin x = (\exp(-i\,x) - \exp(i\,x)) \cdot i/2$. *Used for:* Plane waves, phasors and rotating frames. *Price:* **free**; exact.

230. De Moivre's formula. For every complex number z and every natural number n, $(\cos z + i \sin z)^n = \cos(n\,z) + i \sin(n\,z)$, where the complex cosine and sine are $\cos z = (\exp(i\,z) + \exp(-i\,z))/2$ and $\sin z = (\exp(-i\,z) - \exp(i\,z)) \cdot i/2$. *Used for:* Multiple-angle formulas; n successive rotations, each by one fixed angle θ, make a rotation by $n\,\theta$. *Price:* **free**; exact.

231. Complex cosine extends the real cosine. For every real number x, the complex cosine $(\exp(i\,x) + \exp(-i\,x))/2$ equals the real cosine $\cos x$. *Used for:* Continuing real oscillation formulas to complex frequencies and damped modes. *Price:* **free**; exact.

232. Complex sine extends the real sine. For every real number x, the complex sine $(\exp(-i\,x) - \exp(i\,x)) \cdot i/2$ equals the real sine $\sin x$. *Used for:* Continuing real oscillation formulas to complex frequencies and damped modes. *Price:* **free**; exact.

233. Size of the complex exponential. For every complex number z, $|\exp(z)| = \exp(\operatorname{Re} z)$. *Used for:* Growth and decay rates of damped or unstable modes. *Price:* **free**; exact.

234. A phase factor has size one. For every real number x, $|\exp(i\,x)| = 1$. *Used for:* Phase factors conserve probability; unitarity of phase rotations. *Price:* **free**; exact.

235. Complex exponential never vanishes. For every complex number z, $\exp(z) \neq 0$. *Used for:* Dividing by exponential factors; the phase factor $e^{i\,S/\hbar}$ of a path integral never vanishes. *Price:* **free**; exact.

236. Complex exponential is apart from zero (stronger form). For every complex number z, $|\exp(z)|^2 > 0$, so $\exp(z)$ lies a positive distance away from 0. *Used for:* Dividing by exponential factors such as Boltzmann weights and the phase factors $e^{i\,S/\hbar}$ of a path integral. *Price:* **free**; exact.

237. Exponential series sums to the complex exponential. For every complex number z, the series $\sum z^n/n!$ over n = 0, 1, 2, … converges unconditionally to $\exp(z) = \exp(\mathrm{Re}\ z) \cdot (\cos(\mathrm{Im}\ z) + i \sin(\mathrm{Im}\ z))$, in its real part and in its imaginary part. *Used for:* The exponential series summed term by term: rotating phasors, damped oscillations and perturbation expansions of exponential factors. *Price:* **free**; exact.

238. Real part of the exponential, from its series. For all complex numbers z and w, if the real parts of the terms $z^n/n!$ (n = 0, 1, 2, …) sum unconditionally to Re w, then $\mathrm{Re}\ w = \exp(\mathrm{Re}\ z) \cdot \cos(\mathrm{Im}\ z)$. *Used for:* Damped oscillations $e^{-\gamma t}\cos(\omega t)$ computed from the exponential series. *Price:* **free**; exact.

239. Imaginary part of the exponential, from its series. For all complex numbers z and w, if the imaginary parts of the terms $z^n/n!$ (n = 0, 1, 2, …) sum unconditionally to Im w, then $\mathrm{Im}\ w = \exp(\mathrm{Re}\ z) \cdot \sin(\mathrm{Im}\ z)$. *Used for:* Damped oscillations $e^{-\gamma t}\sin(\omega t)$ computed from the exponential series. *Price:* **free**; exact.

240. When the complex exponential equals one. For every complex number z, $\exp(z) = 1$ exactly when $z = 2\pi i\, n$ for some integer n. *Used for:* Single-valued wave functions $e^{im\varphi}$ and quantized angular momentum; Bloch periodicity; the period lattice of every phase factor. *Price:* **free**; exact.

241. Zeros of the sine are the integer multiples of π. For every real number x, $\sin x = 0$ exactly when $x = n\pi$ for some integer n. *Used for:* Quantization of standing waves: a string of length L fixed at both ends has modes with $k\,L = n\,\pi$; the nodes of a particle in a box. *Price:* **free**; exact.

242. Zeros of the cosine are the odd multiples of $\pi/2$. For every real number θ, $\cos\theta = 0$ exactly when $\theta = (2k + 1)\pi/2$ for some integer k. *Used for:* Modes of a pipe or a string with one open end, $k\,L = (2n + 1)\,\pi/2$; quarter-wave resonances. *Price:* **free**; exact.

243. Cosine equals one exactly at whole turns. For every real number x, $\cos x = 1$ exactly when $x = 2\pi n$ for some integer n. *Used for:* Single-valued phases $e^{im\varphi}$ force an integer m (quantized angular momentum); constructive interference at whole-wavelength path differences. *Price:* **free**; exact.

244. Sine vanishes only at 0 between $-\pi$ and π. For every real number x with $-\pi < x < \pi$, $\sin x = 0$ exactly when $x = 0$. *Used for:* The pendulum's only equilibrium within a half turn of the bottom; the first node of a standing wave. *Price:* **free**; exact.

245. Cosine equals one only at 0 within a full turn. For every real number x with $-2\pi < x < 2\pi$, $\cos x = 1$ exactly when $x = 0$. *Used for:* A rotation by less than a full turn that returns every vector is no rotation; the central interference maximum. *Price:* **free**; exact.

246. Sine of a quarter turn is one. $\sin(\pi/2) = 1$. *Used for:* The peak displacement of an oscillator a quarter period after it passes equilibrium. *Price:* **free**; exact.

247. Sine vanishes at every integer multiple of π. For every integer n, $\sin(n\pi) = 0$. *Used for:* The nodes of a string fixed at both ends. *Price:* **free**; exact.

248. Cosine is one at every whole number of turns. For every integer n, $\cos(2\pi n) = 1$. *Used for:* A rotation by a whole number of turns changes nothing; periodic phases. *Price:* **free**; exact.

249. Cosine is positive within a quarter turn of 0. For every real number x with $-\pi/2 < x < \pi/2$, $\cos x > 0$. *Used for:* The positive projection of a vector tilted by less than a right angle; Malus's law and forward scattering. *Price:* **free**; exact.

250. Cosine is nonnegative within a quarter turn of 0. For every real number x with $-\pi/2 \le x \le \pi/2$, $\cos x \ge 0$. *Used for:* Nonnegative projections and obliquity factors. *Price:* **free**; exact.

251. Sine is nonnegative on the closed half turn. For every real number x with $0 \le x \le \pi$, $\sin x \ge 0$. *Used for:* The first standing-wave mode has one sign; the area element $r^2 \sin\theta$ of spherical coordinates is nonnegative. *Price:* **free**; exact.

252. Sine is negative between $-\pi$ and 0. For every real number x with $-\pi < x < 0$, $\sin x < 0$. *Used for:* The restoring force of a displaced pendulum points back toward equilibrium. *Price:* **free**; exact.

253. Sine is strictly increasing from $-\pi/2$ to $\pi/2$. For all real numbers x and y with $-\pi/2 \le x < y \le \pi/2$, $\sin x < \sin y$. *Used for:* An angle within a quarter turn of 0 is fixed by its sine (Snell's law, the arcsine). *Price:* **free**; exact.

254. Cosine is strictly decreasing from 0 to π. For all real numbers x and y with $0 \le x < y \le \pi$, $\cos y < \cos x$. *Used for:* A scattering angle is fixed by its cosine (the Compton and Rutherford formulas). *Price:* **free**; exact.

255. Equal cosines: angles agree up to sign and whole turns. For all real numbers x and y, $\cos x = \cos y$ exactly when $y = 2\pi k + x$ or $y = 2\pi k - x$ for some integer k. *Used for:* Diffraction maxima and equal phases of two waves; reading an angle from its cosine. *Price:* **LLPO**; exact.

256. Equal sines: angles agree up to reflection and whole turns. For all real numbers x and y, $\sin x = \sin y$ exactly when $y = 2\pi k + x$ or $y = (2k + 1)\pi - x$ for some integer k. *Used for:* The Bragg condition and equal phases of two waves; reading an angle from its sine. *Price:* **LLPO**; exact.

257. Uniqueness of power series coefficients. Let $r > 0$. If, at every real x with $|x| \le r$, the power series $a_0 + a_1x + a_2x^2 + \dots$ and $b_0 + b_1x + b_2x^2 + \dots$ with real coefficients both converge unconditionally and their sums are equal, then $a_n = b_n$ for every n. *Used for:* Matching coefficients order by order in perturbation theory, the Frobenius method for the radial equations of atoms, reading off counts from the generating functions of statistical mechanics. *Price:* **free**; exact.

258. Identity theorem for a power series at a point. Let $r > 0$ and let f be a function on the real line with $f(w + x) = a_0 + a_1x + a_2x^2 + \dots$ (converging unconditionally) for every x with $|x| \le r$. Then these are equivalent: (1) f vanishes at points other than w arbitrarily close to w, in the sense that no $\varepsilon > 0$ makes $f(z) \neq 0$ for every $z \neq w$ with $|z - w| < \varepsilon$; (2) there is an $\varepsilon > 0$ with $f(z) = 0$ for every z with $|z - w| < \varepsilon$. *Used for:* The identity theorem behind analytic continuation (here for a function of a real variable): a response function or a wavefunction given by a convergent expansion that vanishes at points accumulating at a regular point vanishes on a whole neighbourhood of that point. *Price:* **free**; exact.

259. Power series of a locally zero function vanishes. Let $r > 0$ and let f be a function on the real line with $f(w + x) = a_0 + a_1x + a_2x^2 + \dots$ (converging unconditionally) for every x with $|x| \le r$. If there is an $\varepsilon > 0$ with $f(z) = 0$ for every z with $|z - w| < \varepsilon$, then every coefficient a_n is 0. *Used for:* A quantity that vanishes for all small values of a coupling has no perturbative contribution at any order. *Price:* **free**; exact.

260. First power series coefficient is the derivative. Let $r > 0$ and let f be a function on the real line with $f(x + y) = a_0 + a_1y + a_2y^2 + \dots$ (converging unconditionally) for every y with $|y| \le r$. Then f has derivative a_1 at x. *Used for:* Linear response: the first-order coefficient of a convergent expansion in a coupling or a field is the derivative of the response at the expansion point (susceptibilities, first-order perturbation energies). *Price:* **free**; exact.

261. Sine of the arcsine. For every x with $-1 \le x \le 1$ there is an angle θ with $-\pi/2 \le \theta \le \pi/2$ and $\sin\theta = x$ (θ is the arcsine of x, so $\sin(\arcsin x) = x$). *Used for:* Angles read from a sine: the refraction angle in Snell's law, the Bragg angle from $\sin\theta = n\lambda/2d$, the amplitude angle of a pendulum. *Price:* **free**; exact.

262. Arcsine of the sine. If $-\pi/2 \le x \le \pi/2$, then every angle θ with $-\pi/2 \le \theta \le \pi/2$ and $\sin\theta = \sin x$ equals x (so $\arcsin(\sin x) = x$). *Used for:* The refraction angle in Snell's law and the Bragg angle are single-valued: the arcsine undoes the sine within a quarter turn of 0. *Price:* **free**; exact.

263. Arccosine of the cosine. If $0 \le x \le \pi$, then every angle θ with $0 \le \theta \le \pi$ and $\cos\theta = \cos x$ equals x (so $\arccos(\cos x) = x$). *Used for:* A scattering angle is fixed by its cosine (Compton and Rutherford formulas); a bond angle is fixed by the dot product of its bonds. *Price:* **free**; exact.

264. Tangent of the arctangent. For every real x there is an angle θ with $-\pi/2 < \theta < \pi/2$ and $\tan\theta = x$, where $\tan\theta = \sin\theta / \cos\theta$ and $\cos\theta > 0$ on that window (θ is the arctangent of x, so $\tan(\arctan x) = x$). *Used for:* Turning a ratio into an angle: the phase lag of a driven oscillator, the Hall angle, the Brewster angle $\arctan(n_2/n_1)$, the direction of a vector in the plane. *Price:* **free**; exact.

265. Arctangent of the tangent. If $-\pi/2 < x < \pi/2$, then every angle θ with $-\pi/2 < \theta < \pi/2$ and $\tan\theta = \tan x$ equals x (so $\arctan(\tan x) = x$). *Used for:* The arctangent undoes the tangent within a quarter turn of 0: a phase lag or a slope angle is single-valued. *Price:* **free**; exact.

266. Arctangent of zero. The angle 0 lies strictly between $-\pi/2$ and $\pi/2$ and has tangent 0, and every angle strictly between $-\pi/2$ and $\pi/2$ with tangent 0 is 0 (so $\arctan 0 = 0$). *Used for:* An undamped oscillator driven far below resonance moves in phase with the drive; a horizontal line has slope angle 0. *Price:* **free**; exact.

267. Arctangent of one is $\pi/4$. The angle $\pi/4$ lies strictly between $-\pi/2$ and $\pi/2$ and has $\tan(\pi/4) = 1$, and every angle strictly between $-\pi/2$ and $\pi/2$ with tangent 1 is $\pi/4$ (so $\arctan 1 = \pi/4$). *Used for:* The 45° phase lag of the current in a driven series RLC circuit at a half-power frequency; a beam split equally between two perpendicular directions. *Price:* **free**; exact.

268. Hyperbolic sine of the inverse hyperbolic sine. For every real x, $\sinh(\operatorname{arsinh} x) = x$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Rapidity from momentum: $\eta = \operatorname{arsinh}(p/mc)$ with $p = mc\sinh\eta$; the shape of a hanging chain. *Price:* **free**; exact.

269. Inverse hyperbolic sine of the hyperbolic sine. For every real x, $\operatorname{arsinh}(\sinh x) = x$, where $\operatorname{arsinh} y = \ln(y + \sqrt{(1 + y^2)})$. *Used for:* The rapidity is recovered from the momentum it produces; rapidities of boosts along one line add. *Price:* **free**; exact.

270. Hyperbolic cosine of the inverse hyperbolic cosine. For every $x \ge 1$, $\cosh(\operatorname{arcosh} x) = x$, where $\operatorname{arcosh} x = \ln(x + \sqrt{(x^2 - 1)})$. *Used for:* Rapidity from the Lorentz factor: $\eta = \operatorname{arcosh}\gamma$ with $\gamma = \cosh\eta$; the eccentric anomaly of a hyperbolic orbit. *Price:* **free**; exact.

271. Inverse hyperbolic cosine of the hyperbolic cosine. For every $x \ge 0$, $\operatorname{arcosh}(\cosh x) = x$, where $\operatorname{arcosh} y = \ln(y + \sqrt{(y^2 - 1)})$ for $y \ge 1$. *Used for:* A nonnegative rapidity is recovered from its Lorentz

factor $\gamma = \cosh \eta$. *Price:* **free**; exact.

272. Tangent with a value at every real number. For every real x there is a number w such that $\cos x \cdot w = 1$ whenever $\cos x \neq 0$, and $w = 0$ whenever $\cos x = 0$; the tangent $\sin x \cdot w$ is then defined at every real x. *Used for:* Physics reads the tangent where the cosine is away from 0, as in a phase angle $\tan \varphi = \omega L/R$ or the slope of a line, and there it costs nothing. A tangent with a value at every real number, including the odd multiples of $\pi/2$ where the cosine vanishes, is a convention of formal mathematics that physics does not use. *Price:* **LPO**; exact.

273. Zeros of the sine are where the cosine is ±1. For every real x, $\sin x = 0$ if and only if $\cos x = 1$ or $\cos x = -1$. *Used for:* At a node of a standing wave the conjugate quadrature is at its full amplitude, $+1$ or -1; an oscillator's velocity vanishes exactly at its turning points. *Price:* **free**; exact.

274. Zeros of the cosine are where the sine is ±1. For every real x, $\cos x = 0$ if and only if $\sin x = 1$ or $\sin x = -1$. *Used for:* An oscillator passes its equilibrium point at full speed: where the displacement quadrature vanishes the velocity quadrature is $+1$ or -1. *Price:* **free**; exact.

275. Cosine of a whole multiple of π. For every integer k, $|\cos(k\pi)| = 1$. *Used for:* Full amplitude at whole half-periods: a cosine wave sampled at multiples of half its period is $+1$ or -1, the alternating signs $(-1)^k$ of standing-wave modes at a boundary. *Price:* **free**; exact.

276. Cosine is an even function. For every real x, $\cos |x| = \cos x$. *Used for:* Quantities built from the cosine do not see the sign of a displacement or a phase: a pendulum's potential energy $1 - \cos \theta$, the tight-binding band $-2t \cos k$. *Price:* **free**; exact.

277. Hyperbolic cosine is an even function. For every real x, $\cosh |x| = \cosh x$. *Used for:* The Lorentz factor $\gamma = \cosh \eta$ depends only on the size of the rapidity, not on the direction of motion; a hanging chain is symmetric about its lowest point. *Price:* **free**; exact.

278. Absolute value of the hyperbolic sine. For every real x, $|\sinh x| = \sinh |x|$. *Used for:* The size of the momentum $p = mc \sinh \eta$ is fixed by the size of the rapidity η, whatever the direction of the boost. *Price:* **free**; exact.

279. Equal cosines of two angles. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For all real θ and ψ, $\cos \theta = \cos \psi$ if and only if θ and ψ are equal as angles or θ and $-\psi$ are equal as angles. *Used for:* Phase matching of waves: equal cosines fix a phase only up to its sign and whole turns (interference fringes, standing waves, the two solutions of a cosine condition). *Price:* **LLPO**; exact.

280. Equal sines of two angles. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For all real θ and ψ, $\sin \theta = \sin \psi$ if and only if θ and ψ are equal as angles or $\theta + \psi$ and π are equal as angles. *Used for:* The two solutions θ and $\pi - \theta$ of a sine condition (Snell's law, Bragg's law), up to whole turns; phase matching of waves. *Price:* **LLPO**; exact.

281. Zeros of the sine of an angle. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For every real θ, $\sin \theta = 0$ if and only if θ is equal as an angle to 0 or to π. *Used for:* The nodes of a wave on a ring or of a standing wave sit at phase 0 or π, up to whole turns. *Price:* **free**; exact.

282. Zeros of the cosine of an angle. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For every real θ, $\cos \theta = 0$ if and only if θ is equal as an angle to $\pi/2$ or to $-\pi/2$. *Used for:* Quarter-wave points: where the cosine quadrature of a wave vanishes the phase is a quarter turn from 0, one way or the other, up to whole turns (quadrature detection, a driven oscillator at resonance). *Price:* **free**; exact.

283. Angles with equal doubles. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For all real ψ and θ, 2ψ and 2θ are equal as angles if and only if ψ and θ are equal as angles or ψ and $\theta + \pi$ are equal as angles. *Used for:* Directions of lines counted modulo a half turn: a polarisation axis or a liquid-crystal director is fixed by twice its angle. *Price:* **free**; exact.

284. Angles equal to their own negative. Read an angle as a real number up to adding whole turns of 2π: θ and ψ are equal as angles when $\theta - \psi = 2\pi k$ for some integer k. For every real θ, θ and $-\theta$ are equal as angles if and only if θ is equal as an angle to 0 or to π. *Used for:* Phases left unchanged by a reflection or by time reversal are 0 or π, up to whole turns: real amplitudes carry a sign and nothing more. *Price:* **free**; exact.

285. When a real power is below one. For $x > 0$ and every real y, with $x^y = e^{y \ln x}$: $x^y < 1$ if and only if ($1 < x$ and $y < 0$) or ($x < 1$ and $0 < y$). *Used for:* Telling decay from growth for a Boltzmann factor or a transmission coefficient x^y when the sign of the exponent is known strictly. *Price:* **free**; exact.

286. When a real power is above one. For $x > 0$ and every real y, with $x^y = e^{y \ln x}$: $1 < x^y$ if and only if ($1 < x$ and $0 < y$) or ($x < 1$ and $y < 0$). *Used for:* Gain versus loss for an amplification factor or a growth law

x^y when the sign of the exponent is known strictly. *Price:* **free**; exact.

287. When a real power is at most one. For $x > 0$ and every real y, with $x^y = e^{y \ln x}$: $x^y \le 1$ if and only if ($1 \le x$ and $y \le 0$) or ($x \le 1$ and $0 \le y$). *Used for:* Bounding a Boltzmann factor or a transmission coefficient x^y by 1 when the base may be exactly 1 or the exponent exactly 0. *Price:* **LLPO**; exact.

288. Size of the sine from the cosine. For every real x, if $r \ge 0$ and $r^2 = 1 - \cos^2 x$, then $r = |\sin x|$: a nonnegative square root of $1 - \cos^2 x$ can only be $|\sin x|$. *Used for:* The transverse factor $\sin\theta = \sqrt{(1 - \mu^2)}$ of a direction with $\mu = \cos\theta$: spherical coordinates, the associated Legendre functions, the transverse momentum of a scattered particle. *Price:* **free**; exact.

289. Size of the cosine from the sine. For every real x, if $r \ge 0$ and $r^2 = 1 - \sin^2 x$, then $r = |\cos x|$: a nonnegative square root of $1 - \sin^2 x$ can only be $|\cos x|$. *Used for:* The cosine of an angle from its sine: the cosine of a refraction angle from Snell's law in the Fresnel formulas, the longitudinal factor of a direction. *Price:* **free**; exact.

290. The primitive n-th root of unity. For every natural number $n \ge 1$, $\zeta = e^{2\pi i/n}$ is a primitive n-th root of unity: $\zeta^n = 1$, and $\zeta^l = 1$ for a natural number l only when n divides l. *Used for:* The generator of the n-fold cyclic symmetry of a ring of n sites: Bloch phases of a periodic lattice, the n-fold rotation axis of a molecule or a crystal, the clock operator of an n-level system. *Price:* **free**; exact.

291. Roots of unity have modulus one. If z is a complex number with $z^n = 1$ for some natural number $n \ge 1$, then $|z| = 1$. *Used for:* A phase factor that returns to 1 after n steps conserves probability: the eigenvalues of a unitary symmetry of finite order have modulus one. *Price:* **free**; exact.

292. Discrete Fourier orthogonality on the integers mod N. (The standard characters of the integers mod N.) For natural numbers $N \ge 1$ and m, the sum of $e^{2\pi i \cdot jm/N}$ over $j = 0, 1, \ldots, N - 1$ equals N if N divides m, and equals 0 otherwise. *Used for:* Every lattice Fourier transform inverts because of this identity: Bloch's theorem on a ring of N sites, phonon and tight-binding bands, the discrete Fourier transform of a periodic signal, the quantum Fourier transform. *Price:* **free**; exact.

293. The n-th roots of unity are n phases. For every natural number $n \ge 1$ and every complex number x with an inverse: $x^n = 1$ if and only if $x = e^{2\pi i \cdot k/n}$ for some natural number $k < n$. *Used for:* The eigenvalues of an n-fold cyclic symmetry (a ring of n sites, an n-fold rotation axis, the clock operator of an n-level system) are exactly the n phases $e^{2\pi i k/n}$, so every state carries a quasi-momentum label k. *Price:* **free**; exact.

294. Powers of a primitive root of unity sum to zero. (The case of complex numbers.) If $k > 1$ and ζ is a complex primitive k-th root of unity ($\zeta^k = 1$, and $\zeta^l = 1$ for a natural number l only when k divides l), then $1 + \zeta + \zeta^2 + \ldots + \zeta^{k-1} = 0$. *Used for:* The phases of a ring of k sites cancel: a uniform superposition has zero overlap with every nonzero quasi-momentum; the k phasors of balanced polyphase power, such as three-phase current, sum to zero. *Price:* **free**; exact.

295. Termwise derivative of a power series inside its interval. For real numbers: if $f(x + z) = \Sigma\, a_n\, z^n$ (an unconditionally convergent sum) for every real z with $|z| < r$, where $r > 0$, then at every real y with $|y| < r$ the termwise derivative series $\Sigma\, (n + 1)\, a_{n+1}\, y^n$ converges to a number d, and f has derivative d at $x + y$. *Used for:* Differentiating a convergent expansion in one real variable anywhere inside its interval of convergence, and getting a convergent expansion of the derivative: forces from a potential given by its Taylor series, group velocities from a dispersion relation, the response of a quantity expanded in a coupling or a temperature to that parameter. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

296. Strict logarithm bound, partial-order strictness throughout. For every real x with $0 < x$ and $x \ne 1$, where $a < b$ means $a \le b$ and not $b \le a$ in both places, there is a number L with $e^L = x$ (so L is the logarithm of x) and $L < x - 1$. *Used for:* The relative entropy of two distinct probability laws is strictly positive, read with the strictness that a partial order defines in both the hypothesis and the conclusion. *Price:* **MP**; exact.

297. Liouville's theorem for entire power series. Liouville's theorem for functions given by an everywhere convergent power series: if $f(z) = a_0 + a_1 z + a_2 z^2 + \ldots$ converges unconditionally at every complex number z and $|f(z)|^2 \le M^2$ for one number M and every z, then $a_n = 0$ for every $n \ge 1$, so f is the constant a_0. *Used for:* An analytic function that stays bounded on the whole complex plane is constant, so a nonconstant one such as exp, sin or cos must grow without bound somewhere off the real axis; the standard proof that every polynomial has a complex root applies it to the reciprocal of a polynomial that had none. *Price:* **free**; exact.

298. Cauchy's estimate for power series coefficients. Cauchy's estimate for functions given by a power series: if $R > 0$ and $f(z) = a_0 + a_1 z + a_2 z^2 + \ldots$ converges unconditionally (in its real and imaginary parts) at every complex number z with $|z| = R$, with $|f(z)| \le C$ at each of those points, then $|a_n|\, R^n \le C$ for every n. *Used for:* Bounds the Taylor

coefficients of an analytic function by its size on a circle: the standard tool for the error of truncating a Taylor expansion and, in the form where the function is analytic inside the circle, for the radius of convergence of a perturbation series. *Price:* **free**; exact.

299. Machin's formula for π. If θ_1 and θ_2 are angles strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta_1 = 1/5$ and $\tan\theta_2 = 1/239$ (θ_1 is the arctangent of 1/5 and θ_2 the arctangent of 1/239), then $4\theta_1 - \theta_2 = \pi/4$. *Used for:* Computing π to any number of digits, quickly and with a certified error, for every physical formula that contains π: 4π in Coulomb's and Gauss's laws, 2π in angular frequency, the reduced Planck constant $h/2\pi$. *Price:* **free**; exact.

300. Addition formula for the arctangent. For real x and y with $x \cdot y < 1$, if θ, φ and ψ are angles strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta = x$, $\tan\varphi = y$ and $\tan\psi = (x + y)/(1 - x \cdot y)$, then $\theta + \varphi = \psi$ (so $\arctan x + \arctan y = \arctan((x + y)/(1 - x \cdot y))$). *Used for:* Adding the phase lags of two stages in series, such as two first-order filters or two driven oscillators in a chain; composing slope angles; identities such as $\arctan(1/2) + \arctan(1/3) = \pi/4$ that turn arctangent series into fast formulas for π. *Price:* **free**; exact.

301. Arctangent of a reciprocal. For every real $x > 0$, if θ and ψ are angles strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta = x$ and $\tan\psi = 1/x$, then $\psi = \pi/2 - \theta$ (so $\arctan(1/x) = \pi/2 - \arctan x$). *Used for:* Complementary angles of a right triangle; the phases across the resistor and across the capacitor of an RC divider add to $\pi/2$; converting an angle measured from one axis into the angle measured from the other. *Price:* **free**; exact.

302. Gregory's series for the arctangent. For every real x with $|x| < 1$ and every angle θ strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta = x$, the series $x - x^3/3 + x^5/5 - \ldots = \sum_n (-1)^n x^{2n+1}/(2n + 1)$ has sum θ, unconditionally: the sums over finite sets of indices tend to θ, so the order of the terms does not matter (so the series sums to $\arctan x$). *Used for:* Computing arctangents, and with Machin's formula π itself, to any precision with a certified remainder (after N terms the error is at most $|x|^{2N+1}$); small-angle expansions of phase lags, Brewster and Hall angles, and scattering angles. *Price:* **free**; exact.

303. Derivative of the arctangent. For every real x, the arctangent has derivative $1/(1 + x^2)$ at x: for every k there is j such that whenever $|y - x| \le 1/(j + 1)$, the angles θ and φ strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta = x$ and $\tan\varphi = y$ satisfy $|\varphi - \theta - (y - x)/(1 + x^2)| \le |y - x|/(k + 1)$. *Used for:* The Lorentzian (Cauchy) line shape $1/(1 + x^2)$ of a resonance is the derivative of the arctangent; it gives the phase response of a damped oscillator near resonance and the integrals behind Rutherford scattering and Landau–Zener transitions. *Price:* **free**; exact.

304. Derivative of the tangent (cosine away from zero). If $\cos x$ is apart from 0 (known to be positive or known to be negative), then the tangent has derivative $1/\cos^2 x$ at x: for every k there is j such that $\cos y$ is apart from 0 whenever $|y - x| \le 1/(j + 1)$, and for those y, $|\tan y - \tan x - (y - x)/\cos^2 x| \le |y - x|/(k + 1)$, where tan = sin/cos. *Used for:* The sensitivity of a slope to its angle, $d\tan\theta/d\theta = 1/\cos^2\theta = 1 + \tan^2\theta$: an inclined plane, a deflection read on a flat screen, small-angle error propagation in optics, and the substitution $u = \tan\theta$ in Lorentzian integrals. *Price:* **free**; exact.

305. Derivative of the tangent (cosine not zero). If $\cos x \neq 0$ (only the negation of $\cos x = 0$ is known), then the number $1/\cos^2 x$ exists, and for every k there is j such that $\cos y$ is apart from 0 (known to be positive or known to be negative) whenever $|y - x| \le 1/(j + 1)$, and for those y, $|\tan y - \tan x - (y - x)/\cos^2 x| \le |y - x|/(k + 1)$, where tan = sin/cos. *Used for:* The slope sensitivity $d\tan\theta/d\theta = 1/\cos^2\theta$ for an angle known only not to be a right angle; turning that negative knowledge into a usable bound on the slope is exactly Markov's principle. *Price:* **MP**; exact.

306. Derivative of the arcsine inside (−1, 1). If $-1 < x < 1$, then the arcsine has derivative $1/\sqrt{(1 - x^2)}$ at x: for every k there is j such that every y with $|y - x| \le 1/(j + 1)$ also lies strictly between −1 and 1, and for those y the angles θ and φ in $[-\pi/2, \pi/2]$ with $\sin\theta = x$ and $\sin\varphi = y$ satisfy $|\varphi - \theta - (y - x)/\sqrt{(1 - x^2)}| \le |y - x|/(k + 1)$. *Used for:* How fast an angle read from its sine moves: the angle of a pendulum or a rotating vector from its projection, the arcsine position distribution of a harmonic oscillator, and the substitution $x = \sin\theta$ behind the integrals of $dx/\sqrt{(1 - x^2)}$ in oscillator and orbital periods. *Price:* **free**; exact.

307. Derivative of the arcsine (point not equal to ±1). If $-1 \le x \le 1$, $x \neq -1$ and $x \neq 1$ (only the negations of $x = -1$ and $x = 1$ are known), then the number $1/\sqrt{(1 - x^2)}$ exists, and for every k there is j such that every y with $|y - x| \le 1/(j + 1)$ lies strictly between −1 and 1, and for those y the angles θ and φ in $[-\pi/2, \pi/2]$ with $\sin\theta = x$ and $\sin\varphi = y$ satisfy $|\varphi - \theta - (y - x)/\sqrt{(1 - x^2)}| \le |y - x|/(k + 1)$. *Used for:* The rate at which an angle read from its sine moves, for a sine known only not to be ±1; turning that negative knowledge into a bound on the rate is exactly Markov's principle. *Price:* **MP**; exact.

308. Derivative of the arccosine inside (−1, 1). If $-1 < x < 1$, then the arccosine has derivative $-1/\sqrt{(1 - x^2)}$ at x: for every k there is j such that every y with $|y - x| \le 1/(j + 1)$ also lies strictly between −1 and 1, and for those y the angles θ and φ in $[0, \pi]$ with $\cos\theta = x$ and $\cos\varphi = y$ satisfy $|\varphi - \theta + (y - x)/\sqrt{(1 - x^2)}| \le |y -$

$x|/(k + 1)$. *Used for:* How fast an angle read from its cosine moves: a scattering angle from its cosine in the Compton and Rutherford formulas, a bond angle from a dot product, the polar angle of a spin or a rotating vector from its projection on an axis. *Price:* **free**; exact.

309. Adding exponents multiplies powers. For $x > 0$ and all real y and z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^{y+z} = x^y \cdot x^z$. *Used for:* Composing scaling factors: growth by x^y followed by growth by x^z is growth by x^{y+z}, as for decay or amplification over successive intervals. *Price:* **free**; exact.

310. Subtracting exponents divides powers. For $x > 0$ and all real y and z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^{y-z} = x^y / x^z$. *Used for:* Ratios of power-law quantities, such as dividing a scaling law by its value at a reference scale. *Price:* **free**; exact.

311. Power of a power, positive base. For $x > 0$ and all real y and z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^{y \cdot z} = (x^y)^z$. *Used for:* Rewriting a power law in another variable, for example Kepler's law $T^2 \propto a^3$ as $T \propto a^{3/2}$. *Price:* **free**; exact.

312. A negative exponent gives the reciprocal. For $x > 0$ and every real y, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^{-y} = 1/x^y$. *Used for:* Inverse-power laws such as the r^{-2} of gravity and Coulomb's law, written as reciprocals of positive powers. *Price:* **free**; exact.

313. Real powers of positive numbers are positive. For $x > 0$ and every real y, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y > 0$. *Used for:* Positivity of Boltzmann factors, partition-function terms and power-law densities. *Price:* **free**; exact.

314. Logarithm of a real power. For $x > 0$ and every real y, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $\ln(x^y) = y \cdot \ln x$. *Used for:* Reading an exponent as the slope of a log-log plot; decibel and entropy scales of power-law quantities. *Price:* **free**; exact.

315. Exponential of a product as a power. For all real x and y, with real powers of a positive base b defined by $b^y = e^{y \ln b}$: $e^{x \cdot y} = (e^x)^y$. *Used for:* Rewriting a Boltzmann factor or a growth law $e^{r\,t}$ as a power $(e^r)^t$ of a fixed base. *Price:* **free**; exact.

316. Real powers of e are exponentials. For every real x, with real powers of a positive base b defined by $b^y = e^{y \ln b}$: $(e^1)^x = e^x$. *Used for:* Identifying the natural exponential with powers of Euler's number in decay and growth laws. *Price:* **free**; exact.

317. Zeroth power of a positive base is one. For $x > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^0 = 1$. *Used for:* The exponent-zero member of a family of power laws is the constant 1, as in normalising a scaling family. *Price:* **free**; exact.

318. First power of a positive base. For $x > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^1 = x$. *Used for:* Linear laws as the exponent-one member of a family of power laws. *Price:* **free**; exact.

319. Every real power of one is one. For every real y, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $1^y = 1$. *Used for:* A ratio equal to 1 stays 1 under any scaling exponent; normalising a power law at its reference point. *Price:* **free**; exact.

320. Power of a product of positive numbers. For $x > 0$, $y > 0$ and every real z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $(x \cdot y)^z = x^z \cdot y^z$. *Used for:* Splitting a power law of a product of quantities, as in dimensional analysis and the scaling of composite quantities. *Price:* **free**; exact.

321. Power of a reciprocal, positive base. For $x > 0$ and every real y, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $(1/x)^y = 1/x^y$. *Used for:* Moving a power between numerator and denominator, as with inverse-distance and inverse-temperature laws. *Price:* **free**; exact.

322. Power of a quotient of positive numbers. For $x > 0$, $y > 0$ and every real z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $(x/y)^z = x^z / y^z$. *Used for:* Powers of dimensionless ratios such as $(r/r_0)^n$ and $(T/T_0)^\beta$ in scaling laws. *Price:* **free**; exact.

323. Comparing powers of a base above one. For $x > 1$ and all real y and z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y \le x^z$ if and only if $y \le z$. *Used for:* Ordering growth factors by their exponents; comparing levels of a geometric hierarchy of scales. *Price:* **free**; exact.

324. Strictly comparing powers of a base above one. For $x > 1$ and all real y and z, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y < x^z$ if and only if $y < z$. *Used for:* Recovering the order of two exponents from measured growth factors, as in fitting power laws. *Price:* **free**; exact.

325. Larger exponent gives a larger power above one. For $x > 1$ and real numbers $y < z$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y < x^z$. *Used for:* Growth with a larger exponent is larger: populations, compound interest, chained amplifier stages. *Price:* **free**; exact.

326. Larger exponent gives no smaller power from one up. For $x \ge 1$ and real numbers $y \le z$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y \le x^z$. *Used for:* Bounding a growth factor by the one with the larger exponent. *Price:* **free**; exact.

327. Larger exponent gives a smaller power below one. For $0 < x < 1$ and real numbers $z < y$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y < x^z$. *Used for:* Attenuation: a thicker absorber or a longer time gives a smaller transmitted or surviving fraction. *Price:* **free**; exact.

328. Larger exponent gives no larger power up to one. For $0 < x \le 1$ and real numbers $z \le y$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^y \le x^z$. *Used for:* Bounding a survival or transmission fraction raised to a larger exponent by the one with the smaller exponent. *Price:* **free**; exact.

329. A nonnegative power keeps the order of positive bases. For real numbers $0 < x \le y$ and every real $z \ge 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^z \le y^z$. *Used for:* Monotone scaling laws such as radiated power $\propto T^4$: a larger input never gives a smaller output. *Price:* **free**; exact.

330. A positive power keeps strict order of positive bases. For real numbers $0 < x < y$ and every real $z > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^z < y^z$. *Used for:* Strictly monotone scaling laws: a hotter black body radiates strictly more, a heavier star is strictly brighter on its mass-luminosity law. *Price:* **free**; exact.

331. A positive power preserves and reflects order. For $x > 0$, $y > 0$ and every real $z > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^z \le y^z$ if and only if $x \le y$. *Used for:* Inverting a monotone power law to compare inputs from outputs, as when comparing temperatures from radiated powers. *Price:* **free**; exact.

332. A positive power preserves and reflects strict order. For $x > 0$, $y > 0$ and every real $z > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^z < y^z$ if and only if $x < y$. *Used for:* Deciding which of two inputs is larger from the outputs of a power law, such as stellar masses from luminosities. *Price:* **free**; exact.

333. A negative power reverses strict order. For real numbers $0 < x < y$ and every real $z < 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $y^z < x^z$. *Used for:* Inverse-power laws fall with distance: gravity and Coulomb forces $\propto r^{-2}$, density profiles $\propto r^{-\alpha}$. *Price:* **free**; exact.

334. A nonpositive power reverses order. For real numbers $0 < x \le y$ and every real $z \le 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $y^z \le x^z$. *Used for:* Bounding an inverse-power law at a larger distance by its value at a smaller one. *Price:* **free**; exact.

335. Whole-number real powers of a positive base. For $x > 0$ and every whole number n, with real powers of a positive base defined by $x^y = e^{y \ln x}$: x raised to the real exponent n equals the product of n factors $x \cdot x \cdot \ldots \cdot x$ (and 1 when $n = 0$). *Used for:* Polynomial laws such as kinetic energy $\frac{1}{2}mv^2$ and spring energy $\frac{1}{2}kx^2$ as members of real-exponent scaling families. *Price:* **free**; exact.

336. Real square of a positive base. For $x > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: x raised to the real exponent 2 equals $x \cdot x$. *Used for:* Kinetic energy $\frac{1}{2}mv^2$ and inverse-square laws written with real exponents. *Price:* **free**; exact.

337. Square root as the one-half power. For $x > 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $x^{1/2} \ge 0$, $x^{1/2} \cdot x^{1/2} = x$, and every $r \ge 0$ with $r \cdot r = x$ equals $x^{1/2}$; so the square root $\sqrt{x}$ is $x^{1/2}$. *Used for:* Speeds from kinetic energies $v = (2E/m)^{1/2}$, root-mean-square values, diffusion lengths growing as $t^{1/2}$. *Price:* **free**; exact.

338. The n-th root raised to the n-th power. For $x > 0$ and every whole number $n \neq 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $(x^{1/n})^n = x$. *Used for:* n-th roots undo n-th powers: the side of a cube from its volume, Kepler's semi-major axis from the period. *Price:* **free**; exact.

339. The n-th root of the n-th power. For $x > 0$ and every whole number $n \neq 0$, with real powers of a positive base defined by $x^y = e^{y \ln x}$: $(x^n)^{1/n} = x$. *Used for:* Recovering a length from an area or a volume, and an amplitude from a power law of whole order. *Price:* **free**; exact.

340. Derivative of a power law at a positive point. For $x > 0$ and every real p, with real powers of a positive base defined by $x^y = e^{y \ln x}$: the function $y \mapsto y^p$ has derivative $p \cdot x^{p-1}$ at x. Precisely, for every k there is j such that every y with $|y - x| \le 1/(j + 1)$ is positive and, for all such y, $|y^p - x^p - (y - x) \cdot p \cdot x^{p-1}| \le (1/(k + 1)) \cdot |y - x|$. *Used for:* Forces from power-law potentials, the force being minus the derivative of the potential with respect to the distance; the exponent of a scaling law as its logarithmic slope; heat capacities from energy laws $E \propto T^p$. *Price:* **free**; exact.

341. Adding complex exponents multiplies powers. For the principal logarithm of x, that is, any complex number w with $\exp(w) = x$ and $-\pi < \operatorname{Im} w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: $x^{y+z} = x^y \cdot x^z$ for all complex numbers y and z. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. *Used for:* Combining complex power-law factors, such as the frequency factors $(i\omega)^\alpha \cdot (i\omega)^\beta = (i\omega)^{\alpha+\beta}$ of fractional (constant-phase) elements in impedance and viscoelastic models, and complex scaling exponents in critical phenomena. *Price:* **free**; exact.

342. Subtracting complex exponents divides powers. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for all complex numbers y and z and every complex v with $x^z \cdot v = 1$, $x^{y-z} = x^y \cdot v$ (that is, $x^{y-z} = x^y / x^z$). The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. *Used for:* Ratios of complex power-law factors, such as a transfer function $(i\omega)^\alpha / (i\omega)^\beta$ of two fractional elements, or a scaling law divided by its value at a reference scale. *Price:* **free**; exact.

343. Negative complex exponent gives the reciprocal. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for every complex number y, $x^y \cdot x^{-y} = 1$, and every complex v with $x^y \cdot v = 1$ equals x^{-y} (that is, $x^{-y} = 1/x^y$). The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. The case x = 0, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Inverting a complex power law, such as turning the admittance $(i\omega)^\alpha$ of a constant-phase element into its impedance $(i\omega)^{-\alpha}$, or a growth factor into the matching decay factor. *Price:* **free**; exact.

344. Complex power minus one is the reciprocal. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: $x \cdot x^{-1} = 1$, and every complex v with $x \cdot v = 1$ equals x^{-1} (that is, $x^{-1} = 1/x$). The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. The case x = 0, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Consistency of power-law formulas with the reciprocal, such as admittance as the reciprocal of impedance $Z^{-1} = 1/Z$ in an alternating-current circuit. *Price:* **free**; exact.

345. Zeroth complex power of a nonzero number. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: $x^0 = 1$. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. *Used for:* Normalization of power-law factors: a complex power-law factor with zero exponent is 1, as for a fractional element of order zero, which reduces to a plain resistor. *Price:* **free**; exact.

346. First complex power of a nonzero number. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: $x^1 = x$. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. *Used for:* Consistency of complex power laws with the ordinary first power, as when a fractional element of order one reduces to an ordinary capacitor or inductor. *Price:* **free**; exact.

347. Whole-number multiple of a complex exponent. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: $x^{n \cdot y} = (x^y)^n$ for every natural number n and every complex number y, where $(x^y)^n$ is the product of n copies of x^y. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. The case x = 0, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Repeating a complex scaling step n times, as for n identical fractional stages in a cascade, whose total factor is the n-th power of one stage's factor. *Price:* **free**; exact.

348. Complex power with a whole-number exponent. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for every natural number n, x raised to the complex exponent n equals x^n, the product of n copies of x. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. The case x = 0, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Agreement of complex power-law formulas with ordinary powers at whole-number exponents, such as $(i\omega)^2 = -\omega^2$ in the transfer function of a second-order (mass and spring) system. *Price:* **free**; exact.

349. Principal n-th root of a nonzero complex number. For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for every natural number $n \ge 1$, $(x^{1/n})^n = x$, so $x^{1/n} = \exp(w/n)$ is an n-th root of x (the principal n-th root). The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. *Used for:* Taking roots of complex quantities, such as the complex wave number $k = (\omega/c) \cdot \varepsilon^{1/2}$ in an absorbing medium, the momentum $(2mE)^{1/2}$ of a bound or decaying state, and the roots in Cardano's formula. *Price:* **free**; exact.

350. Principal n-th roots of complex numbers (n ≥ 2). For the principal logarithm of x, that is, any complex number w with exp(w) = x and $-\pi < \mathrm{Im}\ w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for every whole number $n \ge 2$, $(x^{1/n})^n = x$; for n = 2 this says $x^{1/2} = \exp(w/2)$ is a square root of x (the principal square root), and for n = 3 that $x^{1/3}$ is a cube root of x. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x

costs exactly LPO. The case $x = 0$, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Square roots of complex numbers throughout physics: the complex refractive index $(\varepsilon)^{1/2}$ of an absorbing medium, the two roots of a damped oscillator's characteristic equation, and the eigenvalues of a 2×2 non-Hermitian Hamiltonian. *Price:* **free**; exact.

351. The exponential is one-to-one on the principal strip. If two complex numbers a and b both have imaginary part in $-\pi < \mathrm{Im} \le \pi$ and $\exp(a) = \exp(b)$, then $a = b$. *Used for:* A phase in the window from $-\pi$ to π is determined by the phase factor it produces: reading scattering phase shifts, WKB phases and the logarithm of an amplitude on one sheet without ambiguity. *Price:* **free**; exact.

352. The logarithm undoes the exponential on the principal strip. For every complex number a with $-\pi < \mathrm{Im}\, a \le \pi$, every principal logarithm of $\exp(a)$, that is, every complex w with $\exp(w) = \exp(a)$ and $-\pi < \mathrm{Im}\, w \le \pi$, equals a (so $\log(\exp a) = a$). *Used for:* Recovering a log-amplitude and phase from a complex amplitude on the principal sheet, as when a scattering phase shift or a WKB phase in the window from $-\pi$ to π is read back from its phase factor. *Price:* **free**; exact.

353. Power of a complex power inside the principal strip. For the principal logarithm of x, that is, any complex number w with $\exp(w) = x$ and $-\pi < \mathrm{Im}\, w \le \pi$, and with complex powers defined by $x^y = \exp(w \cdot y)$: for complex numbers y and z with $-\pi < \mathrm{Im}(w \cdot y) \le \pi$, $x^{y \cdot z} = (x^y)^z$, where $(x^y)^z = \exp(v \cdot z)$ for every principal logarithm v of x^y. The logarithm w is given: the identity holds for every such w, and producing w from a nonzero x costs exactly LPO. The case $x = 0$, with the conventions $0^0 = 1$ and $0^y = 0$, is not priced here. *Used for:* Rewriting a complex power law in another variable, such as $(i\omega)^{\alpha\beta} = ((i\omega)^{\alpha})^{\beta}$ for nested fractional elements, valid as long as the intermediate phase stays in the window from $-\pi$ to π. *Price:* **free**; exact.

354. Double-angle formula for the arctangent. For every real x with $-1 < x < 1$, if θ and ψ are angles strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta = x$ and $\tan\psi = 2x/(1 - x^2)$, then $2\theta = \psi$ (so $2 \arctan x = \arctan(2x/(1 - x^2))$). *Used for:* Doubling a phase lag, as for two identical first-order stages (filters or relaxation processes) in series; the doubling steps in fast arctangent formulas for π. *Price:* **free**; exact.

355. Euler's arctangent formula for π. If θ_1 and θ_2 are angles strictly between $-\pi/2$ and $\pi/2$ with $\tan\theta_1 = 1/2$ and $\tan\theta_2 = 1/3$ (θ_1 is the arctangent of 1/2 and θ_2 the arctangent of 1/3), then $\theta_1 + \theta_2 = \pi/4$. *Used for:* Computing π with fast arctangent series, for every physical formula that contains π (4π in Coulomb's and Gauss's laws, 2π in angular frequency, the reduced Planck constant $h/2\pi$); the 45° total phase of two stages whose phase lags have tangents 1/2 and 1/3. *Price:* **free**; exact.

356. Pythagorean identity for complex angles. For every complex number z, $\cos^2 z + \sin^2 z = 1$, where for every complex number w the complex cosine and sine are $\cos w = (\exp(i\,w) + \exp(-i\,w))/2$ and $\sin w = (\exp(-i\,w) - \exp(i\,w)) \cdot i/2$. *Used for:* Puts the cosine and sine of a complex frequency or a complex propagation constant on an equal footing with real angles, as used for damped oscillators, lossy waveguides and leaky resonator modes. *Price:* **free**; exact.

357. Pythagorean identity, sine first, complex angles. For every complex number z, $\sin^2 z + \cos^2 z = 1$, where for every complex number w the complex cosine and sine are $\cos w = (\exp(i\,w) + \exp(-i\,w))/2$ and $\sin w = (\exp(-i\,w) - \exp(i\,w)) \cdot i/2$. *Used for:* Puts the sine and cosine of a complex frequency or a complex propagation constant on an equal footing with real angles, as used for damped oscillators, lossy waveguides and leaky resonator modes. *Price:* **free**; exact.

358. Sine addition formula for complex angles. For all complex numbers x and y, $\sin(x + y) = \sin x \cdot \cos y + \cos x \cdot \sin y$, where for every complex number w the complex cosine and sine are $\cos w = (\exp(i\,w) + \exp(-i\,w))/2$ and $\sin w = (\exp(-i\,w) - \exp(i\,w)) \cdot i/2$. *Used for:* Combining phases and shifting the argument of a mode with complex frequency or complex wavenumber, for example in damped oscillations and in waves that decay as they travel. *Price:* **free**; exact.

359. Cosine addition formula for complex angles. For all complex numbers x and y, $\cos(x + y) = \cos x \cdot \cos y - \sin x \cdot \sin y$, where for every complex number w the complex cosine and sine are $\cos w = (\exp(i\,w) + \exp(-i\,w))/2$ and $\sin w = (\exp(-i\,w) - \exp(i\,w)) \cdot i/2$. *Used for:* Combining phases and shifting the argument of a mode with complex frequency or complex wavenumber, for example in damped oscillations and in waves that decay as they travel. *Price:* **free**; exact.

360. Complex cosine is even. For every complex number z, $\cos(-z) = \cos z$, where for every complex number w the complex cosine and sine are $\cos w = (\exp(i\,w) + \exp(-i\,w))/2$ and $\sin w = (\exp(-i\,w) - \exp(i\,w)) \cdot i/2$. *Used for:* Symmetric (even) standing-wave modes, and the fact that a cosine mode does not depend on the sign of a complex wavenumber. *Price:* **free**; exact.

361. Complex sine is odd. For every complex number z, $\sin(-z) = -\sin z$, where for every complex

number w the complex cosine and sine are cos w = (exp(i w) + exp(−i w))/2 and sin w = (exp(−i w) − exp(i w)) · i/2. *Used for:* Antisymmetric (odd) standing-wave modes, and the sign change of a sine mode under reversal of a complex wavenumber. *Price:* **free**; exact.

362. Double-angle formula for the complex cosine. For every complex number z, cos(2z) = 2 cos²z − 1, where for every complex number w the complex cosine and sine are cos w = (exp(i w) + exp(−i w))/2 and sin w = (exp(−i w) − exp(i w)) · i/2. *Used for:* Second harmonics and intensities of waves with complex frequency: cos² of a damped oscillation written through the cosine at twice the argument. *Price:* **free**; exact.

363. Double-angle formula for the complex sine. For every complex number z, sin(2z) = 2 sin z · cos z, where for every complex number w the complex cosine and sine are cos w = (exp(i w) + exp(−i w))/2 and sin w = (exp(−i w) − exp(i w)) · i/2. *Used for:* Second harmonics of waves with complex frequency, and products of sine and cosine modes rewritten at twice the argument. *Price:* **free**; exact.

364. Hyperbolic cosine addition formula, complex arguments. For all complex numbers x and y, cosh(x + y) = cosh x · cosh y + sinh x · sinh y, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Composing Lorentz boosts (rapidities add) and transfer matrices of evanescent or tunnelling layers, with complex arguments. *Price:* **free**; exact.

365. Hyperbolic sine addition formula, complex arguments. For all complex numbers x and y, sinh(x + y) = sinh x · cosh y + cosh x · sinh y, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Composing Lorentz boosts (rapidities add) and transfer matrices of evanescent or tunnelling layers, with complex arguments. *Price:* **free**; exact.

366. Square of the complex hyperbolic cosine. For every complex number z, cosh²z = sinh²z + 1, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* The relation $\gamma^2 = (\gamma\beta)^2 + 1$ between the Lorentz factor and the momentum factor of a boost, and the energy bookkeeping of evanescent waves, here for complex arguments. *Price:* **free**; exact.

367. Hyperbolic Pythagorean identity, complex arguments. For every complex number z, cosh²z − sinh²z = 1, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* The invariant hyperbola of special relativity ($\gamma^2 - (\gamma\beta)^2 = 1$) and the parametrization of hyperbolic orbits, here for complex arguments. *Price:* **free**; exact.

368. Complex hyperbolic cosine is even. For every complex number z, cosh(−z) = cosh z, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Symmetric evanescent profiles, such as the even bound state of a double well or the field inside a symmetric barrier. *Price:* **free**; exact.

369. Complex hyperbolic sine is odd. For every complex number z, sinh(−z) = −sinh z, where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Antisymmetric evanescent profiles, such as the odd bound state of a double well. *Price:* **free**; exact.

370. Hyperbolic cosine plus sine is the exponential. For every complex number z, cosh z + sinh z = exp(z), where for every complex number w the complex hyperbolic cosine and sine are cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Splitting a growing or decaying exponential into its even and odd parts, as in barrier-penetration and transfer-matrix calculations. *Price:* **free**; exact.

371. Cosine of an imaginary argument is hyperbolic. For every complex number z, cos(z i) = cosh z, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Continuing a standing wave cos(kx) to an imaginary wavenumber k = iκ gives the evanescent profile cosh(κx) of tunnelling and of the field beyond total internal reflection. *Price:* **free**; exact.

372. Sine of an imaginary argument is hyperbolic. For every complex number z, sin(z i) = sinh(z) · i, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Continuing a standing wave sin(kx) to an imaginary wavenumber k = iκ gives the evanescent profile sinh(κx) of tunnelling through a barrier. *Price:* **free**; exact.

373. Hyperbolic cosine of an imaginary argument is the cosine. For every complex number z, cosh(z i) = cos z, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Turning a

hyperbolic (evanescent or boost) formula into an oscillating one by an imaginary argument, as in the Wick rotation between real and imaginary time. *Price:* **free**; exact.

374. Hyperbolic sine of an imaginary argument is the sine. For every complex number z, sinh(z i) = sin(z) · i, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Turning a hyperbolic (evanescent or boost) formula into an oscillating one by an imaginary argument, as in the Wick rotation between real and imaginary time. *Price:* **free**; exact.

375. Euler's formula, cosine plus i sine form. For every complex number z, cos z + i sin z = exp(i z), where for every complex number w the complex cosine and sine are cos w = (exp(i w) + exp(−i w))/2 and sin w = (exp(−i w) − exp(i w)) · i/2. *Used for:* Writing a combination of cosine and sine as one complex exponential: plane waves, phasors and rotating frames. *Price:* **free**; exact.

376. Complex hyperbolic cosine extends the real one. For every real number x, the complex hyperbolic cosine (exp(x) + exp(−x))/2, computed in the complex numbers, equals the real hyperbolic cosine cosh x. *Used for:* Continuing real evanescent and boost formulas to complex arguments without changing their values on the real axis. *Price:* **free**; exact.

377. Complex hyperbolic sine extends the real one. For every real number x, the complex hyperbolic sine (exp(x) − exp(−x))/2, computed in the complex numbers, equals the real hyperbolic sine sinh x. *Used for:* Continuing real evanescent and boost formulas to complex arguments without changing their values on the real axis. *Price:* **free**; exact.

378. Sine of x plus i y. For all complex numbers x and y, sin(x + y i) = sin x · cosh y + cos x · sinh y · i, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Splits a sine mode with a complex wavenumber or frequency into an oscillating factor and a growing or decaying factor, as for lossy waveguides, leaky modes and damped resonances. *Price:* **free**; exact.

379. Cosine of x plus i y. For all complex numbers x and y, cos(x + y i) = cos x · cosh y − sin x · sinh y · i, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Splits a cosine mode with a complex wavenumber or frequency into an oscillating factor and a growing or decaying factor, as for lossy waveguides, leaky modes and damped resonances. *Price:* **free**; exact.

380. Real and imaginary parts of the complex sine. For every complex number z with real part x and imaginary part y, sin z = sin x · cosh y + cos x · sinh y · i, with x and y taken as complex numbers on the real axis, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Gives the oscillating and the evanescent part of a sine mode at a complex frequency, the starting point for showing where the complex sine can vanish. *Price:* **free**; exact.

381. Real and imaginary parts of the complex cosine. For every complex number z with real part x and imaginary part y, cos z = cos x · cosh y − sin x · sinh y · i, with x and y taken as complex numbers on the real axis, where for every complex number w, cos w = (exp(i w) + exp(−i w))/2, sin w = (exp(−i w) − exp(i w)) · i/2, cosh w = (exp(w) + exp(−w))/2 and sinh w = (exp(w) − exp(−w))/2. *Used for:* Gives the oscillating and the evanescent part of a cosine mode at a complex frequency, the starting point for showing where the complex cosine can vanish. *Price:* **free**; exact.

382. Zeros of the complex sine are real. For every complex number θ, sin θ = 0 exactly when θ = kπ for some integer k, where sin θ = (exp(−iθ) − exp(iθ)) · i/2; so the complex sine vanishes nowhere off the real axis. *Used for:* A string or cavity of length L fixed at both ends: when the standing-wave condition is that the sine of the wavenumber times L vanishes, with a complex wavenumber, every solution is real, the wavenumber times L being nπ, so there are no extra evanescent solutions. *Price:* **free**; exact.

383. Zeros of the complex cosine are real. For every complex number θ, cos θ = 0 exactly when θ = (2k + 1)π/2 for some integer k, where cos θ = (exp(iθ) + exp(−iθ))/2; so the complex cosine vanishes nowhere off the real axis. *Used for:* A pipe or string of length L with one fixed and one free end: when the standing-wave condition is that the cosine of the wavenumber times L vanishes, with a complex wavenumber, every solution is real, the wavenumber times L being (2n + 1)π/2, so there are no extra evanescent solutions. *Price:* **free**; exact.

384. Sine shifted by a half turn. For every real x, sin(x + π) = −sin x. *Used for:* The sign flip of a wave delayed by half a period: reflection of a wave at a fixed end, antisymmetric normal modes, phase inversion of an alternating signal. *Price:* **free**; exact.

385. Sine shifted back by a half turn. For every real x, sin(x − π) = −sin x. *Used for:* The sign flip of a wave advanced by half a period: phase inversion of an alternating signal, the opposite displacement of a pendulum half a cycle earlier. *Price:* **free**; exact.

386. Sine of the supplementary angle. For every real x, $\sin(\pi - x) = \sin x$. *Used for:* Equal sines of supplementary angles: the two launch angles with equal range in projectile motion, the ambiguity of an angle read from its sine in diffraction and refraction. *Price:* **free**; exact.

387. Sine repeats after a full turn. For every real x, $\sin(x + 2\pi) = \sin x$. *Used for:* The periodicity of oscillations and rotating phasors: one full cycle returns a wave, a pendulum or a rotating vector to its starting value. *Price:* **free**; exact.

388. Sine of a full turn minus an angle. For every real x, $\sin(2\pi - x) = -\sin x$. *Used for:* Reflection of a phase angle about a full turn: the sine of a clockwise angle measured from a full cycle, used in the symmetry of Fourier coefficients and rotating frames. *Price:* **free**; exact.

389. Cosine shifted by a half turn. For every real x, $\cos(x + \pi) = -\cos x$. *Used for:* The sign flip of a wave delayed by half a period: destructive interference of waves half a wavelength apart, phase inversion of an alternating signal. *Price:* **free**; exact.

390. Cosine shifted back by a half turn. For every real x, $\cos(x - \pi) = -\cos x$. *Used for:* The sign flip of a wave advanced by half a period: destructive interference of waves half a wavelength apart, the opposite position of an oscillator half a cycle earlier. *Price:* **free**; exact.

391. Cosine of the supplementary angle. For every real x, $\cos(\pi - x) = -\cos x$. *Used for:* Opposite projections of supplementary angles: the reversed horizontal component of a reflected velocity, the law of cosines for an exterior angle. *Price:* **free**; exact.

392. Cosine repeats after a full turn. For every real x, $\cos(x + 2\pi) = \cos x$. *Used for:* The periodicity of oscillations and rotating phasors: one full cycle returns a wave, a pendulum or a rotating vector to its starting projection. *Price:* **free**; exact.

393. Cosine of a full turn minus an angle. For every real x, $\cos(2\pi - x) = \cos x$. *Used for:* A clockwise rotation by x and a counterclockwise rotation by $2\pi -$ x end at one point and have equal cosines, used in Fourier series and rotating frames. *Price:* **free**; exact.

394. Sine shifted by a quarter turn is the cosine. For every real x, $\sin(x + \pi/2) = \cos x$. *Used for:* The quarter-period lead of the cosine over the sine: the 90 degree phase between position and velocity in simple harmonic motion, and between current and voltage in a capacitor or inductor. *Price:* **free**; exact.

395. Sine shifted back by a quarter turn. For every real x, $\sin(x - \pi/2) = -\cos x$. *Used for:* The quarter-period lag of a driven oscillator at resonance behind its drive, and the 90 degree phase of the current in an inductor behind the voltage. *Price:* **free**; exact.

396. Sine of the complementary angle. For every real x, $\sin(\pi/2 - x) = \cos x$. *Used for:* Exchanging sine and cosine for complementary angles: the components of a vector measured from the other axis, the angle of incidence measured from the surface instead of the normal. *Price:* **free**; exact.

397. Cosine shifted by a quarter turn. For every real x, $\cos(x + \pi/2) = -\sin x$. *Used for:* The quarter-period lead of the velocity of a harmonic oscillator, and the 90 degree phase of the current in a capacitor ahead of the voltage. *Price:* **free**; exact.

398. Cosine shifted back by a quarter turn. For every real x, $\cos(x - \pi/2) = \sin x$. *Used for:* Turning a cosine wave into a sine wave by a quarter-period delay: quadrature signals, the in-phase and quadrature components of a modulated wave. *Price:* **free**; exact.

399. Cosine of the complementary angle. For every real x, $\cos(\pi/2 - x) = \sin x$. *Used for:* Exchanging cosine and sine for complementary angles: the components of a vector measured from the other axis, the grazing angle and the angle of incidence in optics. *Price:* **free**; exact.

400. Sine vanishes at natural-number multiples of π. For every natural number n, $\sin(n\pi) = 0$. *Used for:* The nodes of a string fixed at both ends and of a particle in a box: the wavelengths 2L/n satisfy the standing-wave condition. *Price:* **free**; exact.

401. Cosine is one after whole turns. For every natural number n, $\cos(n \cdot 2\pi) = 1$. *Used for:* The return of a rotating phasor to its start after whole cycles: a whole number of cycles satisfies the condition for constructive interference and the periodic boundary condition of a ring. *Price:* **free**; exact.

402. Cosine of 45 degrees. $\cos(\pi/4) = \sqrt{2}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The projection of a unit spin or polarisation vector at 45 degrees: Malus's law at 45 degrees passes half the intensity, and light polarised at 45 degrees splits into equal amplitudes on a polarising beam splitter. *Price:* **free**; exact.

403. Sine of 45 degrees. $\sin(\pi/4) = \sqrt{2}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The equal sine and cosine components of a vector at 45 degrees: equal superpositions of two quantum states, and the equal horizontal and vertical velocity components of a projectile launched at 45 degrees. *Price:* **free**; exact.

404. Cosine of 60 degrees. $\cos(\pi/3) = 1/2$. *Used for:* The 60 degree geometry of hexagonal and triangular lattices (graphene, close-packed crystals), and the projection of a spin or a polarisation vector at 60 degrees. *Price:* **free**; exact.

405. Sine of 30 degrees. $\sin(\pi/6) = 1/2$. *Used for:* The 30 degree geometry of hexagonal lattices and inclined planes: the component of gravity along a 30 degree slope is half the weight. *Price:* **free**; exact.

406. Cosine of 30 degrees. $\cos(\pi/6) = \sqrt{3}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The 30 degree geometry of hexagonal and triangular lattices (the nearest-neighbour vectors of graphene), and the component of a force at 30 degrees. *Price:* **free**; exact.

407. Sine of 60 degrees. $\sin(\pi/3) = \sqrt{3}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The height of an equilateral triangle: lattice spacings of hexagonal and triangular lattices and the geometry of benzene rings. *Price:* **free**; exact.

408. Tangent of 45 degrees. The cosine of $\pi/4$ is apart from 0 (known to be positive or known to be negative), so the tangent $\tan(\pi/4) = \sin(\pi/4)/\cos(\pi/4)$ is defined, and $\tan(\pi/4) = 1$. *Used for:* The slope of a 45 degree incline or ray, and the 45 degree phase shift of a first-order filter at its cutoff frequency. *Price:* **free**; exact.

409. Tangent of 30 degrees. The cosine of $\pi/6$ is apart from 0 (known to be positive or known to be negative), so the tangent $\tan(\pi/6) = \sin(\pi/6)/\cos(\pi/6)$ is defined, and $\tan(\pi/6) \cdot \sqrt{3} = 1$, that is $\tan(\pi/6) = 1/\sqrt{3}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The slope of a 30 degree incline or ray: the friction coefficient at which a block starts to slide on a 30 degree slope, and the angles of hexagonal lattices. *Price:* **free**; exact.

410. Tangent of 60 degrees. The cosine of $\pi/3$ is apart from 0 (known to be positive or known to be negative), so the tangent $\tan(\pi/3) = \sin(\pi/3)/\cos(\pi/3)$ is defined, and $\tan(\pi/3) = \sqrt{3}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The slope of a 60 degree incline or ray, and the Brewster angle of 60 degrees for a medium of refractive index $\sqrt{3}$ (the tangent of the Brewster angle is the index). *Price:* **free**; exact.

411. Cosine of 22.5 degrees. $\cos(\pi/8) = \sqrt{(2 + \sqrt{2})}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The 22.5 degree measurement angles of the CHSH Bell test, where the quantum winning probability is $\cos^2(\pi/8) = (2 + \sqrt{2})/4$, and spin-½ and polarisation projections at 22.5 degrees. *Price:* **free**; exact.

412. Sine of 22.5 degrees. $\sin(\pi/8) = \sqrt{(2 - \sqrt{2})}/2$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The 22.5 degree measurement angles of the CHSH Bell test and of quantum state discrimination, and polarisation projections at 22.5 degrees. *Price:* **free**; exact.

413. Half-angle formula for the cosine. For every real x with $-\pi \le x \le \pi$, $\cos(x/2) = \sqrt{((1 + \cos x)/2)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The amplitude of a spin-½ state rotated by an angle x, whose square $(1 + \cos x)/2$ is the probability of keeping the spin direction; Rabi oscillations and the half-angle of Bloch-sphere rotations. *Price:* **free**; exact.

414. Half-angle formula for the size of the sine. For every real x, $|\sin(x/2)| = \sqrt{((1 - \cos x)/2)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The amplitude of a spin-½ flip after a rotation by x, whose square $(1 - \cos x)/2$ is the flip probability; the chord length $2|\sin(x/2)|$ between two points of a unit circle at angle x. *Price:* **free**; exact.

415. Half-angle formula for the sine on a turn. For every real x with $0 \le x \le 2\pi$, $\sin(x/2) = \sqrt{((1 - \cos x)/2)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The spin-flip amplitude after a rotation by an angle between 0 and a full turn, and the chord of a circle subtending that angle. *Price:* **free**; exact.

416. Half-angle formula for the sine on a reversed turn. For every real x with $-2\pi \le x \le 0$, $\sin(x/2) = -\sqrt{((1 - \cos x)/2)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* The signed spin-flip amplitude after a rotation in the negative sense by up to a full turn. *Price:* **free**; exact.

417. Cosine from the sine on a half turn. For every real x with $-\pi/2 \le x \le \pi/2$, $\cos x = \sqrt{(1 - \sin^2 x)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* Recovering a cosine from a measured sine: the refraction angle in Snell's law, the transmitted component at an interface, the direction cosines of a vector. *Price:* **free**; exact.

418. Sine from the cosine on a half turn. For every real x with $0 \le x \le \pi$, $\sin x = \sqrt{(1 - \cos^2 x)}$, where $\sqrt{}$ is the nonnegative square root. *Used for:* Recovering a sine from a measured cosine: the transverse component of a vector from its projection, the scattering-angle factor $\sqrt{(1 - \cos^2\theta)}$ in cross sections and dipole radiation. *Price:* **free**; exact.

419. Hyperbolic sine of zero. $\sinh 0 = 0$. *Used for:* Zero rapidity carries zero momentum; the slope of a hanging chain vanishes at its lowest point. *Price:* **free**; exact.

420. Hyperbolic cosine of zero. $\cosh 0 = 1$. *Used for:* A particle at rest has Lorentz factor $\gamma = \cosh 0 = 1$. *Price:* **free**; exact.

421. Hyperbolic sine is odd. For every real x, $\sinh(-x) = -\sinh x$. *Used for:* Reversing a boost reverses the momentum it produces. *Price:* **free**; exact.

422. Hyperbolic cosine is even. For every real x, $\cosh(-x) = \cosh x$. *Used for:* Opposite rapidities give equal energies γmc^2; a hanging chain is symmetric about its lowest point. *Price:* **free**; exact.

423. Subtraction formula for the hyperbolic sine. For all real x and y, $\sinh(x - y) = \sinh x \cosh y - \cosh$

x sinh y. *Used for:* Relative rapidity of two frames along one line, and the momentum seen from a moving frame. *Price:* **free**; exact.

424. Subtraction formula for the hyperbolic cosine. For all real x and y, $\cosh(x - y) = \cosh x \cosh y - \sinh x \sinh y$. *Used for:* The relative Lorentz factor of two frames, $\gamma = \gamma_1\gamma_2(1 - \beta_1\beta_2)$. *Price:* **free**; exact.

425. Hyperbolic cosine plus sine is the exponential, real line. For every real x, $\cosh x + \sinh x = e^x$. *Used for:* The Doppler factor of a boost with rapidity η is $\cosh \eta + \sinh \eta = e^\eta$. *Price:* **free**; exact.

426. Hyperbolic sine plus cosine is the exponential. For every real x, $\sinh x + \cosh x = e^x$. *Used for:* The Doppler factor of a boost with rapidity η is $\sinh \eta + \cosh \eta = e^\eta$. *Price:* **free**; exact.

427. Exponential minus hyperbolic cosine. For every real x, $e^x - \cosh x = \sinh x$. *Used for:* Splitting a growing exponential into its odd part; momentum from the Doppler factor and the energy. *Price:* **free**; exact.

428. Exponential minus hyperbolic sine. For every real x, $e^x - \sinh x = \cosh x$. *Used for:* Splitting a growing exponential into its even part; energy from the Doppler factor and the momentum. *Price:* **free**; exact.

429. Hyperbolic cosine minus sine. For every real x, $\cosh x - \sinh x = e^{-x}$. *Used for:* The inverse Doppler factor $e^{-\eta}$ of a boost; the decaying part of a hyperbolic solution. *Price:* **free**; exact.

430. Hyperbolic sine minus cosine. For every real x, $\sinh x - \cosh x = -e^{-x}$. *Used for:* The inverse Doppler factor of a boost with its sign reversed; the decaying part of a hyperbolic solution. *Price:* **free**; exact.

431. Hyperbolic Pythagorean identity, difference form. For every real x, $\cosh^2 x - \sinh^2 x = 1$. *Used for:* The mass shell $E^2 - p^2c^2 = m^2c^4$ in rapidity form, and the invariance of the interval under boosts. *Price:* **free**; exact.

432. Square of the hyperbolic sine. For every real x, $\sinh^2 x = \cosh^2 x - 1$. *Used for:* Momentum from the Lorentz factor: $(\gamma\beta)^2 = \gamma^2 - 1$. *Price:* **free**; exact.

433. Double rapidity formula for the hyperbolic cosine. For every real x, $\cosh 2x = \cosh^2 x + \sinh^2 x$. *Used for:* Composing two equal boosts; the photon-number factors cosh 2r of squeezed light. *Price:* **free**; exact.

434. Double rapidity formula for the hyperbolic sine. For every real x, $\sinh 2x = 2 \sinh x \cosh x$. *Used for:* Composing two equal boosts; the correlations sinh 2r of a two-mode squeezed state. *Price:* **free**; exact.

435. Triple rapidity formula for the hyperbolic cosine. For every real x, $\cosh 3x = 4 \cosh^3 x - 3 \cosh x$. *Used for:* Solving cubic equations with one real root by a hyperbolic substitution, as for cubic equations of state. *Price:* **free**; exact.

436. Triple rapidity formula for the hyperbolic sine. For every real x, $\sinh 3x = 4 \sinh^3 x + 3 \sinh x$. *Used for:* Solving depressed cubic equations with one real root by the substitution $x = 2\sqrt{(p/3)} \sinh t$. *Price:* **free**; exact.

437. Hyperbolic tangent of zero. $\tanh 0 = 0$, where $\tanh x = \sinh x / \cosh x$. *Used for:* Zero rapidity is zero velocity; zero field gives zero magnetisation of a paramagnet. *Price:* **free**; exact.

438. Hyperbolic tangent is odd. For every real x, $\tanh(-x) = -\tanh x$, where $\tanh x = \sinh x / \cosh x$. *Used for:* Reversing a boost reverses the velocity; reversing the field reverses the magnetisation. *Price:* **free**; exact.

439. Hyperbolic tangent from exponentials. For every real x, $\tanh x = (e^x - e^{-x})/(e^x + e^{-x})$, where $\tanh x = \sinh x / \cosh x$. *Used for:* The thermal polarisation $\tanh(E/(k \cdot T))$ of a two-level system or a spin ½ from its two Boltzmann weights, with k Boltzmann's constant and T the temperature. *Price:* **free**; exact.

440. Hyperbolic sine is below hyperbolic cosine. For every real x, $\sinh x < \cosh x$. *Used for:* Momentum stays below energy for a massive particle: $\gamma\beta < \gamma$, that is $pc < E$. *Price:* **free**; exact.

441. Hyperbolic tangent is above minus one. For every real x, $-1 < \tanh x$, where $\tanh x = \sinh x / \cosh x$. *Used for:* Velocities stay above $-c$ for every rapidity; magnetisation stays above negative saturation. *Price:* **free**; exact.

442. Square of the hyperbolic tangent is below one. For every real x, $\tanh^2 x < 1$, where $\tanh x = \sinh x / \cosh x$. *Used for:* $\beta^2 < 1$ for every rapidity, so the Lorentz factor $1/\sqrt{(1 - \beta^2)}$ is always defined. *Price:* **free**; exact.

443. Size of the hyperbolic tangent is below one. For every real x, $|\tanh x| < 1$, where $\tanh x = \sinh x / \cosh x$. *Used for:* Speeds stay below the speed of light for every finite rapidity; mean-field magnetisation stays below saturation. *Price:* **free**; exact.

444. Hyperbolic sine of a logarithm. For every $x > 0$, $\sinh(\ln x) = (x - 1/x)/2$. *Used for:* Momentum from the Doppler factor k of a boost: $\gamma\beta = (k - 1/k)/2$. *Price:* **free**; exact.

445. Hyperbolic cosine of a logarithm. For every $x > 0$, $\cosh(\ln x) = (x + 1/x)/2$. *Used for:* The Lorentz factor from the Doppler factor k, $\gamma = (k + 1/k)/2$; the recognition cost $J(x) = (x + 1/x)/2 - 1$ equals $\cosh(\ln x) - 1$. *Price:* **free**; exact.

446. Exponential of half is a square root. For every real x, $e^{x/2} = \sqrt{(e^x)}$. *Used for:* Amplitudes as square roots of Boltzmann weights or probabilities: $e^{-E/(2k\cdot T)} = \sqrt{(e^{-E/(k\cdot T)})}$, with k Boltzmann's constant and T the temperature. *Price:* **free**; exact.

447. Hyperbolic sine is strictly increasing. For all real $x < y$, $\sinh x < \sinh y$. *Used for:* Momentum increases strictly with rapidity, so a measured momentum fixes the rapidity. *Price:* **free**; exact.

448. Hyperbolic sine is one to one. For all real x and y, $\sinh x = \sinh y$ implies $x = y$. *Used for:* A momentum determines its rapidity uniquely. *Price:* **free**; exact.

449. Equal hyperbolic sines have equal arguments. For all real x and y, $\sinh x = \sinh y$ if and only if $x = y$. *Used for:* Two particles of equal mass have equal momenta exactly when they have equal rapidities. *Price:* **free**; exact.

450. Hyperbolic sine preserves and reflects order. For all real x and y, $\sinh x \le \sinh y$ if and only if $x \le y$. *Used for:* Comparing the momenta of equal-mass particles is comparing their rapidities. *Price:* **free**; exact.

451. Hyperbolic sine preserves and reflects strict order. For all real x and y, $\sinh x < \sinh y$ if and only if $x < y$. *Used for:* A larger momentum means a larger rapidity and conversely, for particles of equal mass. *Price:* **free**; exact.

452. Hyperbolic sine vanishes only at zero. For every real x, $\sinh x = 0$ if and only if $x = 0$. *Used for:* A particle has zero momentum exactly when its rapidity is zero. *Price:* **free**; exact.

453. Hyperbolic sine is nonzero away from zero. For every real x, $\sinh x \neq 0$ if and only if $x \neq 0$. *Used for:* A particle has nonzero momentum exactly when its rapidity is nonzero. *Price:* **free**; exact.

454. Hyperbolic sine is positive exactly for positive arguments. For every real x, $0 < \sinh x$ if and only if $0 < x$. *Used for:* Momentum and rapidity point in one direction: the momentum $m\cdot c\cdot\sinh \eta$ of a particle is positive exactly when its rapidity η is positive. *Price:* **free**; exact.

455. Hyperbolic sine is nonnegative exactly for nonnegative arguments. For every real x, $0 \le \sinh x$ if and only if $0 \le x$. *Used for:* Momentum and rapidity point in one direction, including zero: the momentum $m\cdot c\cdot\sinh \eta$ of a particle is nonnegative exactly when its rapidity η is nonnegative. *Price:* **free**; exact.

456. Hyperbolic sine is negative exactly for negative arguments. For every real x, $\sinh x < 0$ if and only if $x < 0$. *Used for:* Momentum and rapidity point in one direction: the momentum $m\cdot c\cdot\sinh \eta$ of a particle is negative exactly when its rapidity η is negative. *Price:* **free**; exact.

457. Hyperbolic sine is nonpositive exactly for nonpositive arguments. For every real x, $\sinh x \le 0$ if and only if $x \le 0$. *Used for:* Momentum and rapidity point in one direction, including zero: the momentum $m\cdot c\cdot\sinh \eta$ of a particle is nonpositive exactly when its rapidity η is nonpositive. *Price:* **free**; exact.

458. Exponential of the inverse hyperbolic sine. For every real x, $e^{\operatorname{arsinh} x} = x + \sqrt{(1 + x^2)}$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* The Doppler factor from the momentum: $e^{\eta} = p/mc + \sqrt{(1 + (p/mc)^2)}$. *Price:* **free**; exact.

459. Inverse hyperbolic sine of zero. $\operatorname{arsinh} 0 = 0$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Zero momentum gives zero rapidity. *Price:* **free**; exact.

460. Inverse hyperbolic sine is odd. For every real x, $\operatorname{arsinh}(-x) = -\operatorname{arsinh} x$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Reversing the momentum reverses the rapidity. *Price:* **free**; exact.

461. Hyperbolic cosine of the inverse hyperbolic sine. For every real x, $\cosh(\operatorname{arsinh} x) = \sqrt{(1 + x^2)}$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* The Lorentz factor from the momentum: $\gamma = \sqrt{(1 + (p/mc)^2)}$. *Price:* **free**; exact.

462. Hyperbolic tangent of the inverse hyperbolic sine. For every real x, $\tanh(\operatorname{arsinh} x) = x/\sqrt{(1 + x^2)}$, where $\tanh y = \sinh y / \cosh y$ and where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Velocity from momentum: $v/c = (p/mc)/\sqrt{(1 + (p/mc)^2)}$. *Price:* **free**; exact.

463. Inverse hyperbolic sine is one to one. For all real x and y, $\operatorname{arsinh} x = \operatorname{arsinh} y$ implies $x = y$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* A rapidity determines its momentum uniquely. *Price:* **free**; exact.

464. Equal inverse hyperbolic sines have equal arguments. For all real x and y, $\operatorname{arsinh} x = \operatorname{arsinh} y$ if and only if $x = y$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Two equal-mass particles have equal rapidities exactly when they have equal momenta. *Price:* **free**; exact.

465. Inverse hyperbolic sine is strictly increasing. For all real $x < y$, $\operatorname{arsinh} x < \operatorname{arsinh} y$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Rapidity increases strictly with momentum. *Price:* **free**; exact.

466. Inverse hyperbolic sine preserves and reflects order. For all real x and y, $\operatorname{arsinh} x \le \operatorname{arsinh} y$ if and only if $x \le y$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* Comparing rapidities of equal-mass particles is comparing their momenta. *Price:* **free**; exact.

467. Inverse hyperbolic sine preserves and reflects strict order. For all real x and y, $\operatorname{arsinh} x < \operatorname{arsinh} y$ if and only if $x < y$, where $\operatorname{arsinh} x = \ln(x + \sqrt{(1 + x^2)})$. *Used for:* A larger momentum means a

larger rapidity and conversely, for particles of equal mass. *Price:* **free**; exact.

468. Inverse hyperbolic sine vanishes only at zero. For every real x, arsinh x = 0 if and only if x = 0, where arsinh x = ln(x + √(1 + x²)). *Used for:* Zero rapidity exactly at zero momentum. *Price:* **free**; exact.

469. Inverse hyperbolic sine is nonnegative exactly for nonnegative arguments. For every real x, 0 ≤ arsinh x if and only if 0 ≤ x, where arsinh x = ln(x + √(1 + x²)). *Used for:* Rapidity and momentum point in one direction, including zero: the rapidity arsinh(p/(m·c)) is nonnegative exactly when the momentum p is nonnegative. *Price:* **free**; exact.

470. Inverse hyperbolic sine is nonpositive exactly for nonpositive arguments. For every real x, arsinh x ≤ 0 if and only if x ≤ 0, where arsinh x = ln(x + √(1 + x²)). *Used for:* Rapidity and momentum point in one direction, including zero: the rapidity arsinh(p/(m·c)) is nonpositive exactly when the momentum p is nonpositive. *Price:* **free**; exact.

471. Inverse hyperbolic sine is positive exactly for positive arguments. For every real x, 0 < arsinh x if and only if 0 < x, where arsinh x = ln(x + √(1 + x²)). *Used for:* Rapidity and momentum point in one direction: the rapidity arsinh(p/(m·c)) is positive exactly when the momentum p is positive. *Price:* **free**; exact.

472. Inverse hyperbolic sine is negative exactly for negative arguments. For every real x, arsinh x < 0 if and only if x < 0, where arsinh x = ln(x + √(1 + x²)). *Used for:* Rapidity and momentum point in one direction: the rapidity arsinh(p/(m·c)) is negative exactly when the momentum p is negative. *Price:* **free**; exact.

473. Lower decimal bound for one over e. $0.36787944116 < e^{-1}$. *Used for:* A certified lower bound on the fraction 1/e left after one lifetime, one attenuation length or one RC time constant. *Price:* **free**; exact.

474. Upper decimal bound for one over e. $e^{-1} < 0.3678794412$. *Used for:* A certified upper bound on the fraction 1/e left after one lifetime, one attenuation length or one RC time constant. *Price:* **free**; exact.

475. Rational approximation of e to ten digits. $|e - 2244083/825552| \le 1/10^{10}$. *Used for:* An exact rational stand-in for e in numerical checks of decay and growth laws, good to ten digits. *Price:* **free**; exact.

476. Rational approximation of ln 2 to ten digits. $|\ln 2 - 287209/414355| \le 1/10^{10}$. *Used for:* Landauer's bound k·T·ln 2 per erased bit (k Boltzmann's constant, T the temperature) and half-lives t = τ ln 2, with an exact rational stand-in good to ten digits. *Price:* **free**; exact.

477. Cauchy's coefficient formula from equally spaced samples. Let $a_0, a_1, a_2, \ldots$ be complex numbers such that at every point z of the circle |z| = R the series $a_0 + a_1 z + a_2 z^2 + \ldots$ converges (real and imaginary parts unconditionally) to a sum of modulus at most M; let 0 < r < R, and let f be a function equal to the sum of this series at every point of the circle |z| = r. (Here the function is assumed to be given by such a series; that every complex-differentiable function is, which is the classical theorem of Cauchy, is not part of this row.) Then for every n the averages $(1/N) \cdot \Sigma$ over k < N of $\omega^{-kn} \cdot f(r\,\omega^k)$, over the N equally spaced points $r\,\omega^k$ of that circle ($\omega = e^{2\pi i/N}$), converge to $a_n\, r^n$ as N grows. These averages are the Riemann sums of Cauchy's circle integral for the n-th coefficient, so the coefficient formula holds with no integral needed. *Used for:* Computing Taylor coefficients of response functions and generating functions from equally spaced samples on a circle by the discrete Fourier transform. *Price:* **free**; exact.

478. Mean value property on a circle. Let $a_0, a_1, a_2, \ldots$ be complex numbers such that at every point z of the circle |z| = R the series $a_0 + a_1 z + a_2 z^2 + \ldots$ converges (real and imaginary parts unconditionally) to a sum of modulus at most M; let 0 < r < R, and let f be a function equal to the sum of this series at every point of the circle |z| = r. (Here the function is assumed to be given by such a series; that every complex-differentiable function is, which is the classical theorem of Cauchy, is not part of this row.) Let f(0) be the sum of the series at the center. Then the averages $(1/N) \cdot \Sigma$ over k < N of $f(r\,\omega^k)$, over the N equally spaced points $r\,\omega^k$ of the circle |z| = r ($\omega = e^{2\pi i/N}$), converge to f(0) as N grows. *Used for:* A two-dimensional potential that is the real part of a power series bounded on a larger circle (electrostatics, ideal fluid flow, steady heat flow): its value at the centre is the limit of its averages over equally spaced points of the circle. *Price:* **free**; exact.

479. Cauchy's coefficient formula from dyadic circle samples. Let $a_0, a_1, a_2, \ldots$ be complex numbers such that at every point z of the circle |z| = R the series $a_0 + a_1 z + a_2 z^2 + \ldots$ converges (real and imaginary parts unconditionally) to a sum of modulus at most M; let 0 < r < R, and let f be a function equal to the sum of this series at every point of the circle |z| = r. (Here the function is assumed to be given by such a series; that every complex-differentiable function is, which is the classical theorem of Cauchy, is not part of this row.) Then for every n and every tolerance 1/(j + 1) there is m_0 such that for every $m \ge m_0$ the average over the 2^m equally spaced points of the circle |z| = r, $(1/2^m) \cdot \Sigma$ over k < 2^m of $\omega^{-kn} \cdot f(r\,\omega^k)$ with $\omega = e^{2\pi i/2\hat{}m}$, is within 1/(j + 1) of $a_n\, r^n$ (in squared modulus). *Used for:* The radix-2 fast Fourier

transform of samples on a circle, used to compute Fourier and Taylor coefficients of analytic signals and response functions. *Price:* **free**; exact.

480. Shifting a monic polynomial to a new center. For a monic polynomial $p(z) = z^n + b_{n-1}z^{n-1} + \ldots + b_1 z + b_0$ with complex coefficients, $n \geq 1$, and any complex point z, there are complex numbers $c_0, c_1, \ldots, c_n$ with $c_0 = p(z)$ and $c_n = 1$ such that $p(z + h) = c_0 + c_1 h + \ldots + c_n h^n$ for every complex h. *Used for:* Expanding a polynomial potential or a characteristic polynomial about an operating point, the shift step of every polynomial root finder, and the expansion step in the proof that every polynomial has a root. *Price:* **free**; exact.

481. Approximate roots of a monic polynomial. For every monic polynomial $p(z) = z^n + b_{n-1}z^{n-1} + \ldots + b_0$ with complex coefficients and $n \geq 1$, and every k, there is a complex number z with $|p(z)|^2 \leq 1/(k + 1)$. *Used for:* Eigenvalue and zero-finding by iteration: every characteristic polynomial of a finite system has points where it is as small as one wishes, with no step that decides a sign or a zero. *Price:* **free**; exact.

482. Fundamental theorem of algebra for monic polynomials. Every monic polynomial $p(z) = z^n + b_{n-1}z^{n-1} + \ldots + b_1 z + b_0$ with complex coefficients and $n \geq 1$ has a complex root: there is z with $p(z) = 0$. *Used for:* Normal modes of coupled oscillators, energy levels of a finite quantum system, poles of a response function: every characteristic polynomial of a finite system has a root. *Price:* **free**; exact.

483. Polynomial roots when the leading coefficient is apart from zero. Every polynomial $a_0 + a_1 z + \ldots + a_n z^n$ with complex coefficients, degree $n \geq 1$ and leading coefficient of positive size, $|a_n| > 0$, has a complex root. *Used for:* Characteristic polynomials of normal modes, eigenvalues of a finite Hamiltonian and poles of a transfer function or propagator, when the leading coefficient is a known quantity of positive size (a mass, a coupling, a determinant computed to be positive). *Price:* **free**; exact.

484. Fundamental theorem of algebra with nonzero leading coefficient. Every polynomial $a_0 + a_1 z + \ldots + a_n z^n$ with complex coefficients, degree $n \geq 1$ and leading coefficient $a_n \neq 0$ has a complex root. *Used for:* Generalized eigenvalue problems $\det(\lambda B - A) = 0$ and pole-finding when all that is known of the leading coefficient (such as $\det B$) is that it is not zero. *Price:* **MP**; exact.

485. Principal square root of a complex number. For every complex number x there is a complex number s with $\mathrm{Re}\, s = \sqrt{((|x| + \mathrm{Re}\, x)/2)}$, with $\mathrm{Im}\, s = \sqrt{((|x| - \mathrm{Re}\, x)/2)}$ if $0 \leq \mathrm{Im}\, x$, and with $\mathrm{Im}\, s = -\sqrt{((|x| - \mathrm{Re}\, x)/2)}$ if $\mathrm{Im}\, x < 0$. (This s is x to the power 1/2 on the principal branch; a root is given for each x separately, and one function giving all of them is a stronger statement.). *Used for:* Complex momenta $k = \sqrt{(2m(E - V))}$ below a barrier (the principal branch gives the decaying solution), the complex refractive index $\sqrt{\varepsilon}$ of a passive lossy medium, and the plasma dispersion relation $kc = \sqrt{(\omega^2 - \omega_p{}^2)}$: the branch cut along the negative real axis fixes the sign. *Price:* **WLPO**; exact.

486. Derivative of the complex exponential. For every complex number z, the exponential has derivative exp z at z: for every k there is j such that every complex h with $|h| \leq 1/(j + 1)$ satisfies $|\exp(z + h) - \exp z - \exp z \cdot h| \leq |h|/(k + 1)$. *Used for:* Phasors and alternating-current circuits, damped oscillations $e^{(-\gamma + i\omega)\cdot t}$, plane waves $e^{i\cdot(k\cdot x - \omega\cdot t)}$, and the Schrödinger evolution $e^{-i\cdot E\cdot t/\hbar}$. *Price:* **free**; exact.

487. Derivative of the complex cosine. For every complex number z, the cosine has derivative $-\sin z$ at z: for every k there is j such that every complex h with $|h| \leq 1/(j + 1)$ satisfies $|\cos(z + h) - \cos z + \sin z \cdot h| \leq |h|/(k + 1)$. *Used for:* Waves with a complex wavenumber (damped and evanescent waves), AC circuit analysis, and analytic continuation of oscillator responses. *Price:* **free**; exact.

488. Derivative of the complex sine. For every complex number z, the sine has derivative cos z at z: for every k there is j such that every complex h with $|h| \leq 1/(j + 1)$ satisfies $|\sin(z + h) - \sin z - \cos z \cdot h| \leq |h|/(k + 1)$. *Used for:* Waves with a complex wavenumber, AC circuit analysis, and analytic continuation of oscillator responses. *Price:* **free**; exact.

489. Derivative of the complex hyperbolic cosine. For every complex number z, the hyperbolic cosine has derivative sinh z at z: for every k there is j such that every complex h with $|h| \leq 1/(j + 1)$ satisfies $|\cosh(z + h) - \cosh z - \sinh z \cdot h| \leq |h|/(k + 1)$. *Used for:* Hyperbolic functions of complex arguments in transmission lines, heat and diffusion kernels, and partition functions continued to complex temperature. *Price:* **free**; exact.

490. Derivative of the complex hyperbolic sine. For every complex number z, the hyperbolic sine has derivative cosh z at z: for every k there is j such that every complex h with $|h| \leq 1/(j + 1)$ satisfies $|\sinh(z + h) - \sinh z - \cosh z \cdot h| \leq |h|/(k + 1)$. *Used for:* Hyperbolic functions of complex arguments in transmission lines, heat and diffusion kernels, and partition functions continued to complex temperature. *Price:* **free**; exact.

491. Termwise derivative of a complex power series, derivative's sum given. For complex numbers: if $r > 0$ and $f(x + z) = \Sigma\, a_n\, z^n$ (real and imaginary parts converging unconditionally) for every complex z with $|z| < r$, and y is a complex

number with $|y| < r$ at which the series $\Sigma\ (n + 1)\ a_{n+1}\ y^n$ converges to d, then f has complex derivative d at $x + y$: for every k there is j such that every complex h with $|h| \le 1/(j + 1)$ has $|f(x + y + h) - f(x + y) - d \cdot h| \le |h|/(k + 1)$. *Used for:* Differentiating analytic response functions and Green's functions inside their disc of convergence, the complex potential of two-dimensional flow and electrostatics, and perturbation series in a complex coupling. *Price:* **free**; exact.

492. Termwise derivative of a complex power series. For complex numbers: if $r > 0$ and $f(x + z) = \Sigma\ a_n\ z^n$ for every complex z with $|z| < r$, then at every complex y with $|y| < r$ the termwise derivative series $\Sigma\ (n + 1)\ a_{n+1}\ y^n$ converges to a complex number d, and f has complex derivative d at $x + y$. *Used for:* Differentiating a convergent complex expansion anywhere inside its disc of convergence and getting a convergent expansion of the derivative: analytic response functions, complex potentials, perturbation series in a complex coupling. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

493. Cauchy product of absolutely convergent complex series. If the moduli $|a_n|$ and $|b_n|$ of two complex series have convergent sums, then $\Sigma\ a_n$ and $\Sigma\ b_n$ converge, to s and t, and the series of Cauchy coefficients $c_n = a_0b_n + a_1b_{n-1} + \ldots + a_nb_0$ converges (unconditionally) to $s \cdot t$. *Used for:* Multiplying two convergent expansions order by order: products of Taylor series, the exponential law for series, generating functions in statistical mechanics, and perturbation series. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

494. Lower decimal bracket of e. $2.7182818283 < e$. *Used for:* A ten-digit lower bound for e, used to bound the 1/e survival fraction after one lifetime and Boltzmann factors at one thermal energy. *Price:* **free**; exact.

495. Upper decimal bracket of e. $e < 2.7182818286$. *Used for:* A ten-digit upper bound for e, used to bound the 1/e survival fraction after one lifetime and Boltzmann factors at one thermal energy. *Price:* **free**; exact.

496. Lower decimal bracket of the natural logarithm of 2. $0.6931471803 < \ln 2$. *Used for:* A ten-digit lower bound for ln 2, used to bound Landauer's entropy k ln 2 per erased bit and the entropy of a two-state system. *Price:* **free**; exact.

497. Upper decimal bracket of the natural logarithm of 2. $\ln 2 < 0.6931471808$. *Used for:* A ten-digit upper bound for ln 2, used to bound Landauer's entropy k ln 2 per erased bit and the entropy of a two-state system. *Price:* **free**; exact.

498. Hyperbolic cosine exceeds one at every nonzero number. For every real x, $1 < \cosh x$ if and only if $x \neq 0$, where $x \neq 0$ says only that $x = 0$ is false. *Used for:* A moving particle has Lorentz factor $\gamma = \cosh \eta$ strictly above one; the recognition cost $\cosh(\ln x) - 1$ is strictly positive at every ratio $x \neq 1$. *Price:* **MP**; exact.

499. Hyperbolic cosine exceeds one for numbers apart from zero. For every real x, $1 < \cosh x$ if and only if x is apart from 0 ($x < 0$ or $x > 0$ is known). *Used for:* The Lorentz factor of a particle whose rapidity is known to be positive or known to be negative is strictly above one; the recognition cost $\cosh(\ln x) - 1$ is strictly positive at every ratio x known to be above one or known to be below one. *Price:* **free**; exact.

500. Hyperbolic cosine increases on the nonnegative half-line. For all real x and y with $0 \le x$, $0 \le y$ and $x < y$, $\cosh x < \cosh y$. *Used for:* The Lorentz factor $\gamma = \cosh \eta$ grows strictly with the rapidity $\eta \ge 0$, so the energy of a particle grows strictly with its speed. *Price:* **free**; exact.

501. Hyperbolic cosine compares the sizes of its arguments. For all real x and y, $\cosh x \le \cosh y$ if and only if $|x| \le |y|$. *Used for:* Comparing the Lorentz factors of two particles is comparing the sizes of their rapidities, whatever their directions of motion. *Price:* **free**; exact.

502. Strict comparison of hyperbolic cosines by size. For all real x and y, $\cosh x < \cosh y$ if and only if $|x| < |y|$. *Used for:* A larger Lorentz factor means a larger rapidity in size and conversely, for particles moving in either direction. *Price:* **free**; exact.

503. Hyperbolic sine versus its argument: at least when nonnegative. For every real x, $x \le \sinh x$ if and only if $0 \le x$. *Used for:* For a forward boost the momentum in units of mc, $\gamma\beta = \sinh \eta$, is at least the rapidity η. *Price:* **free**; exact.

504. Hyperbolic sine versus its argument: at most when nonpositive. For every real x, $\sinh x \le x$ if and only if $x \le 0$. *Used for:* For a backward boost the momentum in units of mc, $\gamma\beta = \sinh \eta$, is at most the rapidity η. *Price:* **free**; exact.

505. Hyperbolic sine exceeds its argument exactly for positive arguments. For every real x, $x < \sinh x$ if and only if $0 < x$. *Used for:* Relativistic momentum in units of mc, $\gamma\beta = \sinh \eta$ exceeds the rapidity η for every forward boost, so the small-rapidity approximation $\sinh \eta \approx \eta$ always undershoots. *Price:* **free**; exact.

506. Hyperbolic sine is below its argument exactly for negative arguments. For every real x, $\sinh x < x$ if and only if $x < 0$. *Used for:* Relativistic momentum in units of mc, $\gamma\beta = \sinh \eta$ lies below the

rapidity η for every backward boost. *Price:* **free**; exact.

507. Cosine is nonnegative from $-\pi/2$ to $\pi/2$. For every real x with $-\pi/2 \le x \le \pi/2$, $0 \le \cos x$. *Used for:* The in-phase component of a wave is nonnegative within a quarter period of a crest; the projection of a spin or a polarisation within 90° of an axis is nonnegative. *Price:* **free**; exact.

508. Cosine is negative between quarter and three-quarter turns. For every real x with $\pi/2 < x < \pi + \pi/2$, $\cos x < 0$. *Used for:* A cosine wave is below its rest position strictly between a quarter and three quarters of a period; the projection onto an axis more than 90° away is negative. *Price:* **free**; exact.

509. Cosine is nonpositive between quarter and three-quarter turns. For every real x with $\pi/2 \le x \le \pi + \pi/2$, $\cos x \le 0$. *Used for:* A wave's displacement is on the trough side from a quarter to three quarters of a period; projections at 90° or more from an axis are not positive. *Price:* **free**; exact.

510. Sine is nonpositive on the negative half turn. For every real x with $-\pi \le x \le 0$, $\sin x \le 0$. *Used for:* An oscillator that crosses zero going upward at time zero was on the negative side for the half period before; the sign of a wave's displacement over half a cycle. *Price:* **free**; exact.

511. Sine is nonnegative on the interval from 0 to π. For every real x with $0 \le x \le \pi$, $0 \le \sin x$. *Used for:* The fundamental mode $\sin(\pi x/L)$ of a string fixed at both ends is nonnegative along the string; the positive half of an alternating signal. *Price:* **free**; exact.

512. Sine is positive inside the first half turn. For every real x with $0 < x < \pi$, $0 < \sin x$. *Used for:* The ground state $\sin(\pi x/L)$ of a particle in a box and the fundamental mode of a string have no node inside the interval. *Price:* **free**; exact.

513. Sine preserves order within a quarter turn of zero. For all real x and y with $-\pi/2 \le x \le y \le \pi/2$, $\sin x \le \sin y$. *Used for:* Comparing angles through their sines within a quarter turn either side of zero, as in Snell's law $n_1 \sin\theta_1 = n_2 \sin\theta_2$ and Bragg's law. *Price:* **free**; exact.

514. Cosine reverses order on the first half turn. For all real x and y with $0 \le x \le y \le \pi$, $\cos y \le \cos x$. *Used for:* A wider scattering angle gives a smaller cosine: the Compton factor $1 - \cos\theta$ grows with the angle up to a half turn, and a polariser's transmitted amplitude $\cos\theta$ falls as it turns from 0 to a half turn. *Price:* **free**; exact.

515. Cosine strictly decreases on the first quarter turn. For all real x and y with $0 \le x < y \le \pi/2$, $\cos y < \cos x$. *Used for:* Tilting a polariser or a spin axis further from alignment strictly lowers the projected amplitude within a quarter turn. *Price:* **free**; exact.

516. Sine is strictly increasing within a quarter turn of zero. For all real x and y with $-\pi/2 \le x \le \pi/2$, $-\pi/2 \le y \le \pi/2$ and $x < y$, $\sin x < \sin y$. *Used for:* An angle within a quarter turn either side of zero is fixed by its sine, as when Snell's law is solved for the refraction angle. *Price:* **free**; exact.

517. Cosine is strictly decreasing on the first half turn. For all real x and y with $0 \le x \le \pi$, $0 \le y \le \pi$ and $x < y$, $\cos y < \cos x$. *Used for:* A scattering angle between 0 and π is fixed by its cosine, as in Compton scattering and the Rutherford cross-section. *Price:* **free**; exact.

518. Sine is injective within a quarter turn of zero. For all real x and y with $-\pi/2 \le x \le \pi/2$ and $-\pi/2 \le y \le \pi/2$, $\sin x = \sin y$ implies $x = y$. *Used for:* A measured sine fixes an angle within a quarter turn either side of zero, as for refraction and diffraction angles. *Price:* **free**; exact.

519. Cosine is one to one on the first half turn. For all real x and y with $0 \le x \le \pi$ and $0 \le y \le \pi$, $\cos x = \cos y$ implies $x = y$. *Used for:* A measured cosine fixes a scattering or bond angle between 0 and π. *Price:* **free**; exact.

520. Tangent is positive on the open first quarter turn. For every real x with $0 < x < \pi/2$, $0 < \tan x$, where $\tan x = \sin x / \cos x$ (the cosine is positive there). *Used for:* A positive inclination has a positive slope: inclined planes, the friction angle with $\tan\theta = \mu$, a positive Hall angle. *Price:* **free**; exact.

521. Tangent is nonnegative on the first quarter turn where defined. For every real x with $0 \le x \le \pi/2$, $0 \le \tan x$ wherever the tangent $\tan x = \sin x / \cos x$ is defined, that is wherever $\cos x$ is known to be apart from 0. *Used for:* Slopes and friction coefficients read from angles between zero and a right angle are never negative. *Price:* **free**; exact.

522. Tangent is negative on the open negative quarter turn. For every real x with $-\pi/2 < x < 0$, $\tan x < 0$, where $\tan x = \sin x / \cos x$ (the cosine is positive there). *Used for:* A downward inclination has a negative slope; a negative Hall angle or phase angle has a negative tangent. *Price:* **free**; exact.

523. Tangent is nonpositive on the negative quarter turn where defined. For every real x with $-\pi/2 \le x \le 0$, $\tan x \le 0$ wherever the tangent $\tan x = \sin x / \cos x$ is defined, that is wherever $\cos x$ is known to be apart from 0. *Used for:* Slopes read from downward angles down to a right angle are never positive. *Price:* **free**; exact.

524. Tangent is strictly increasing within a quarter turn of zero. For all real x and y with $-\pi/2 < x < y < \pi/2$, $\tan x < \tan y$, where $\tan x = \sin x / \cos x$

(the cosine is positive there). *Used for:* A steeper angle gives a steeper slope; phase lags of a driven oscillator below resonance and Hall angles are ordered by their tangents. *Price:* **free**; exact.

525. Tangent is strictly increasing on the first quarter turn. For all real x and y with $0 \le x < y < \pi/2$, tan x < tan y, where tan x = sin x / cos x (the cosine is positive there). *Used for:* A steeper inclination between level and vertical gives a steeper slope, as for inclined planes and friction angles. *Price:* **free**; exact.

526. Tangent is strictly increasing on the open central half turn. For all real x and y strictly between $-\pi/2$ and $\pi/2$ with x < y, tan x < tan y, where tan x = sin x / cos x (the cosine is positive there). *Used for:* An angle strictly within a quarter turn either side of zero is fixed by its slope: Brewster's angle, the phase of a driven oscillator below resonance, the Hall angle. *Price:* **free**; exact.

527. Tangent is injective on the open central half turn. For all real x and y strictly between $-\pi/2$ and $\pi/2$, tan x = tan y implies x = y, where tan x = sin x / cos x (the cosine is positive there). *Used for:* A measured slope fixes the angle strictly within a quarter turn either side of zero: Brewster's angle from $\tan\theta = n_2/n_1$, the phase lag of a driven oscillator below resonance. *Price:* **free**; exact.

528. Equal tangents give equal angles in the central half turn. For all real x and y with $-\pi/2 < x < \pi/2$ and $-\pi/2 < y < \pi/2$, tan x = tan y implies x = y, where tan x = sin x / cos x (the cosine is positive there). *Used for:* Two angles strictly within a quarter turn either side of zero with equal slopes are equal, as in reading a Hall angle or a phase lag from a measured ratio. *Price:* **free**; exact.

529. Every complex number has n-th roots. For every complex number x and every whole number $n \ge 1$ there is a complex number z with $z^n = x$. *Used for:* n-th roots of complex impedances, propagation constants and transfer functions, and the roots behind fractional powers of complex quantities when no particular branch is required. *Price:* **free**; exact.

530. Every complex number is a square. For every complex number x there is a complex number z with $x = z \cdot z$. *Used for:* Square roots of discriminants when solving quadratic dispersion relations and characteristic equations, where either root may be used because the other is its negative. *Price:* **free**; exact.

531. Eigenvalues of a 2 × 2 complex matrix. For every 2 × 2 matrix with complex entries a, b (first row) and c, d (second row) there are complex numbers λ_1 and λ_2 with $(w - a)(w - d) - b\cdot c = (w - \lambda_1)(w - \lambda_2)$ for every complex number w, so λ_1 and λ_2 are the roots of the characteristic polynomial counted with multiplicity; their sum is the trace, $\lambda_1 + \lambda_2 = a + d$, and their product is the determinant, $\lambda_1 \cdot \lambda_2 = a\cdot d - b\cdot c$. *Used for:* Two-level quantum systems (the two energy levels of a 2 × 2 Hamiltonian, with sum equal to the trace and product equal to the determinant), two coupled oscillators, and the trace and determinant of a two-dimensional linear system as the sum and product of its eigenvalues. *Price:* **free**; exact.

532. Monic polynomials split into linear factors. For every monic polynomial $p(w) = w^n + b_{n-1}w^{n-1} + \dots + b_1 w + b_0$ with complex coefficients ($n \ge 0$) there are complex numbers $z_1, \dots, z_n$ such that $p(w) = (w - z_1)(w - z_2)\cdots(w - z_n)$ for every complex number w (for n = 0 the product is 1). *Used for:* Normal modes and eigenvalues of a finite system: the characteristic polynomial is a product of n linear factors, so it has n roots counted with multiplicity; the pole-zero factorization of rational transfer functions and propagators. *Price:* **free**; exact.

533. Polynomial factorization when the leading coefficient is apart from zero. For every polynomial $p(w) = a_0 + a_1 w + \dots + a_n w^n$ with complex coefficients whose leading coefficient has positive size, $|a_n| > 0$, there are complex numbers $z_1, \dots, z_n$ such that $p(w) = a_n(w - z_1)(w - z_2)\cdots(w - z_n)$ for every complex number w. *Used for:* Factoring a characteristic or dispersion polynomial into its roots when the leading coefficient is a known quantity of positive size (a mass, a coupling, a determinant computed to be positive): eigenvalues with multiplicity, poles and zeros of a response function. *Price:* **free**; exact.

534. Polynomial factorization with nonzero leading coefficient. For every polynomial $p(w) = a_0 + a_1 w + \dots + a_n w^n$ with complex coefficients and leading coefficient $a_n \ne 0$ there are complex numbers $z_1, \dots, z_n$ such that $p(w) = a_n(w - z_1)(w - z_2)\cdots(w - z_n)$ for every complex number w. *Used for:* Factoring a generalized characteristic polynomial $\det(\lambda B - A)$ or the denominator of a transfer function into its roots when all that is known of the leading coefficient is that it is not zero. *Price:* **MP**; exact.

535. Cauchy product of absolutely convergent complex series, sums given. If $\Sigma\, a_n$ and $\Sigma\, b_n$ are complex series with sums s and t whose moduli $|a_n|$ and $|b_n|$ have convergent sums, then the series of Cauchy coefficients $c_n = a_0 b_n + a_1 b_{n-1} + \dots + a_n b_0$ converges (unconditionally) to $s \cdot t$. *Used for:* Multiplying two convergent expansions order by order: products of Taylor series, the exponential law for series, generating functions in statistical mechanics, and perturbation series. *Price:* **free**; exact.

Q.4 Integrals and measure

536. Constant multiple of an integral. On [0, 1], if a function has the integral I, as a limit of Riemann sums, then c times the function has the integral c·I. *Used for:* Pulling normalization constants and couplings out of integrals. *Price:* **free**; exact.

537. Integral of a difference. On [0, 1], if f and g have the integrals I and J, as limits of Riemann sums, then f − g has the integral I − J. *Used for:* Work and energy differences. *Price:* **free**; exact.

538. Integral of a finite sum. On [0, 1], if each of finitely many functions has an integral, as a limit of Riemann sums, then their sum has as its integral the sum of their integrals. *Used for:* Superposing modes; finite expansions. *Price:* **free**; exact.

539. Integral of the absolute value bounds the integral. On [0, 1], if f has the integral I and |f| has the integral J, as limits of Riemann sums, then $|I| \le J$. *Used for:* Error and perturbation bounds. *Price:* **free**; exact.

540. Uniform limits pass under the integral. If functions with integrals over [0, 1] converge uniformly on [0, 1] to a function with an integral, their integrals converge to the integral of the limit. *Used for:* Limits of approximate solutions. *Price:* **free**; exact.

541. Term-by-term integration of a series. If the partial sums of a series of functions converge uniformly on [0, 1], and every term and the limit have integrals over [0, 1], then the partial sums of the term integrals converge to the integral of the limit. *Used for:* Fourier and perturbation series. *Price:* **free**; exact.

542. Monotone convergence theorem, value of the limit. On [0, 1], the integrals of an increasing sequence of uniformly continuous functions whose integrals stay bounded converge to a number. *Used for:* Partition functions and normalizations as limits of truncations. *Price:* **LPO + AC**$_\omega$; exact.

543. Improper integral of a nonnegative function. A nonnegative continuous function on the half-line whose integrals up to each bound stay bounded has an integral over the whole half-line. *Used for:* Normalizing over the half-line without a decay rate. *Price:* **LPO + AC**$_\omega$; exact.

544. Comparison test for improper integrals. On the half-line [0, ∞), a continuous function whose size is bounded by a continuous function with a convergent integral over the half-line also has a convergent integral there. *Used for:* Dominated tails such as exponential or inverse-square decay. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

545. Differentiation under the integral sign. On [0, 1], if f(s, x) has a derivative in the parameter s that is uniform in s and x together, then the integral of f(s, x) over x has as its derivative in s the integral of that derivative. *Used for:* Hellmann–Feynman, Green's functions, parameter tricks. *Price:* **free**; exact.

546. Continuity of a parameter integral. If f(s, x) is uniformly continuous on the unit square [0, 1] × [0, 1], its integral over x from 0 to 1 is a uniformly continuous function of s. *Used for:* Potentials depending continuously on their sources. *Price:* **free**; exact.

547. Mean value theorem for integrals. A uniformly continuous function on [0, 1] equals its integral over [0, 1], its mean value, at some point of the closed interval [0, 1]. *Used for:* Mean-value estimates. *Price:* **LLPO + AC**$_\omega$; exact.

548. Mean value theorem for integrals, interior point. A uniformly continuous function on [0, 1] equals its integral over [0, 1], its mean value, at some point strictly between 0 and 1. *Used for:* Mean-value estimates. *Price:* **LPO + AC**$_\omega$; exact.

549. Cauchy–Schwarz inequality for integrals. On [0, 1], if f·g, f^2 and g^2 have the integrals I, A and B, as limits of Riemann sums, then $I^2 \le A{\cdot}B$. *Used for:* Uncertainty relations, overlap bounds. *Price:* **free**; exact.

550. Fubini's theorem on the unit square. For a uniformly continuous function on the unit square [0, 1] × [0, 1], the integral taken first in one variable and then in the other equals the integral taken in the opposite order. *Used for:* Every iterated two- and three-dimensional integral. *Price:* **free**; exact.

551. Zero integral of a nonnegative function. A uniformly continuous function that is nonnegative on [0, 1] and has integral zero over [0, 1] is zero at every point of [0, 1]. *Used for:* A state of zero norm is the zero state. *Price:* **free**; exact.

552. Dini's theorem for integrals. If uniformly continuous functions on [0, 1] increase at every point of [0, 1] to a uniformly continuous limit, their integrals over [0, 1] converge to the integral of the limit. *Used for:* Removing a cutoff or regulator under an integral. *Price:* **open**; equivalent, over countable choice, to the measure form of the Heine–Borel theorem (the lengths of a countable cover of the interval by open intervals add up to at least one); the direction from the theorem to the principle uses no choice; not one of the price letters; also at most LLPO + AC$_\omega$ and at most the decidable fan theorem with countable choice.

553. Bounded convergence theorem for integrals. If uniformly continuous functions on [0, 1], all bounded in size by one constant, converge at every point of [0, 1] to a uniformly continuous limit, their integrals over [0, 1] converge to the integral of the limit. *Used for:* Limits under the integral without monotonicity or a rate. *Price:* **open**; equivalent over countable choice to continuity of measure from above in sequence form (for decreasing open sets with no common point, any prescribed finite parts of the later sets eventually have small measure); the direction from the theorem to the principle uses no choice; not one of the price letters; at most LPO + AC_ω; at least the measure form of the Heine–Borel theorem.

554. Integrals over adjacent pieces of [0, 1] add. On the line, let f be uniformly continuous on [0, 1] and $0 \le a \le c \le b \le 1$. If the integrals of f from a to c, from c to b and from a to b exist, the first two add up to the third. *Used for:* Splitting a path, a time interval or a region into pieces. *Price:* **free**; exact.

555. Fundamental theorem of calculus, first half, on [0, 1]. On the line, if f is uniformly continuous on [0, 1] and F(x) is the integral of f from 0 to x for every x in [0, 1], then F has derivative f on [0, 1], uniformly in the point. *Used for:* Recovering a rate from an accumulated quantity (charge from current, work from force). *Price:* **free**; exact.

556. Reversing the interval negates the integral. The integral from b to a is minus the integral from a to b. *Used for:* Orientation of line integrals and time reversal. *Price:* **free**; exact.

557. Linear change of variable in an integral. Substituting $x = c\,t + d$ turns the integral of f over the image interval into the integral of c times $f(c\,t + d)$ over the original interval. *Used for:* Rescaling units and shifting origins. *Price:* **free**; exact.

558. Integrability on every subinterval of [0, 1]. On the line, a function f uniformly continuous on [0, 1] has an integral from a to b for all points a and b of [0, 1]. *Used for:* Every definite integral of a continuous quantity. *Price:* **free**; exact (a modulus of uniform continuity is chosen by countable choice of natural numbers; the Riemann sums then form a Cauchy sequence with a known modulus, and its limit point uses the completeness of the line: countable choice of rational pairs, Corollary 12.35).

559. Change of variables by a differentiable map. On the line, let f be uniformly continuous on [0, 1], let g have the uniform derivative g' on [0, 1] and map [0, 1] into itself, and let a and b lie in [0, 1]. If f has the integral I from g(a) to g(b), then $f(g(x))\cdot g'(x)$ has the integral I from a to b. *Used for:* Changing coordinates along a path, in time or in energy. *Price:* **free**; exact.

560. Integration by parts on an interval. On the line, let u and v have uniform derivatives u' and v' on [0, 1], and let a and b lie in [0, 1]. If $u'\cdot v$ has the integral J from a to b, then $u\cdot v'$ has the integral $u(b)\cdot v(b) - u(a)\cdot v(a) - J$ from a to b. *Used for:* Moving derivatives between factors: weak forms, virial and expectation-value identities. *Price:* **free**; exact.

561. Mean value theorem for integrals on an interval. On the line, let f be uniformly continuous on [0, 1] and $0 \le a \le b \le 1$. If f has the integral I from a to b, then $(b - a)\cdot f(c) = I$ at some point c with $a \le c \le b$. *Used for:* Mean-value estimates over any interval. *Price:* **LLPO + AC_ω**; exact.

562. Mean value theorem for integrals, interior point, on an interval. On the line, let f be uniformly continuous on [0, 1] and let $a < b$ be points of [0, 1]. If f has the integral I from a to b, then $(b - a)\cdot f(c) = I$ at some point c strictly between a and b, at a known positive distance from both. *Used for:* Mean-value estimates over any interval. *Price:* **LPO + AC_ω**; exact.

563. Integrals preserve order on an interval. For points $0 \le a \le b \le 1$ of the line, if $f \le g$ at every point of [a, b] and f and g have the integrals I and J from a to b, then $I \le J$. *Used for:* Comparison bounds on energies, probabilities and errors. *Price:* **free**; exact.

564. Bound on an integral by a bound on the integrand. For points $0 \le a \le b \le 1$ of the line, if $|f(x)| \le C$ at every point x of [a, b] and f has the integral I from a to b, then $|I| \le C\cdot(b - a)$. *Used for:* Error estimates and a-priori bounds. *Price:* **free**; exact.

565. Cauchy–Schwarz inequality for integrals on an interval. For any points a and b of the line, if $f\cdot g$, f^2 and g^2 have the integrals I, A and B from a to b, then $I^2 \le A\cdot B$. *Used for:* Uncertainty relations and overlap bounds on a finite range. *Price:* **free**; exact.

566. Fubini's theorem on a rectangle. For points $0 \le a \le b \le 1$ and $0 \le c \le d \le 1$ of the line and a function f(x, y) uniformly continuous on the unit square, suppose the integrals of f over x from a to b (for each y in [c, d]) and over y from c to d (for each x in [a, b]) exist, and so do the two iterated integrals over the rectangle [a, b] × [c, d]. Then the iterated integral taken first in x and then in y equals the iterated integral taken first in y and then in x. *Used for:* Every iterated integral over a rectangular region. *Price:* **free**; exact.

567. Differentiation under the integral sign on an interval. For points $0 \le a \le b \le 1$ of the line, let f(s, x) have the derivative $f'(s, x)$ in the parameter s, uniformly for s in [0, 1] and x in [a, b] together (one accuracy rate for all of them). If, for every s in [0, 1], the function $x \mapsto f(s, x)$ has the integral G(s) and $x \mapsto f'(s, x)$ has the integral D(s) from a to b, then G has the derivative D, uniformly on [0, 1]. *Used for:*

Hellmann–Feynman, Green's functions, parameter tricks on a finite range. *Price:* **free**; exact.

568. Continuity of a parameter integral on an interval. For points $0 \le a \le b \le 1$ of the line and a function f(s, x) uniformly continuous on the unit square $[0, 1] \times [0, 1]$, if G(s) is the integral of $x \mapsto f(s, x)$ from a to b for every s in [0, 1], then G is uniformly continuous on [0, 1]. *Used for:* Potentials and responses that vary continuously with their sources. *Price:* **free**; exact.

569. Gamma function at whole numbers. The integral from 0 to infinity of t to the power n times e to the minus t equals n factorial, for every whole number n. *Used for:* Partition functions, Bose and Fermi integrals, Laplace transforms, radial normalizations. *Price:* **free**; exact.

570. Beta integral at whole numbers. For whole numbers a and b: if t to the power a times (1 − t) to the power b has an integral I from 0 to 1 (its Riemann sums come within every tolerance of I), then (a + b + 1)! times I equals a! times b!, so I = a! b!/(a + b + 1)!. *Used for:* Order statistics and Bayesian priors, phase-space integrals, binomial weights. *Price:* **free**; exact.

571. Laplace transform of a power. For every whole number n and every $s > 0$, the integral from 0 to infinity of t to the power n times e to the minus s t equals n! divided by s to the power n + 1. *Used for:* Response functions, relaxation and decay laws, partition functions at temperature 1/s. *Price:* **free**; exact.

572. Gamma function at real arguments. For every real $s > 0$, the integral of t to the power s − 1 times e to the minus t exists over every closed interval inside (0, infinity), and these integrals converge as the interval grows to (0, infinity). *Used for:* Partition functions and densities of states in any dimension, Maxwell–Boltzmann moments, radial integrals with non-integer exponents. *Price:* **free**; exact (the integral over each closed interval is that of a uniformly continuous function, as in row 1467; the parts below ε and beyond R are at most ε^s/s and a constant times $e^{-R/2}$, so the integrals converge with a known modulus; the limit point uses the completeness of the line: countable choice of rational pairs).

573. Gamma recurrence at real arguments. For every real $s > 0$, Gamma of s + 1 equals s times Gamma of s. *Used for:* Factorial-type normalizations at non-integer order, thermal averages in d dimensions. *Price:* **free**; exact.

574. Gamma function is positive. For every real $s > 0$, Gamma of s is strictly positive. *Used for:* Positivity of partition functions and normalization constants. *Price:* **free**; exact.

575. Beta integral at real arguments. For real a, $b > 0$, the integral of t to the power a − 1 times (1 − t) to the power b − 1 exists over every closed interval inside (0, 1), and these integrals converge as the interval grows to (0, 1). *Used for:* Beta distributions and Bayesian priors, Dirichlet and phase-space integrals, scattering amplitudes. *Price:* **free**; exact (the integral over each closed interval is that of a uniformly continuous function, as in row 1467; the parts within ε of 0 and of 1 are at most a constant times ε^a/a and ε^b/b, so the integrals converge with a known modulus; the limit point uses the completeness of the line: countable choice of rational pairs).

576. Beta function is symmetric. For real a, $b > 0$, the Beta integral with exponents a, b equals the one with exponents b, a. *Used for:* Exchange symmetry of two-body phase space and of Beta priors. *Price:* **free**; exact.

577. Gamma and Beta functions are linked. For real a, $b > 0$, Gamma of a times Gamma of b equals Gamma of a + b times the Beta integral with exponents a and b. *Used for:* Dirichlet and phase-space integrals, Beta-distribution normalizations, Veneziano-type amplitudes. *Price:* **free**; exact.

578. Recurrence of the Beta integral in its first argument. For real a, $b > 0$, (a + b) times the Beta integral at (a + 1, b) equals a times the Beta integral at (a, b). *Used for:* Moment recursions of Beta distributions; reduction of phase-space integrals. *Price:* **free**; exact.

579. Gamma function is log-convex. For real y, $d > 0$ and θ between 0 and 1, Gamma at y + θd is at most Gamma at y to the power 1 − θ times Gamma at y + d to the power θ. *Used for:* Bounds on partition functions and thermodynamic convexity; ratio bounds for Gamma functions. *Price:* **free**; exact.

580. Gamma at one. The integral of e to the minus t from 0 to infinity equals 1. *Used for:* Normalization of exponential decay and waiting-time laws. *Price:* **free**; exact.

581. Euler–Gauss limit for the Gamma function. For real $s > 0$, n to the power s times n factorial divided by $s(s + 1)\cdots(s + n)$ tends to Gamma of s as n grows. *Used for:* Numerical evaluation of Gamma; infinite-product forms of partition functions. *Price:* **free**; exact.

582. Bohr–Mollerup characterization of the Gamma function. A positive function on the positive half-line with f(1) = 1, f(y + 1) = y f(y) and log-convex values equals the Gamma function at every positive point. *Used for:* Identifying factorial-type normalizations by their recurrence and

convexity. *Price:* **free**; exact.

583. Gamma at one half. Gamma of one half is positive and its square equals π. *Used for:* Gaussian and error-function normalizations, half-integer partition functions, the volume of balls. *Price:* **free**; exact.

584. Legendre duplication formula. For real $s > 0$, Gamma of s times Gamma of $s + 1/2$ equals Gamma of 2s times 2 to the power $1 - 2s$ times the square root of π. *Used for:* Half-integer Gamma values in d-dimensional integrals and Bessel normalizations. *Price:* **free**; exact.

585. Euler's reflection formula. For real s strictly between 0 and 1, Gamma of s times Gamma of $1 - s$ times the sine of π s equals π. *Used for:* Fermi–Dirac and Bose–Einstein integrals, the Casimir and Planck constants' Gamma–zeta factors, analytic continuation in field theory. *Price:* **free**; exact.

586. Euler's product for the sine. For every real x, π x times the product over $j < n$ of $(1 - x^2/(j + 1)^2)$ tends to the sine of π x as n grows. *Used for:* Spectra of strings and drums (zeros of sine), partition functions of oscillator chains. *Price:* **free**; exact.

587. Bose–Einstein integral as Gamma times zeta. For real $s > 1$, the integral from 0 to infinity of t to the power $s - 1$ divided by (e to the t minus 1) equals Gamma of s times zeta of s. *Used for:* Black-body radiation and the Stefan–Boltzmann law, Bose gases and Bose–Einstein condensation. *Price:* **free**; exact.

588. Fermi–Dirac integral through Gamma and zeta. For real $s > 1$, the integral from 0 to infinity of t to the power $s - 1$ divided by (e to the t plus 1) equals $(1 - 2$ to the power $1 - s)$ times Gamma of s times zeta of s. *Used for:* Degenerate electron gases, white dwarfs and metals, relic neutrino densities. *Price:* **free**; exact.

589. Convergence of the p-series for real exponents above one. For real $s > 1$, the sums of 1 over k to the power s, for k from 1 to n, converge as n grows (this limit is zeta of s). *Used for:* Zeta values in thermal physics, lattice sums, Casimir energies. *Price:* **free**; exact (the sum beyond n is at most $n^{1-s}/(s - 1)$, a known Cauchy modulus; the limit point uses the completeness of the line: countable choice of rational pairs).

590. Basel problem: the sum of inverse squares. The sum of 1 over k squared, for k from 1 to infinity, equals π squared over 6. *Used for:* Thermal and Casimir sums, string and lattice zero-point energies, Debye models. *Price:* **free**; exact. Proved in Theorem 12.97.

591. Sum of inverse fourth powers. The sum of 1 over k to the fourth power, for k from 1 to infinity, equals π to the fourth over 90. *Used for:* Black-body radiation, Stefan–Boltzmann constant, photon gas energy density. *Price:* **free**; exact. Proved in Theorem 12.97.

592. Black-body integral of the Planck spectrum. The integral from 0 to infinity of t cubed divided by (e to the t minus 1) equals π to the fourth over 15. *Used for:* The Stefan–Boltzmann law and the energy density of thermal radiation. *Price:* **free**; exact.

Q.5 Differential equations and dynamics

593. Grönwall's bound as one function. There is one function $g(\delta, K, \varepsilon, x)$ equal to $\delta + \varepsilon x$ when $K = 0$ and satisfying $K\cdot g = K\delta e^{Kx} + \varepsilon(e^{Kx} - 1)$ for every K; it is $\delta e^{Kx} + \varepsilon x\cdot\psi(Kx)$ with $\psi(y) = \Sigma\, y^m/(m+1)!$. *Used for:* The envelope that bounds the growth of every perturbation and every numerical error in a differential equation. *Price:* **free**; exact.

594. Grönwall's bound without feedback. When the growth rate K is 0, Grönwall's bound $\delta e^{Kx} + \varepsilon x\cdot\varphi(Kx)$, where $\varphi(u) = \Sigma\, u^m/(m+1)!$ over $m \geq 0$, so that $\varepsilon x\cdot\varphi(Kx) = (\varepsilon/K)(e^{Kx} - 1)$ when $K \neq 0$, is $\delta + \varepsilon x$. *Used for:* Error growth from a steady error source in a system with no amplification. *Price:* **free**; exact.

595. Closed form of Grönwall's bound. K times Grönwall's bound $g(x)$ equals $K\delta e^{Kx} + \varepsilon(e^{Kx} - 1)$, so $g(x) = \delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$ whenever K is apart from 0. *Used for:* The explicit exponential envelope of perturbation growth in a system with amplification rate K. *Price:* **free**; exact.

596. Derivative of Grönwall's bound. Grönwall's bound $g(x) = \delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$ has derivative $Kg(x) + \varepsilon$ at every x. *Used for:* Showing the envelope solves the comparison equation $g' = Kg + \varepsilon$ that bounds a growing error. *Price:* **free**; exact.

597. Derivative of the shifted Grönwall bound. The function $x \mapsto g(x - a)$, with g Grönwall's bound $\delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$, has derivative $Kg(x - a) + \varepsilon$ at every x. *Used for:* The comparison envelope for an error that starts growing at time a. *Price:* **free**; exact.

598. Grönwall's bound at time zero. Grönwall's bound $\delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$ equals δ at $x = 0$. *Used for:* The envelope starts at the initial size of the perturbation. *Price:* **free**; exact.

599. Grönwall's bound with no error source. With $\varepsilon = 0$, Grönwall's bound is δe^{Kx}. *Used for:*

Exponential separation of two exact motions of a law with Lipschitz constant K. *Price:* **free**; exact.

600. Grönwall's bound from nothing is nothing. With $\delta = 0$ and $\varepsilon = 0$, Grönwall's bound is 0 for every x and K. *Used for:* Uniqueness: two motions that start together never separate. *Price:* **free**; exact.

601. Grönwall's bound is continuous in the error rate. For fixed δ, K and x, Grönwall's bound $\delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$ depends continuously on ε. *Used for:* Passing from error rates slightly above ε to ε itself in perturbation bounds. *Price:* **free**; exact.

602. Grönwall's bound only grows. For δ, ε, $K \geq 0$, Grönwall's bound $\delta e^{Kx} + (\varepsilon/K)(e^{Kx} - 1)$ is nondecreasing in x. *Used for:* Error envelopes never shrink, so a bound at a later time covers every earlier time. *Price:* **free**; exact.

603. Grönwall comparison for a real function. Let f be a real function on [a, b] with $f(a) \leq \delta$, and suppose that for every tolerance there is one closeness such that every forward difference quotient $(f(t) - f(s))/(t - s)$ with $a \leq s < t \leq b$ and t that close to s is at most $f'(s)$ plus the tolerance. If $f'(x) \leq K \cdot f(x) + \varepsilon$ for $a \leq x < b$, then $f(x) \leq \delta \cdot \exp(K(x - a)) + (\varepsilon/K)(\exp(K(x - a)) - 1)$ on [a, b] ($\delta + \varepsilon(x - a)$ when K = 0). *Used for:* Bounding energies, Lyapunov functions and other scalar quantities that grow at most in proportion to themselves. *Price:* **free**; exact.

604. Grönwall's inequality for the size of a motion. Let f(t) be a motion of states with d real coordinates (size of a state: its largest absolute coordinate) on [a, b], with right derivative f' uniform on [a, b] (one accuracy rate for all times). If $\|f(a)\| \leq \delta$ and $\|f'(t)\| \leq K\|f(t)\| + \varepsilon$ for $a \leq t < b$, then $\|f(t)\| \leq \delta \cdot \exp(K(t - a)) + (\varepsilon/K)(\exp(K(t - a)) - 1)$ on [a, b] ($\delta + \varepsilon(t - a)$ when K = 0). *Used for:* Growth of perturbations, stability estimates and error bounds for every differential equation. *Price:* **free**; exact.

605. A state that starts at zero stays at zero. Let f(t) be a motion of states with d real coordinates (size of a state: its largest absolute coordinate) on [a, b], with right derivative f' uniform on [a, b] (one accuracy rate for all times). If $f(a) = 0$ and $\|f'(t)\| \leq K\|f(t)\|$ for $a \leq t < b$, then $f(t) = 0$ for every t in [a, b]. *Used for:* A system at rest under a law that vanishes at rest stays at rest; the core of uniqueness. *Price:* **free**; exact.

606. Separation of approximate motions in a region. Let v(t, x) be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on sets S(t) for $a \leq t < b$. Let f and g stay in S(t), have right derivatives uniform on [a, b], and satisfy $\|f'(t) - v(t, f(t))\| \leq \varepsilon_1$, $\|g'(t) - v(t, g(t))\| \leq \varepsilon_2$ and $\|f(a) - g(a)\| \leq \delta$. Then $\|f(t) - g(t)\| \leq \delta \cdot \exp(K(t - a)) + ((\varepsilon_1 + \varepsilon_2)/K)(\exp(K(t - a)) - 1)$ on [a, b] ($\delta + (\varepsilon_1 + \varepsilon_2)(t - a)$ when K = 0). *Used for:* Error bounds for numerical integrators and for approximate solutions confined to a region. *Price:* **free**; exact.

607. Separation of approximate motions. Let v(t, x) be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on all states at every time. Let f and g have right derivatives uniform on [a, b] and satisfy $\|f'(t) - v(t, f(t))\| \leq \varepsilon_1$, $\|g'(t) - v(t, g(t))\| \leq \varepsilon_2$ and $\|f(a) - g(a)\| \leq \delta$. Then $\|f(t) - g(t)\| \leq \delta \cdot \exp(K(t - a)) + ((\varepsilon_1 + \varepsilon_2)/K)(\exp(K(t - a)) - 1)$ on [a, b] ($\delta + (\varepsilon_1 + \varepsilon_2)(t - a)$ when K = 0). *Used for:* Global error bounds for numerical integration of a law with a uniform Lipschitz constant. *Price:* **free**; exact.

608. Separation of exact motions in a region. Let v(t, x) be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on sets S(t) for $a \leq t < b$. Two motions f and g that stay in S(t), solve $f' = v(t, f)$ and $g' = v(t, g)$ with right derivatives uniform on [a, b], and start with $\|f(a) - g(a)\| \leq \delta$ satisfy $\|f(t) - g(t)\| \leq \delta \cdot \exp(K(t - a))$ on [a, b]. *Used for:* Sensitivity to initial data: nearby states separate at most exponentially, with rate at most K. *Price:* **free**; exact.

609. Separation of exact motions. Let v(t, x) be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on all states at every time. Two motions f and g that solve $f' = v(t, f)$ and $g' = v(t, g)$ with right derivatives uniform on [a, b] and start with $\|f(a) - g(a)\| \leq \delta$ satisfy $\|f(t) - g(t)\| \leq \delta \cdot \exp(K(t - a))$ on [a, b]. *Used for:* Bounding how fast initial uncertainty spreads in a deterministic system. *Price:* **free**; exact.

610. Uniqueness forward in time. Two motions of a law Lipschitz on a region containing both, with equal states at time a, agree at every time of [a, b]. *Used for:* Determinism: the present state and the law fix the future. *Price:* **free**; exact.

611. Uniqueness backward in time. Two motions of a law Lipschitz on a region containing both, with equal states at the final time b, agree at every time of [a, b]. *Used for:* Determinism: the present state and the law fix the past. *Price:* **free**; exact.

612. Uniqueness from an inner time. Let v(t, x) be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on sets S(t) for $a < t < b$. Two motions that stay in S(t) for $a < t < b$, solve $x' = v(t, x)$ with a two-sided derivative uniform on the closed interval [a, b] (ends included), and agree at one time t_0 with $a < t_0 < b$ agree at every time in [a, b]. *Used for:* Determinism in both directions of time from a state

given in the middle of an interval. *Price:* **free**; exact.

613. Uniqueness on an open time interval. Let $v(t, x)$ be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on sets $S(t)$ for $a < t < b$. Two motions that stay in $S(t)$, solve $x' = v(t, x)$ with derivatives uniform on every closed interval inside (a, b), and agree at one time t_0 in (a, b) agree at every time in (a, b). *Used for:* Determinism for motions defined only on an open time interval, such as up to a collision. *Price:* **free**; exact.

614. Uniqueness for a globally Lipschitz law. Two motions on $[a, b]$ of a law that is Lipschitz everywhere, with equal states at time a, agree on all of $[a, b]$. *Used for:* Determinism for laws with a uniform Lipschitz constant, such as linear laws. *Price:* **free**; exact.

615. Uniqueness of motions for all time. Let $v(t, x)$ be a law of motion for states with d real coordinates (size of a state: its largest absolute coordinate) that is K-Lipschitz in x, $K \geq 0$, on sets $S(t)$ at every time. Two motions defined at all times that stay in $S(t)$, solve $x' = v(t, x)$ with derivatives uniform on every bounded time interval, and agree at one time agree at every time. *Used for:* Determinism of a physical system over its whole history. *Price:* **free**; exact.

616. Picard–Lindelöf existence theorem. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law $f(t, y)$ be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, continuous in t uniformly there (one accuracy rate for all those times and states), and let $t_1 \leq t_0 \leq t_2$ with $L \cdot \max(t_2 - t_0, t_0 - t_1) \leq a - r$. Then from every state x within r of x_0 there is a motion through x at time t_0 on all of $[t_1, t_2]$, whose velocity $f(t, \text{state})$ is its derivative uniformly on $[t_1, t_2]$. *Used for:* Existence of the motion of a mechanical, electrical or chemical system from a given initial state. *Price:* **free**; exact: no omniscience principle; the proof chooses a modulus of continuity in time, a choice of natural numbers, and then proceeds as in row 617, whose only choice is of representatives; both choices are inside the free allowance.

617. Picard–Lindelöf with a known continuity modulus. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law $f(t, y)$ be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), and let $t_1 \leq t_0 \leq t_2$ with $L \cdot \max(t_2 - t_0, t_0 - t_1) \leq a - r$. Then from every state x within r of x_0 there is a motion through x at time t_0 on all of $[t_1, t_2]$, whose velocity $f(t, \text{state})$ is its derivative uniformly on $[t_1, t_2]$. *Used for:* Existence of the motion of a system whose law varies in time at a known rate, as integrators compute it. *Price:* **free**; exact: no omniscience principle; the only choice is one countable choice of representatives, which the free allowance contains.

618. Picard–Lindelöf from the centre of the region. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law $f(t, y)$ be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, continuous in t uniformly there (one accuracy rate for all those times and states), and let $t_1 \leq t_0 \leq t_2$ with $L \cdot \max(t_2 - t_0, t_0 - t_1) \leq a$. Then there is a motion through x_0 at time t_0 on all of $[t_1, t_2]$, whose velocity $f(t, \text{state})$ is its derivative uniformly on $[t_1, t_2]$. *Used for:* Existence of the motion of a system started at the point about which its law is known. *Price:* **free**; exact: no omniscience principle; this is row 616 with $r = 0$, and its choices, of a modulus of continuity and of representatives, are inside the free allowance.

619. Motion of a linear system. For every constant real $d \times d$ matrix A and every initial state x_0, there is a motion defined at every time that starts at x_0 at time 0 and whose velocity is A times its state, with the derivative uniform on every bounded time interval. *Used for:* Small oscillations, linear circuits, and the evolution of a finite quantum system. *Price:* **free**; exact.

620. Picard–Lindelöf for a law given by a formula. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law $f(t, y)$ be computed from approximations of its arguments, as every law written by a formula (sums, products, maxima, minima, rational constants) is. Let it be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), where a, r, L and K are nonnegative, $t_1 \leq t_0 \leq t_2$ and $L \cdot \max(t_2 - t_0, t_0 - t_1) \leq a - r$. Then from every state x within r of x_0 there is a motion through x at time t_0 on all of $[t_1, t_2]$, with its derivative uniform there. *Used for:* Existence of the motion of any mechanical, electrical or chemical system whose law is written as a formula. *Price:* **free**; exact.

621. Evolution of a linear system composes in time. For every constant real $d \times d$ matrix A there is one function $\Phi(x, t)$ of the initial state x and the time t such that, from every initial state x, the motion $t \mapsto \Phi(x, t)$ solves $x' = A\,x$ at all times (with the derivative uniform on every bounded time interval) and starts at $\Phi(x, 0) = x$; it satisfies $\Phi(x, s + t) = \Phi(\Phi(x, s), t)$, so evolving for time s and then for time t is evolving for $s + t$; and it is linear in the initial state. *Used for:*

Propagating small oscillations, linear circuits and a finite quantum system in real coordinates step by step in time. *Price:* **free**; exact.

622. Flow of a formula law, Lipschitz in the initial state. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law f(t, y) be computed from approximations of its arguments, as every law written by a formula (sums, products, maxima, minima, rational constants) is. Let it be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), where a, r, L and K are nonnegative, $t_1 \le t_0 \le t_2$ and $L\cdot\max(t_2 - t_0, t_0 - t_1) \le a - r$. Then there is one function $\alpha(x, t)$ of the initial state and the time that, for every x within r of x_0, is a motion through x at time t_0 on all of $[t_1, t_2]$ with its derivative uniform there, and one constant $L' \ge 0$ with $\|\alpha(x, t) - \alpha(y, t)\| \le L'\cdot\|x - y\|$ for all x and y within r of x_0 and every t in $[t_1, t_2]$. *Used for:* The flow of a mechanical or chemical system as a map of initial states, continuous in them: the basis of sensitivity analysis and of phase portraits. *Price:* **free**; exact.

623. Chain rule along a path. Let H be a real function of states with d real coordinates (size of a state: its largest absolute coordinate) whose gradient G exists uniformly on a region (one closeness for each accuracy, everywhere in the region) and is bounded there. If a path α stays in the region and has velocity α' uniformly on [a, b], with α' bounded, then $t \mapsto H(\alpha(t))$ has derivative $G(\alpha(t))\cdot\alpha'(t)$ uniformly on [a, b]. *Used for:* Rates of change of energy, entropy or any observable along a moving state. *Price:* **free**; exact.

624. Conserved quantities stay constant along motions. Let H be a real function of states with d real coordinates (size of a state: its largest absolute coordinate) whose gradient G exists uniformly on a region (one closeness for each accuracy, everywhere in the region) and is bounded there. Let α be a motion of a law f on [a, b], with velocity $f(t, \alpha(t))$ and the derivative uniform on [a, b], that stays in the region, with the speed $f(t, \alpha(t))$ bounded. If $G(\alpha(t))\cdot f(t, \alpha(t)) = 0$ for every t in [a, b], then $H(\alpha(s)) = H(\alpha(t))$ for all s and t in [a, b]. *Used for:* Energy conservation for Hamiltonian systems, conservation of momentum and of every first integral along the motion. *Price:* **free**; exact.

625. Lyapunov functions do not increase along motions. Let H be a real function of states with d real coordinates (size of a state: its largest absolute coordinate) whose gradient G exists uniformly on a region (one closeness for each accuracy, everywhere in the region) and is bounded there. Let α be a motion of a law f on [a, b], with velocity $f(t, \alpha(t))$ and the derivative uniform on [a, b], that stays in the region, with the speed $f(t, \alpha(t))$ bounded. If $G(\alpha(t))\cdot f(t, \alpha(t)) \le 0$ for every t in [a, b], then $H(\alpha(t)) \le H(\alpha(s))$ whenever $a \le s \le t \le b$. *Used for:* Stability arguments: energy that can only dissipate, entropy-like quantities that can only move one way, Lyapunov's direct method. *Price:* **free**; exact.

626. Local uniqueness of motions near a time. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law v(t, x) be K-Lipschitz in x, $K \ge 0$, on sets S(t) for every time t in some open interval around t_0. Let two motions f and g stay in S(t) and solve $x' = v(t, x)$ on open intervals around t_0, with derivatives uniform on every closed interval inside those intervals. If $f(t_0) = g(t_0)$, then f and g agree at every time of some open interval around t_0. *Used for:* Determinism over short times, where a law is only known to be well behaved near the present. *Price:* **free**; exact.

627. Time-independent laws meet the existence hypotheses. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law f(y) that does not depend on time be bounded by L and K-Lipschitz on the closed ball of radius a about x_0, where a, r, L and K are nonnegative, $t_1 \le t_0 \le t_2$ and $L\cdot\max(t_2 - t_0, t_0 - t_1) \le a - r$. Then f satisfies every hypothesis of the Picard–Lindelöf theorem on $[t_1, t_2]$, and since it does not change in time, any rule serves as its modulus of continuity in time. *Used for:* Autonomous systems: a pendulum, a planet, a chemical network whose rules do not change in time. *Price:* **free**; exact.

628. Existence of the flow of a formula law. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law f(t, y) be computed from approximations of its arguments, as every law written by a formula (sums, products, maxima, minima, rational constants) is. Let it be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), where a, r, L and K are nonnegative, $t_1 \le t_0 \le t_2$ and $L\cdot\max(t_2 - t_0, t_0 - t_1) \le a - r$. Then there is one function $\alpha(x, t)$ of the initial state and the time that, for every x within r of x_0, is a motion through x at time t_0 on all of $[t_1, t_2]$, with its derivative uniform there. *Used for:* The flow map of a system: every initial state evolved by one rule. *Price:* **free**; exact.

629. Continuity of the flow of a formula law. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law f(t, y) be computed from approximations of its arguments, as every law written by a formula (sums, products, maxima, minima, rational constants) is. Let it be

K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), where a, r, L and K are nonnegative, $t_1 \le t_0 \le t_2$ and $L \cdot \max(t_2 - t_0, t_0 - t_1) \le a - r$. Then there is one function $\alpha(x, t)$ that, for every x within r of x_0, is a motion through x at time t_0 on all of $[t_1, t_2]$ with its derivative uniform there, and α is uniformly continuous jointly in the initial state x (within r of x_0) and the time t (in $[t_1, t_2]$). *Used for:* Small changes in the initial state and the time give small changes in the evolved state: the basis of numerical prediction. *Price:* **free**; exact.

630. Motions with ordinary derivatives on the open interval. For states with d real coordinates (size of a state: its largest absolute coordinate), let a law f(t, y) be computed from approximations of its arguments, as every law written by a formula (sums, products, maxima, minima, rational constants) is. Let it be K-Lipschitz in y and bounded by L on the closed ball of radius a about x_0 for every time t in $[t_1, t_2]$, with a known modulus of continuity in t (a rule giving, for each accuracy, a time step that achieves it for all states of the ball), where a, r, L and K are nonnegative, $t_1 \le t_0 \le t_2$ and $L \cdot \max(t_2 - t_0, t_0 - t_1) \le a - r$. Then from every state x within r of x_0 there is a motion α through x at time t_0 that has the velocity $f(t, \alpha(t))$, as an ordinary two-sided derivative, at every time t strictly between t_1 and t_2. *Used for:* Existence of the motion with an ordinary derivative at every inner time, as textbooks state it. *Price:* **free**; exact.

631. The evolution of the zero law is the identity. For states with d real coordinates, every evolution map Φ of the law $x' = 0$ (any map with $\Phi(x, 0) = x$ whose motions $t \mapsto \Phi(x, t)$ solve the law, with derivatives uniform on every bounded time interval) leaves every state where it is: $\Phi(x, t) = x$ for every state x and time t. *Used for:* The trivial evolution: nothing moves when no force acts. *Price:* **free**; exact.

632. Linear evolution can be run backward. Let A be a constant real d × d matrix and $\Phi(x, t)$ any evolution map of the law $x' = A\,x$ (any map with $\Phi(x, 0) = x$ whose motions $t \mapsto \Phi(x, t)$ solve the law, with derivatives uniform on every bounded time interval). Then evolving for time t and then for time −t returns every state to itself, and so does evolving for time −t and then for time t: $\Phi(\Phi(x, t), -t) = x$ and $\Phi(\Phi(x, -t), t) = x$. *Used for:* Reversibility of linear dynamics: recovering an earlier state from a later one. *Price:* **free**; exact.

633. Decoupled modes evolve separately. Let A be a constant real d × d matrix whose entries off the diagonal are 0, and $\Phi(x, t)$ any evolution map of the law $x' = A\,x$ (any map with $\Phi(x, 0) = x$ whose motions $t \mapsto \Phi(x, t)$ solve the law, with derivatives uniform on every bounded time interval). Then coordinate c of $\Phi(x, t)$ is $\exp(t \cdot a)$ times coordinate c of x, where a is the diagonal entry of A in row c. *Used for:* Normal modes: independent oscillators or decaying channels each evolve by their own rate. *Price:* **free**; exact.

634. Linear evolution in another basis. Let A, U and V be constant real d × d matrices with $U \cdot V = V \cdot U = I$. Let $\Phi(x, t)$ be an evolution map of the law $x' = A\,x$ and $\Psi(x, t)$ one of the law $x' = (U \cdot A \cdot V)\,x$: maps with $\Phi(x, 0) = x$ and $\Psi(x, 0) = x$ whose motions in t solve their laws, with derivatives uniform on every bounded time interval. Then $\Psi(x, t) = U \cdot \Phi(V \cdot x, t)$ for every state x and time t. *Used for:* Solving a linear system by changing to the basis of its modes and back. *Price:* **free**; exact.

635. Exponential stability from a quadratic Lyapunov function. Let A and P be constant real d × d matrices, and let $\Phi(x, t)$ be an evolution map of the law $x' = A\,x$: a map with $\Phi(x, 0) = x$ whose motions $t \mapsto \Phi(x, t)$ solve the law at all times, with derivatives uniform on every bounded time interval. Suppose that $\lambda \cdot \|x\|^2 \le x^{\mathsf{T}} P\,x \le \Lambda \cdot \|x\|^2$ and $x^{\mathsf{T}} (A^{\mathsf{T}} P + P A)\,x \le -\varepsilon \cdot \|x\|^2$ for every state x, where $\|x\|$ is the Euclidean length, and let $c \ge 0$ with $c \cdot \Lambda \le \varepsilon$. Then $\lambda \cdot \|\Phi(x, t)\|^2 \le \Lambda \cdot \exp(-c \cdot t) \cdot \|x\|^2$ for every state x and every time $t \ge 0$. *Used for:* Proving that an equilibrium of a linear system (or the linearization of a nonlinear one) is stable with a decay rate: control design, damped oscillators, circuits. *Price:* **free**; exact.

636. Deciding whether a linear law is stable. Deciding, for every real number a, whether no motion of the law $x' = a\,x$ ever grows (that is, $\exp(a \cdot t) \le 1$ for every time $t \ge 0$, which holds exactly when $a \le 0$) or not, is exactly the weak limited principle of omniscience. *Used for:* Classifying an equilibrium as stable or unstable from a measured rate, without a margin. *Price:* **WLPO**; exact.

637. Deciding whether a linear law is asymptotically stable. Deciding, for every real number a, whether every motion of the law $x' = a\,x$ decays to 0 (that is, for every tolerance there is a time after which $\exp(a \cdot t)$ stays below it, which holds exactly when $a < 0$) or not, is exactly the limited principle of omniscience. *Used for:* Classifying an equilibrium as attracting or not from a measured rate, without a margin. *Price:* **LPO**; exact.

638. Duhamel's formula (variation of constants). Let A be a constant real d × d matrix and $\Phi(x, t)$ an evolution map of the law $x' = A\,x$: a map with $\Phi(x, 0) = x$ whose motions $t \mapsto \Phi(x, t)$ solve the law at all times, with derivatives uniform on every bounded time interval. Let b(t) be a forcing term and x(t) a motion of the driven law $x' = A\,x + b(t)$ at all times, with its derivative uniform on every bounded time

interval. Then for every time t, x(t) = Φ(x(0), t) + (the integral from 0 to t of Φ(b(s), t − s) ds), coordinate by coordinate, where the integral is the limit of Riemann sums on [0, 1] after the substitution s = t·u. *Used for:* Driven linear systems: forced oscillators, circuits with sources, linear response of a quantum system to a field. *Price:* **free**; exact.

Q.6 Linear algebra and spectra

639. Determinant of a product. For every size n and every two n × n matrices A and B on the line: det(AB) = det(A)·det(B). *Used for:* Jacobians and volume scaling under composed linear maps; the determinant conditions defining SO(n) and SL(n) are preserved by products. *Price:* **free**; exact.

640. Determinant of the identity matrix. For every size n, the n × n identity matrix on the line has determinant 1. *Used for:* The identity transformation scales every volume by exactly 1: normalisation of Jacobians and of expansions of det(1 + εA). *Price:* **free**; exact.

641. Laplace expansion along a column. For every n ≥ 0, every (n + 1) × (n + 1) matrix A on the line and every column i: $\det(A) = \sum_k (-1)^{k+i} \cdot A_{ki} \cdot$ det(A with row k and column i deleted), the sum running over all rows k. *Used for:* Expanding secular determinants and Slater determinants by cofactors. *Price:* **free**; exact.

642. Two equal columns give determinant zero. For every size n and every n × n matrix A on the line: if two different columns of A are equal entry by entry, then det(A) = 0. *Used for:* Pauli exclusion: a Slater determinant with one orbital placed in two columns vanishes. *Price:* **free**; exact.

643. Determinant is additive in one column. For every size n, every n × n matrix A on the line, every column j and every two column vectors u and v: the determinant of A with column j replaced by u + v equals the determinant of A with column j replaced by u plus the determinant of A with column j replaced by v. *Used for:* Linearity of a Slater determinant in each orbital: a superposed orbital splits the determinant into a sum. *Price:* **free**; exact.

644. Determinant scales with one column. For every size n, every n × n matrix A on the line, every column j, every number c and every column vector u: the determinant of A with column j replaced by c·u equals c times the determinant of A with column j replaced by u. *Used for:* Stretching one axis by a factor c scales a volume, a Jacobian or a Slater determinant by c. *Price:* **free**; exact.

645. Adjugate times matrix is the determinant. For every size n and every n × n matrix A on the line: adj(A)·A = det(A)·1. Here adj(A) is the adjugate: its (i, j) entry is $(-1)^{i+j}$ times the determinant of A with row j and column i deleted. *Used for:* Closed-form inverses A^{-1} = adj(A)/det(A), and Jacobi's formula for the derivative of a determinant. *Price:* **free**; exact.

646. Matrix times adjugate is the determinant. For every size n and every n × n matrix A on the line: A·adj(A) = det(A)·1, where adj(A) is the adjugate, whose (i, j) entry is $(-1)^{i+j}$ times the determinant of A with row j and column i deleted. *Used for:* Cofactor inverses of small matrices, such as a 3 × 3 inertia tensor or metric. *Price:* **free**; exact.

647. A one-sided inverse of a square matrix is two-sided. For every size n and every two n × n matrices A and B on the line: AB = 1 exactly when BA = 1. *Used for:* Checking a rotation needs only $O^TO = 1$, since $OO^T = 1$ then follows; a left inverse found by solving equations is also a right inverse. *Price:* **free**; exact.

648. Invertibility criterion through the determinant. For every size n, an n × n matrix A of real numbers (on the line) has a two-sided inverse, a matrix B with AB = 1 and BA = 1, exactly when det(A) has an inverse, a number e with det(A)·e = 1. *Used for:* Deciding when a change of frame, a transfer matrix or a linear response map can be undone. *Price:* **free**; exact.

649. An invertible determinant gives an inverse matrix. For every size n and every n × n matrix A on the line: if det(A) has an inverse, a number e with det(A)·e = 1, then A has a two-sided inverse, a matrix B with AB = 1 and BA = 1. *Used for:* Inverting a metric, a Jacobian or a coefficient matrix once its determinant is known to be invertible. *Price:* **free**; exact.

650. A nonzero determinant gives an inverse matrix. For every size n and every n × n matrix A on the line: if det(A) ≠ 0, then A has a two-sided inverse, a matrix B with AB = 1 and BA = 1. The hypothesis says only that det(A) is not zero; no inverse of det(A) is given. *Used for:* Inverting a matrix known only to be nonsingular: normal-mode problems, inverse metrics, linear response. *Price:* **MP**; exact.

651. Cayley–Hamilton theorem for square matrices. For every size n and every n × n matrix M on the line there are numbers $c_0, c_1, \ldots, c_n$ with $c_n = 1$ such that $\det(t\cdot 1 - M) = c_0 + c_1 t + \ldots + c_n t^n$ for every number t, and $c_0\cdot 1 + c_1 M + c_2 M^2 + \ldots + c_n M^n = 0$. So

every square matrix satisfies its own characteristic polynomial. *Used for:* Writing exp(t A) or any function of a transfer matrix or spin generator as a polynomial of degree below n. *Price:* **free**; exact.

652. Determinant of a product in either order. For every size n and every two n × n matrices A and B on the line: det(AB) = det(BA). *Used for:* The volume factor of two composed linear maps, such as successive frame changes or transfer matrices, does not depend on their order. *Price:* **free**; exact.

653. Determinant is unchanged by a change of basis. For every size n, every n × n matrix M on the line with a given two-sided inverse M^{-1} ($MM^{-1} = 1$ and $M^{-1}M = 1$) and every n × n matrix N: det(M N M^{-1}) = det(N). *Used for:* The determinant of an operator does not depend on the basis: similarity transforms and changes of frame. *Price:* **free**; exact.

654. Determinant is unchanged by the inverse change of basis. For every size n, every n × n matrix M on the line with a given two-sided inverse M^{-1} ($MM^{-1} = 1$ and $M^{-1}M = 1$) and every n × n matrix N: det(M^{-1} N M) = det(N). *Used for:* Basis independence of the volume factor for an operator written in new coordinates as $M^{-1}NM$. *Price:* **free**; exact.

655. Determinant of the negative of a matrix. For every size n and every n × n matrix A on the line: $\det(-A) = (-1)^n \det(A)$. *Used for:* Spatial inversion $x \mapsto -x$ reverses orientation in odd dimensions (determinant −1 in three dimensions); sign conventions of characteristic polynomials. *Price:* **free**; exact.

656. Determinant of a diagonal matrix. For every size n and all numbers $d_1, \ldots, d_n$ on the line: the diagonal matrix with diagonal entries $d_1, \ldots, d_n$ has determinant $d_1 \cdot d_2 \cdot \ldots \cdot d_n$. *Used for:* The determinant of a diagonalised operator is the product of its eigenvalues; Gaussian integrals over normal modes. *Price:* **free**; exact.

657. Determinant of an upper triangular matrix. For every size n and every n × n matrix A on the line that is upper triangular (every entry below the diagonal is 0): det(A) is the product of the diagonal entries $A_{11} \cdot A_{22} \cdot \ldots \cdot A_{nn}$. *Used for:* Reading a determinant off a triangular (Schur or LU) form; the volume of a sheared box. *Price:* **free**; exact.

658. Determinant of a lower triangular matrix. For every size n and every n × n matrix A on the line that is lower triangular (every entry above the diagonal is 0): det(A) is the product of the diagonal entries $A_{11} \cdot A_{22} \cdot \ldots \cdot A_{nn}$. *Used for:* Jacobians of triangular changes of variables, such as the Cholesky factor of a covariance matrix. *Price:* **free**; exact.

659. Cramer's rule equals the adjugate applied to the right side. For every size n, every n × n matrix A on the line and every vector b: the Cramer vector of A and b, whose i-th entry is the determinant of A with column i replaced by b, equals adj(A)·b, where adj(A) is the adjugate (the transposed matrix of signed cofactors). *Used for:* Solving small linear systems in closed form: Kirchhoff circuit equations, coupled oscillators with a drive. *Price:* **free**; exact.

660. Cramer's rule without division. For every size n, every n × n matrix A on the line and every vector b: A applied to the Cramer vector of A and b equals det(A)·b. The Cramer vector has as its i-th entry the determinant of A with column i replaced by b. *Used for:* Circuit currents and driven normal-mode amplitudes, up to the common factor det(A). *Price:* **free**; exact.

661. Unique solution of a linear system with invertible determinant. For every size n, every n × n matrix A on the line, every vector b and every number e with det(A)·e = 1: the vector x = e·adj(A)·b solves Ax = b, and every solution of Ax = b equals it. Here adj(A) is the adjugate, the transposed matrix of signed cofactors. *Used for:* The unique response of a linear system to a source: circuit currents, forced oscillation amplitudes, linear transport equations. *Price:* **free**; exact.

662. A nonzero determinant makes a linear system solvable. For every size n, every n × n matrix A on the line and every vector b: if $\det(A) \neq 0$, then the system Ax = b has a solution x. The hypothesis says only that det(A) is not zero; no inverse of det(A) is given. *Used for:* Solving linear equations known only to be nonsingular: normal-mode amplitudes, network equations, linearised equilibrium conditions. *Price:* **MP**; exact.

663. An orthogonal matrix has determinant squaring to one. For every size n and every n × n orthogonal matrix A on the line ($A^TA = 1$ and $AA^T = 1$): det(A)·det(A) = 1. *Used for:* Rigid motions preserve volume up to orientation: |det| = 1 for every rotation or reflection. *Price:* **free**; exact.

664. Square roots of one are plus or minus one. For every real number d (on the line): d·d = 1 exactly when d = 1 or d = −1. *Used for:* Eigenvalues of parity, of a reflection or of any operator squaring to the identity are +1 or −1. *Price:* **free**; exact.

665. An orthogonal matrix has determinant plus or minus one. For every size n and every n × n orthogonal matrix A on the line ($A^TA = 1$ and $AA^T = 1$): det(A) = 1 or det(A) = −1. *Used for:* Splitting the orthogonal group into proper rotations (determinant 1) and orientation-reversing motions such as parity (determinant −1). *Price:* **free**; exact.

666. Determinant of the conjugate transpose. For every size n and every n × n matrix A with

complex entries (real and imaginary parts on the line): det(A†) is the complex conjugate of det(A), where A† is the conjugate transpose of A. *Used for:* Determinants of adjoint operators; the determinant of a Hermitian matrix is real. *Price:* **free**; exact.

667. A unitary matrix has determinant of absolute value one. For every size n and every n × n unitary matrix U with complex entries (real and imaginary parts on the line), meaning U†U = 1 and UU† = 1: conj(det(U))·det(U) = 1 and det(U)·conj(det(U)) = 1, where conj is complex conjugation. So det(U) is a phase, a complex number of absolute value 1. *Used for:* A unitary evolution multiplies volumes by a pure phase; SU(n) is the set of unitaries whose phase det(U) is 1. *Price:* **free**; exact.

668. Determinant of a block upper triangular matrix. For all block sizes m and n and matrices on the line A (m × m), B (m × n) and D (n × n): the (m + n) × (m + n) block matrix with top block row A, B and bottom block row 0, D has determinant det(A)·det(D). *Used for:* One-way coupled subsystems: the characteristic polynomial of a block triangular generator, such as a rate matrix with an absorbing sector, is the product of the blocks' characteristic polynomials. *Price:* **free**; exact.

669. Determinant of a block lower triangular matrix. For all block sizes m and n and matrices on the line A (m × m), C (n × m) and D (n × n): the (m + n) × (m + n) block matrix with top block row A, 0 and bottom block row C, D has determinant det(A)·det(D). *Used for:* Cascaded sectors that feed forward without feedback, such as a decay chain's rate matrix split into parent and daughter blocks. *Price:* **free**; exact.

670. Determinant of a block diagonal matrix. For all n and m and all m × m matrices M_1, ..., M_n on the line: the block diagonal matrix with M_1, ..., M_n along its diagonal (size nm) has determinant $\det(M_1)\cdot\det(M_2)\cdot\ldots\cdot\det(M_n)$. *Used for:* A Hamiltonian or transfer matrix that splits into independent symmetry sectors has determinant and characteristic polynomial equal to products over the sectors. *Price:* **free**; exact.

671. Determinant of a Kronecker product. For all sizes n and m, every n × n matrix A and every m × m matrix B on the line: the Kronecker product A ⊗ B, of size nm, has determinant $\det(A)^m \cdot \det(B)^n$. *Used for:* Determinants of operators on a composite system: product evolutions and product frame changes on two subsystems. *Price:* **free**; exact.

672. Strict row dominance gives a nonzero determinant. For every size n and every n × n matrix A on the line that is strictly row dominant, meaning the sum of $|A_{kj}|$ over all columns j ≠ k is less than $|A_{kk}|$ for every row k: det(A) ≠ 0. *Used for:* Unique solvability of discretised operators: implicit diffusion steps, a finite-difference Laplacian plus a positive mass term. *Price:* **free**; exact.

673. Strict column dominance gives a nonzero determinant. For every size n and every n × n matrix A on the line that is strictly column dominant, meaning the sum of $|A_{ik}|$ over all rows i ≠ k is less than $|A_{kk}|$ for every column k: det(A) ≠ 0. *Used for:* Implicit time steps of master equations, whose matrices are strictly column dominant, have a unique solution. *Price:* **free**; exact.

674. Gershgorin's circle theorem for real eigenvalues. For every size n, every n × n matrix A on the line and every real number μ that is an eigenvalue in the sense that the equation Av = μv does not force v = 0: there is a row k with $|\mu - A_{kk}|$ at most the sum of $|A_{kj}|$ over all columns j ≠ k. *Used for:* Locating energy levels: every level lies within the total hopping of some on-site energy in a tight-binding Hamiltonian. *Price:* **LLPO**; exact.

675. Spectral theorem for complex Hermitian matrices. For every size n and every n × n Hermitian matrix H with complex entries (real and imaginary parts on the line, H† = H): there are an n × n matrix V with V†V = 1 and real numbers λ_1, ..., λ_n with HV = V·diag(λ_1, ..., λ_n). So H = V·diag(λ_1, ..., λ_n)·V† with V unitary: the columns of V form an orthonormal basis of eigenvectors with real eigenvalues. *Used for:* Diagonalising a finite Hamiltonian or observable: the energy eigenbasis, real measurement outcomes, normal modes. *Price:* **LLPO + AC**$_\omega$; exact.

676. Highest-energy eigenstate of a Hermitian matrix. For every size n ≥ 1 and every n × n Hermitian matrix H with complex entries (real and imaginary parts on the line, H† = H): there are a unit vector v (⟨v, v⟩ = 1) and a real number l with Hv = l·v such that the real part of ⟨w, Hw⟩ is at most l for every unit vector w. So v is an eigenvector for the largest energy. *Used for:* The state that maximises the expectation value of a finite observable, attained at its largest eigenvalue. *Price:* **LLPO + AC**$_\omega$; exact.

677. Ground state of a Hermitian matrix. For every size n ≥ 1 and every n × n Hermitian matrix H with complex entries (real and imaginary parts on the line, H† = H): there are a unit vector v (⟨v, v⟩ = 1) and a real number l with Hv = l·v such that l is at most the real part of ⟨w, Hw⟩ for every unit vector w. So v is a ground state, an eigenvector for the lowest energy. *Used for:* The ground state of a finite quantum system and its energy, the minimiser of the variational principle. *Price:* **LLPO + AC**$_\omega$; exact.

678. Trace of a Hermitian matrix from its eigenbasis. For every size n, all n × n matrices H and V with complex entries (real and imaginary parts on

the line) and all real numbers $\lambda_1, \ldots, \lambda_n$: if $V\dagger V = 1$ and $HV = V\cdot\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$, so that the k-th column of V is an eigenvector of H with eigenvalue λ_k, then the trace of H is $\lambda_1 + \ldots + \lambda_n$. *Used for:* The sum of the energy levels of a finite Hamiltonian is its trace: sum rules and the high-temperature expansion of the partition function. *Price:* **free**; exact.

679. Determinant of a Hermitian matrix from its eigenbasis. For every size n, all n × n matrices H and V with complex entries (real and imaginary parts on the line) and all real numbers $\lambda_1, \ldots, \lambda_n$: if $V\dagger V = 1$ and $HV = V\cdot\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$, so that the k-th column of V is an eigenvector of H with eigenvalue λ_k, then $\det(H) = \lambda_1\cdot\lambda_2\cdot\ldots\cdot\lambda_n$. *Used for:* The product of the energy levels is the determinant: Gaussian integrals and determinants of finite Hermitian operators. *Price:* **free**; exact.

680. A singular matrix has a unit null vector. For every size $n \geq 1$ and every n × n matrix A on the line with $\det(A) = 0$: there is a unit vector v ($v\cdot v = 1$) with $Av = 0$. *Used for:* Zero modes and gauge modes: a singular Hamiltonian or stiffness matrix has a normalised static mode. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

681. A nonzero null vector forces a zero determinant. For every size n, every n × n matrix A on the line and every vector $v \neq 0$ with $Av = 0$: $\det(A) = 0$. *Used for:* A zero mode, such as a gauge direction or a static solution, makes a stiffness or kinetic matrix singular. *Price:* **free**; exact.

682. Secular equation for eigenvalues. For every size $n \geq 1$, every n × n matrix A on the line and every real number l: A has a unit eigenvector for l, a vector v with $v\cdot v = 1$ and $Av = l\cdot v$, exactly when $\det(l\cdot 1 - A) = 0$. *Used for:* Finding energy levels and squared normal-mode frequencies as roots of a secular determinant, with a normalised state for each root. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

683. Eigenvalues are roots of the characteristic polynomial. For every size n, every n × n matrix A on the line, every real number l and every unit vector v ($v\cdot v = 1$) with $Av = l\cdot v$: $\det(l\cdot 1 - A) = 0$. *Used for:* Every energy found with a normalised eigenvector is a root of the secular equation $\det(E\cdot 1 - H) = 0$, as in Hückel and tight-binding calculations. *Price:* **free**; exact.

684. A singular matrix has a nonzero null vector. For every size $n \geq 1$ and every n × n matrix A on the line with $\det(A) = 0$: there is a vector $v \neq 0$ with $Av = 0$. *Used for:* Existence of a zero mode of a singular Hamiltonian, stiffness or constraint matrix. *Price:* **open**; at most LLPO + AC_ω (upper bound only).

685. Positive semidefinite: ⟨x, Ax⟩ is a nonnegative real. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: $A \succeq 0$ if and only if $A\dagger = A$ and, for every complex vector x, $\langle x, Ax\rangle$ is a nonnegative real number (its real part is ≥ 0 and its imaginary part is 0). *Used for:* Density matrices: a quantum state $\rho \succeq 0$ assigns every normalized state vector ψ a real, nonnegative weight $\langle\psi, \rho\psi\rangle$, the probability of finding the system in ψ. *Price:* **free**; exact.

686. A† A is positive semidefinite. For all sizes m and n and every complex m × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the n × n matrix $A\dagger A$ is positive semidefinite, where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Gram matrices and measurement operators: the overlap matrix of any list of state vectors ($A\dagger A$, with the vectors as columns of A) and every operator $M\dagger M$ of a quantum measurement are positive semidefinite. *Price:* **free**; exact.

687. A A† is positive semidefinite. For all sizes m and n and every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the n × n matrix $AA\dagger$ is positive semidefinite, where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Building density matrices: $\rho = \psi_1\psi_1\dagger + \ldots + \psi_m\psi_m\dagger$ for any list of (unnormalized) state vectors, and the reduced state $AA\dagger$ of a bipartite pure state with coefficient matrix A, are positive semidefinite. *Price:* **free**; exact.

688. Sum of positive semidefinite matrices. For every size n and all complex n × n matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$ and $B \succeq 0$, then $A + B \succeq 0$. *Used for:* Mixing quantum states: a sum of positive operators is positive, so a mixture $p_1\rho_1 + p_2\rho_2$ of density matrices, whose weighted terms $p_1\rho_1$ and $p_2\rho_2$ are positive, is again positive. *Price:* **free**; exact.

689. Nonnegative multiple of a positive semidefinite matrix. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number a

that is a nonnegative real (real part ≥ 0, imaginary part 0), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$, then $a \cdot A \succeq 0$. *Used for:* Weighting and normalizing states: $p\rho$ for a probability $p \geq 0$, and ρ divided by its trace, stay positive. *Price:* **free**; exact.

690. Congruence B† A B preserves positive semidefiniteness. For all sizes n and m, every complex $n \times n$ matrix A and every complex $n \times m$ matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$, then the $m \times m$ matrix $B\dagger AB \succeq 0$. *Used for:* Transforming positive operators: a positive observable or state stays positive under a change of basis or in the Heisenberg picture ($U\dagger AU$), and under restriction to a subspace (B an isometry onto it). *Price:* **free**; exact.

691. Congruence B A B† preserves positive semidefiniteness. For all sizes n and m, every complex $n \times n$ matrix A and every complex $m \times n$ matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$, then the $m \times m$ matrix $BAB\dagger \succeq 0$. *Used for:* Quantum operations: each Kraus term $K\rho K\dagger$ of a quantum channel applied to a density matrix ρ is positive, including channels between spaces of different dimension. *Price:* **free**; exact.

692. Diagonal entries of a positive semidefinite matrix are nonnegative. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$, then every diagonal entry A_{ii} is a nonnegative real number (real part ≥ 0, imaginary part 0). *Used for:* Populations: in any basis, the diagonal entries of a density matrix are the occupation probabilities of the basis states, and they are nonnegative. *Price:* **free**; exact.

693. Trace of a positive semidefinite matrix is nonnegative. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: if $A \succeq 0$, then its trace $A_{11} + \ldots + A_{nn}$ is a nonnegative real number (real part ≥ 0, imaginary part 0). *Used for:* Total probability: the trace of a density matrix or of any positive operator is a nonnegative real number; a normalized state has trace 1. *Price:* **free**; exact.

694. Identity matrix is positive semidefinite. For every size n, the complex $n \times n$ identity matrix 1 is positive semidefinite, where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* The identity is positive, so the maximally mixed state $1/n$, a positive multiple of it, is a valid density matrix; the identity is also the measurement operator of a certain outcome. *Price:* **free**; exact.

695. Zero matrix is positive semidefinite. For every size n, the complex $n \times n$ zero matrix is positive semidefinite, where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* The measurement operator of an impossible outcome, and the starting point when positive operators are summed. *Price:* **free**; exact.

696. Diagonal matrix is positive semidefinite exactly when its entries are. For every size n and all complex numbers $d_1, \ldots, d_n$ (in the complex numbers over the line), where a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$: the diagonal matrix $\mathrm{diag}(d_1, \ldots, d_n) \succeq 0$ if and only if every d_k is a nonnegative real number (real part ≥ 0, imaginary part 0). *Used for:* Classical probability inside quantum mechanics: a state diagonal in a known basis, such as a thermal state in the energy basis, $\mathrm{diag}(p_1, \ldots, p_n)$, is valid exactly when every $p_k \geq 0$. *Price:* **free**; exact.

697. Positive semidefinite exactly when the eigenvalues are nonnegative. For every size n, every complex $n \times n$ matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian ($H\dagger = H$), every complex $n \times n$ matrix V with $V\dagger V = 1$, and all real numbers $\lambda_1, \ldots, \lambda_n$ on the line with $HV = V\,\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ (the columns of V are an orthonormal eigenbasis of H with these eigenvalues): H is positive semidefinite if and only if $\lambda_1, \ldots, \lambda_n$ are all ≥ 0. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. The eigenbasis is given, not constructed. *Used for:* Reading positivity off the spectrum: once an orthonormal eigenbasis is known, a candidate density matrix or a Hamiltonian bounded below by zero is

checked through its eigenvalues. *Price:* **free**; exact.

698. Eigenvalues of a positive semidefinite matrix are nonnegative. For every size n, every positive semidefinite complex n × n matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), every complex n × n matrix V with V†V = 1, and all real numbers $\lambda_1, \ldots, \lambda_n$ on the line with HV = V diag($\lambda_1, \ldots, \lambda_n$): every $\lambda_k \geq 0$. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. The eigenbasis is given, not constructed. *Used for:* The eigenvalues of a density matrix are the probabilities of its pure-state components, and positive observables such as $H - E_0$ (E_0 the ground energy) have nonnegative spectrum. *Price:* **free**; exact.

699. Square root of a positive semidefinite matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$, there is a complex n × n matrix B with B† = B, $B \succeq 0$ and BB = A. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Square roots of density matrices: the fidelity $F(\rho, \sigma) = (\mathrm{tr}\, \sqrt{(\sqrt{\rho}\, \sigma\, \sqrt{\rho})})^2$ between quantum states, the purification of a mixed state, and polar decompositions of operators. *Price:* **free**; exact.

700. Positive semidefinite exactly when A = B† B. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): $A \succeq 0$ if and only if A = B†B for some complex n × n matrix B. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Every density matrix can be written ρ = B†B, the starting point of purifications and of Gram-matrix descriptions of sets of quantum states. *Price:* **free**; exact.

701. Spectral theorem for positive semidefinite matrices. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$, there are a complex n × n matrix V with V†V = 1 and real numbers $\lambda_1, \ldots, \lambda_n$ on the line, all ≥ 0, with AV = V diag($\lambda_1, \ldots, \lambda_n$). Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Spectral decomposition of a density matrix, $\rho = p_1 v_1 v_1^\dagger + \ldots + p_n v_n v_n^\dagger$ with orthonormal pure states v_k and probabilities $p_k \geq 0$, used for the von Neumann entropy $-\Sigma\, p_k \ln p_k$. *Price:* **LLPO + AC$_\omega$**; exact.

702. Zero expectation in a positive semidefinite matrix means kernel. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$ and every complex vector x: $\langle x, Ax\rangle = 0$ if and only if Ax = 0. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* A state with zero weight under a density matrix ρ ($\langle \psi, \rho\psi\rangle = 0$) is annihilated by ρ, so it is orthogonal to the support of ρ; this holds for every positive observable as well. *Price:* **free**; exact.

703. Positive semidefinite matrix of zero trace is zero. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$: the trace $A_{11} + \ldots + A_{nn}$ is 0 if and only if A = 0. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* A positive operator with zero total weight vanishes: a block of a density matrix or a measurement operator of trace zero is zero. *Price:* **free**; exact.

704. Powers of a positive semidefinite matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$: every power A^k, k = 0, 1, 2, ..., is positive semidefinite ($A^0 = 1$). Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Powers of density matrices: the purity $\mathrm{tr}\, \rho^2$ and the Rényi entropies built from $\mathrm{tr}\, \rho^k$, and powers of positive Hamiltonians. *Price:* **free**; exact.

705. Transpose of a positive semidefinite matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if $A \succeq 0$, then its transpose $A^T \succeq 0$. Here a square complex matrix A is positive semidefinite, $A \succeq 0$, when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* The transpose (equivalently the complex conjugate) of a density matrix is a valid state; the partial transpose of a two-part state need not be, which is the Peres test for entanglement. *Price:* **free**; exact.

706. Conjugate transpose of a positive semidefinite matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if $A \succeq 0$, then $A^\dagger \succeq 0$. Here a

square complex matrix A is positive semidefinite, $A \succeq 0$, when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Density matrices and positive observables are self-adjoint, so passing to the adjoint, as in the Heisenberg-picture dual, leaves them valid. *Price:* **free**; exact.

707. Trace of a sum. For every size n and all n × n matrices A and B with entries on the line: tr(A + B) = tr A + tr B, where tr is the sum of the diagonal entries. *Used for:* Expectation values add over the terms of an observable (with the distributive law): $\langle A + B\rangle = \langle A\rangle + \langle B\rangle$, such as energy as kinetic plus potential energy. *Price:* **free**; exact.

708. Trace of a difference. For every size n and all n × n matrices A and B with entries on the line: tr(A − B) = tr A − tr B, where tr is the sum of the diagonal entries. *Used for:* The expectation value of a perturbation $H_2 - H_1$ is the difference of the two expectation values, as in energy shifts between two Hamiltonians. *Price:* **free**; exact.

709. Trace of a scalar multiple. For every set of scalars S acting on the line additively (r·(a + b) = r·a + r·b and r·0 = 0; for example, multiplication by a number on the line), every r in S, every size n and every n × n matrix A with entries on the line: tr(r·A) = r·tr A, where r·A multiplies every entry by r and tr is the sum of the diagonal entries. *Used for:* Scaling an observable by a number scales its expectation value, as with a coupling constant in front of an interaction term. *Price:* **free**; exact.

710. Trace of the zero matrix. For every size n, the trace (the sum of the diagonal entries) of the n × n zero matrix with entries on the line is 0. *Used for:* The zero operator has expectation value zero in every state. *Price:* **free**; exact.

711. Trace of the transpose. For every size n and every n × n matrix A with entries on the line: $\mathrm{tr}(A^{\mathrm{T}}) = \mathrm{tr}\, A$, where A^{T} is the transpose and tr is the sum of the diagonal entries. *Used for:* Real observables and states: transposing (the adjoint over the reals) leaves traces and expectation values unchanged. *Price:* **free**; exact.

712. Trace of the identity is the dimension. For every size n, the trace (the sum of the diagonal entries) of the n × n identity matrix with entries on the line is n, the natural number n read on the line. *Used for:* The dimension of a state space as $\mathrm{tr}\, 1 = n$; the normalisation of the maximally mixed state 1/n. *Price:* **free**; exact.

713. Trace of a product is cyclic. For all natural numbers m and n, every m × n matrix A and every n × m matrix B with entries on the line: tr(AB) = tr(BA), where tr is the sum of the diagonal entries (of the m × m matrix AB and of the n × n matrix BA). *Used for:* Expectation values can be written either way round, $\mathrm{tr}(\rho A) = \mathrm{tr}(A\rho)$; traces and partition functions do not depend on the basis. *Price:* **free**; exact.

714. Trace of three factors is cyclic. For all natural numbers m, n and p and matrices with entries on the line, A of shape m × n, B of shape n × p and C of shape p × m: tr((AB)C) = tr((CA)B), where tr is the sum of the diagonal entries. *Used for:* Moving an operator around a trace of three factors, as in showing that the Schrödinger and Heisenberg pictures give equal expectation values. *Price:* **free**; exact.

715. Matrix multiplication is associative. For all natural numbers m and n, any index sets I and K, and matrices with entries on the line, L of shape I × m, M of shape m × n and N of shape n × K: (LM)N = L(MN). *Used for:* Successive linear transformations, such as evolution steps, rotations and transfer matrices, compose without regard to grouping. *Price:* **free**; exact.

716. Identity matrix is a left unit. For every natural number m, any index set K and every m × K matrix M with entries on the line: 1M = M, where 1 is the m × m identity matrix. *Used for:* The identity transformation composed with any linear map changes nothing, as with a zero-time evolution applied after an operation. *Price:* **free**; exact.

717. Identity matrix is a right unit. For every natural number n, any index set I and every I × n matrix M with entries on the line: M1 = M, where 1 is the n × n identity matrix. *Used for:* Inserting the identity, written as a complete set of basis states, between two factors leaves a product unchanged. *Price:* **free**; exact.

718. Matrix product distributes over a sum on the right. For every natural number n, any index sets I and K, every I × n matrix L and all n × K matrices M and N with entries on the line: L(M + N) = LM + LN. *Used for:* Linearity of operators: an operator applied to a sum of operators, or to a superposition of state columns, acts term by term. *Price:* **free**; exact.

719. Matrix product distributes over a sum on the left. For every natural number m, any index sets I and K, all I × m matrices L and M and every m × K matrix N with entries on the line: (L + M)N = LN + MN. *Used for:* A sum of operators acts term by term, as for a Hamiltonian H = T + V applied to states. *Price:* **free**; exact.

720. Scalar factor in the left matrix of a product. For every monoid of scalars S acting on the line as a distributive action (1·a = a, (st)·a = s·(t·a), s·(a + b) = s·a + s·b and s·0 = 0) with (s·a)b = s·(ab) for all a, b on the line (for example, multiplication by a number on the line), every s in S, every natural number m, any

index sets I and K, every I × m matrix M and every m × K matrix N with entries on the line: (s·M)N = s·(MN), where s·M multiplies every entry by s. *Used for:* Coupling constants and time steps factor out of products of operators, as in (τH)N = τ(HN) in a time-stepping scheme. *Price:* **free**; exact.

721. Scalar factor in the right matrix of a product. For every monoid of scalars S acting on the line as a distributive action (1·a = a, (st)·a = s·(t·a), s·(a + b) = s·a + s·b and s·0 = 0) with a(s·b) = s·(ab) for all a, b on the line (for example, multiplication by a number on the line), every s in S, every natural number m, any index sets I and K, every I × m matrix M and every m × K matrix N with entries on the line: M(s·N) = s·(MN), where s·N multiplies every entry by s. *Used for:* Moving numerical factors, such as normalisations, through a product of operators. *Price:* **free**; exact.

722. Transpose of a product reverses the order. For every natural number m, any index sets I and K, every I × m matrix M and every m × K matrix N with entries on the line: $(MN)^{T} = N^{T}M^{T}$, where ^{T} is the transpose. *Used for:* Undoing a sequence of rotations: for orthogonal matrices, $(R_1R_2)^{T} = R_2{}^{T}R_1{}^{T}$ applies the inverse steps in reverse order; adjoints of products of real operators. *Price:* **free**; exact.

723. Successive matrix-vector products. For all natural numbers n and o, any index set I, every I × n matrix M, every n × o matrix N and every vector v of length o with entries on the line: M(Nv) = (MN)v, where Xv is the matrix-vector product, $(Xv)(i) = \Sigma_j X(i, j)v(j)$. *Used for:* Applying two transformations to a state vector in turn equals applying their product once, as for successive evolution steps or rotations. *Price:* **free**; exact.

724. Matrix times a sum of vectors. For every natural number n, any index set I, every I × n matrix A and all vectors x and y of length n with entries on the line: A(x + y) = Ax + Ay, where $(Av)(i) = \Sigma_j A(i, j)v(j)$. *Used for:* Superposition: a linear evolution or a linear response acts on a sum of states or of inputs term by term. *Price:* **free**; exact.

725. Dot product is symmetric. For every length n and all vectors v and w of length n with entries on the line: v · w = w · v, where $v \cdot w = \Sigma_i v(i)w(i)$. *Used for:* Symmetry of the Euclidean inner product: the work F · d of a force along a displacement, or a projection, can be computed either way round. *Price:* **free**; exact.

726. Trace of three factors is cyclic, right-grouped. For all natural numbers m, n and p and matrices with entries on the line, A of shape m × n, B of shape n × p and C of shape p × m: tr(A(BC)) = tr(C(AB)), where tr is the sum of the diagonal entries. *Used for:* Rearranging traces of operator products in perturbation theory and linear response, such as tr(ρ(HA)) = tr(A(ρH)). *Price:* **free**; exact.

727. Trace of a product of transposes. For all natural numbers m and n, every m × n matrix A and every n × m matrix B with entries on the line: $\mathrm{tr}(A^{T}B^{T}) = \mathrm{tr}(AB)$, where ^{T} is the transpose and tr is the sum of the diagonal entries. *Used for:* Trace formulas for real operators do not depend on the row-vector or column-vector convention: transposing every factor keeps the trace. *Price:* **free**; exact.

728. Product with a zero matrix on the right. For every natural number n, any index sets I and K and every I × n matrix M with entries on the line: M0 = 0, where the first 0 is the zero n × K matrix and the second is the zero I × K matrix. *Used for:* Any operator applied after the zero operator still gives zero: a switched-off coupling contributes nothing to a product of operators. *Price:* **free**; exact.

729. Product with a zero matrix on the left. For every natural number m, any index sets I and K and every m × K matrix M with entries on the line: 0M = 0, where the first 0 is the zero I × m matrix and the second is the zero I × K matrix. *Used for:* An operator that sends every state to zero composes with any operator to the zero operator. *Price:* **free**; exact.

730. Matrix times the zero vector. For every natural number n, any index set I and every I × n matrix A with entries on the line: A0 = 0, that is, A sends the zero vector of length n to the zero vector indexed by I, where $(Av)(i) = \Sigma_j A(i, j)v(j)$. *Used for:* Linear response: no input (zero displacement, zero applied field) gives no output. *Price:* **free**; exact.

731. Sum of matrices times a vector. For every natural number n, any index set I, all I × n matrices A and B and every vector x of length n with entries on the line: (A + B)x = Ax + Bx, where $(Av)(i) = \Sigma_j A(i, j)v(j)$. *Used for:* Several couplings acting on one state add their effects: $(H_1 + H_2)\psi = H_1\psi + H_2\psi$. *Price:* **free**; exact.

732. Matrix times a scaled vector. For every set of scalars S acting on the line additively (s·(a + b) = s·a + s·b and s·0 = 0) with a(s·b) = s·(ab) for all a, b on the line (for example, multiplication by a number on the line), every s in S, every natural number n, any index set I, every I × n matrix M and every vector v of length n with entries on the line: M(sv) = s(Mv), where sv multiplies every entry by s and $(Mv)(i) = \Sigma_j M(i, j)v(j)$. *Used for:* Linear response: scaling the input, such as an applied field or a displacement, scales the output; the overall normalisation of a state passes through an operator. *Price:* **free**; exact.

733. Identity matrix times a vector. For every length m and every vector v of length m with entries on the line: 1v = v, where 1 is the m × m identity matrix and $(Av)(i) = \Sigma_j A(i, j)v(j)$. *Used for:* The

identity evolution leaves every state vector unchanged. *Price:* **free**; exact.

734. Dot product is additive in the first vector. For every length n and all vectors u, v and w of length n with entries on the line: $(u + v) \cdot w = u \cdot w + v \cdot w$, where $x \cdot y = \Sigma_i\, x(i)y(i)$. *Used for:* The work done by a sum of forces is the sum of their works, $(F_1 + F_2) \cdot d$. *Price:* **free**; exact.

735. Dot product is additive in the second vector. For every length n and all vectors u, v and w of length n with entries on the line: $u \cdot (v + w) = u \cdot v + u \cdot w$, where $x \cdot y = \Sigma_i\, x(i)y(i)$. *Used for:* The work done by a force along two successive displacements adds, $F \cdot (d_1 + d_2) = F \cdot d_1 + F \cdot d_2$. *Price:* **free**; exact.

736. Scalar factor in the first vector of a dot product. For every set of scalars S acting on the line additively ($s\cdot(a + b) = s\cdot a + s\cdot b$ and $s\cdot 0 = 0$) with $(s\cdot a)b = s\cdot(ab)$ for all a, b on the line (for example, multiplication by a number on the line), every s in S, every length n and all vectors v and w of length n with entries on the line: $(sv) \cdot w = s(v \cdot w)$, where sv multiplies every entry by s and $x \cdot y = \Sigma_i\, x(i)y(i)$. *Used for:* Scaling a force scales the work it does and the power it delivers. *Price:* **free**; exact.

737. Scalar factor in the second vector of a dot product. For every set of scalars S acting on the line additively ($s\cdot(a + b) = s\cdot a + s\cdot b$ and $s\cdot 0 = 0$) with $a(s\cdot b) = s\cdot(ab)$ for all a, b on the line (for example, multiplication by a number on the line), every s in S, every length n and all vectors v and w of length n with entries on the line: $v \cdot (sw) = s(v \cdot w)$, where sw multiplies every entry by s and $x \cdot y = \Sigma_i\, x(i)y(i)$. *Used for:* Scaling a displacement or a velocity scales the projection of a force onto it, as in the power $F \cdot v$. *Price:* **free**; exact.

738. Transpose of the identity matrix. For every size n, the transpose of the n × n identity matrix with entries on the line is the identity matrix: $1^{\mathrm{T}} = 1$. *Used for:* The identity operator is its own adjoint over the reals, so it is a valid real observable; the Euclidean metric, the identity matrix, is symmetric. *Price:* **free**; exact.

739. Trace of the negative of a matrix. For every size n and every n × n matrix A with entries on the line: $\mathrm{tr}(-A) = -\mathrm{tr}\, A$, where tr is the sum of the diagonal entries. *Used for:* Reversing the sign of an observable, such as the coupling to an applied field, reverses its expectation value. *Price:* **free**; exact.

740. Trace of an outer product is a dot product. For every length n and all vectors a and b of length n with entries on the line: the trace of the outer product ab^{T} (the n × n matrix with entry a(i)b(j)) equals $a \cdot b = \Sigma_i\, a(i)b(i)$. *Used for:* Pure-state normalisation: for a real state vector v, $\mathrm{tr}(vv^{\mathrm{T}}) = v \cdot v$, so a unit vector gives a density matrix of trace 1. *Price:* **free**; exact.

741. Trace is unchanged by a change of basis. For every size m, all m × m matrices M and W with entries on the line such that MW = 1 and WM = 1 (W is the inverse of M), and every m × m matrix N: $\mathrm{tr}((MN)W) = \mathrm{tr}\, N$, where tr is the sum of the diagonal entries. *Used for:* Basis independence: a change of basis $N \mapsto MNM^{-1}$ keeps traces, partition functions and expectation values. *Price:* **free**; exact.

742. Trace is unchanged by the inverse change of basis. For every size m, all m × m matrices M and W with entries on the line such that MW = 1 and WM = 1 (W is the inverse of M), and every m × m matrix N: $\mathrm{tr}((WN)M) = \mathrm{tr}\, N$, where tr is the sum of the diagonal entries. *Used for:* Traces agree whichever way a basis change is written, $N \mapsto M^{-1}NM$; diagonalising a matrix keeps its trace, so the trace is the sum of the eigenvalues on the diagonal. *Price:* **free**; exact.

743. Only the zero vector has zero squared length. For every length n and every vector v of length n with entries on the line: $v \cdot v = 0$ exactly when v = 0, where $v \cdot v = \Sigma_i\, v(i)^2$. *Used for:* Positive definiteness of the Euclidean inner product: a displacement or a field configuration with zero squared length is zero. *Price:* **free**; exact.

744. Trace of a commutator is zero. For every size n and all n × n matrices X and Y with entries on the line: $\mathrm{tr}(XY - YX) = 0$, where tr is the sum of the diagonal entries. *Used for:* No matrices of any finite size $n \geq 1$ satisfy a canonical commutation relation $XP - PX = c\cdot 1$ with $c \neq 0$ (the left side has trace 0, the right side $n\cdot c$), which is why position and momentum need an infinite-dimensional state space. *Price:* **free**; exact.

745. Moving a matrix across a dot product. For all natural numbers m and n, every vector v of length m, every m × n matrix A and every vector w of length n with entries on the line: $v \cdot (Aw) = (v\, A) \cdot w$, where $(Aw)(i) = \Sigma_j\, A(i, j)w(j)$, $(v\, A)(j) = \Sigma_i\, v(i)A(i, j)$ and $x \cdot y = \Sigma_k\, x(k)y(k)$. *Used for:* Matrix elements $v^{\mathrm{T}}Aw$ of an operator or of a bilinear form can be evaluated from either side, as for the energy $x^{\mathrm{T}}Ky$ of a network of springs. *Price:* **free**; exact.

746. Successive row-vector products. For all natural numbers m and n, any index set K, every vector v of length m, every m × n matrix M and every n × K matrix N with entries on the line: $(v\, M)\, N = v\, (M\, N)$, where the row-vector product is $(v\, X)(j) = \Sigma_i\, v(i)X(i, j)$. *Used for:* Probability row vectors of a Markov chain: two steps taken in turn equal one step with the product of the transition matrices, $(p\, P)\, Q = p\, (P\, Q)$. *Price:* **free**; exact.

747. Transposed matrix times a vector. For every natural number m, any index set K, every m × K matrix A and every vector x of length m with entries

on the line: $A^{T}x = x\,A$, where $(A^{T}x)(j) = \Sigma_i\, A(i, j)x(i)$ is the matrix-vector product with the transpose and $(x\,A)(j) = \Sigma_i\, x(i)A(i, j)$ is the row-vector product. *Used for:* Switching between row and column conventions: a probability distribution p evolved by a stochastic matrix P as the row product p P equals the column product $P^{T}p$. *Price:* **free**; exact.

748. Vector times a transposed matrix. For every natural number n, any index set I, every I × n matrix A and every vector x of length n with entries on the line: $xA^{T} = Ax$, where $(xA^{T})(i) = \Sigma_j\, x(j)A(i, j)$ is the row-vector product with the transpose and $(Ax)(i) = \Sigma_j\, A(i, j)x(j)$. *Used for:* Writing the action of a real linear map on row vectors (covectors such as gradients) through the transpose, and converting back to the column product. *Price:* **free**; exact.

749. Row vector times a sum of matrices. For every natural number m, any index set K, all m × K matrices A and B and every vector x of length m with entries on the line: $x(A + B) = x\,A + x\,B$, where $(x\,A)(j) = \Sigma_i\, x(i)A(i, j)$. *Used for:* A distribution driven by a generator that is a sum of processes changes term by term: the rate matrices of a master equation add. *Price:* **free**; exact.

750. Sum of row vectors times a matrix. For every natural number m, any index set K, every m × K matrix A and all vectors x and y of length m with entries on the line: $(x + y)A = x\,A + y\,A$, where $(x\,A)(j) = \Sigma_i\, x(i)A(i, j)$. *Used for:* Mixtures evolve term by term: a weighted combination of probability distributions under one Markov step. *Price:* **free**; exact.

751. Row vector times the identity matrix. For every length m and every vector v of length m with entries on the line: $v1 = v$, where 1 is the m × m identity matrix and $(v\,A)(j) = \Sigma_i\, v(i)A(i, j)$. *Used for:* A trivial Markov step (the identity transition matrix) leaves every distribution unchanged. *Price:* **free**; exact.

752. Row vector times the zero matrix. For every natural number m, any index set K and every vector v of length m with entries on the line: $v0 = 0$, where 0 is the zero m × K matrix, the result is the zero vector indexed by K, and $(v\,A)(j) = \Sigma_i\, v(i)A(i, j)$. *Used for:* A zero coupling or transfer matrix sends every row vector, such as a source distribution, to zero. *Price:* **free**; exact.

753. Row vector times an outer product. For every natural number m, any index set K, all vectors u and v of length m and every vector w indexed by K with entries on the line: $u(vw^{T}) = (u \cdot v)w$, where vw^{T} is the outer product with entry $v(i)w(j)$, $(u\,X)(j) = \Sigma_i\, u(i)X(i, j)$ and $u \cdot v = \Sigma_i\, u(i)v(i)$. *Used for:* A rank-one operator vw^{T} acting on a vector gives the overlap times the target vector, as for a real projector vv^{T} onto a unit vector v. *Price:* **free**; exact.

754. Outer product of a sum of vectors. For any index sets I and K, all vectors w_1 and w_2 indexed by I and every vector v indexed by K with entries on the line: $(w_1 + w_2)v^{T} = w_1v^{T} + w_2v^{T}$, where xv^{T} is the outer product with entry $x(i)v(j)$. *Used for:* Expanding dyadic products of sums, as for inertia and stress tensors or real density matrices built from superposed vectors. *Price:* **free**; exact.

755. Trace of a 1 × 1 matrix. For every 1 × 1 matrix A with its entry on the line, the trace of A is its single entry. *Used for:* A one-level system: an operator is a single number, such as one energy level, and its trace is that number. *Price:* **free**; exact.

756. Trace of a 2 × 2 matrix. For every 2 × 2 matrix A with entries on the line: $\operatorname{tr} A = A_{11} + A_{22}$, the sum of its two diagonal entries. *Used for:* Two-level systems (spin ½, qubits): the trace of a 2 × 2 operator, such as the normalisation $p_1 + p_2 = 1$ of the two diagonal populations of a qubit. *Price:* **free**; exact.

757. Trace of a 3 × 3 matrix. For every 3 × 3 matrix A with entries on the line: $\operatorname{tr} A = A_{11} + A_{22} + A_{33}$, the sum of its three diagonal entries. *Used for:* Three-dimensional space and three-level systems: the pressure is minus one third of the trace of the stress tensor, and a rotation by angle θ has trace $1 + 2\cos\theta$. *Price:* **free**; exact.

758. Conjugate transpose of a product reverses the order. For every natural number m, any index sets I and K, every I × m matrix A and every m × K matrix B with complex entries (on the complex numbers over the line): $(AB)\dagger = B\dagger A\dagger$, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* Undoing a sequence of quantum gates or evolutions: $(UV)\dagger = V\dagger U\dagger$ applies the inverses in reverse order. *Price:* **free**; exact.

759. Conjugate transpose taken twice. For any index sets I and K and every I × K matrix X with complex entries (on the complex numbers over the line): $(X\dagger)\dagger = X$, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* Taking the adjoint twice returns the operator; turning a column state into a row state and back returns the state. *Price:* **free**; exact.

760. Trace of the conjugate transpose. For every size n and every n × n matrix A with complex entries (on the complex numbers over the line): $\operatorname{tr}(A\dagger) = \overline{\operatorname{tr} A}$, where A† is the conjugate transpose (its entry at (i, j) is the complex conjugate of A(j, i)), conj is complex conjugation and tr is the sum of the diagonal entries. *Used for:* The trace of a Hermitian operator (A† = A) equals its own complex conjugate,

so it is real; complex conjugates of traces of operator products. *Price:* **free**; exact.

761. A matrix times its conjugate transpose is Hermitian. For every natural number m, any index set I and every I × m matrix A with complex entries (on the complex numbers over the line): (AA†)† = AA†, that is, AA† is Hermitian, where A† is the conjugate transpose (its entry at (i, j) is the complex conjugate of A(j, i)). *Used for:* The reduced density matrix ρ = AA† of a two-part pure state, with A the matrix of its amplitudes, is Hermitian. *Price:* **free**; exact.

762. Conjugate transpose times the matrix is Hermitian. For every natural number m, any index set K and every m × K matrix A with complex entries (on the complex numbers over the line): (A†A)† = A†A, that is, A†A is Hermitian, where A† is the conjugate transpose (its entry at (i, j) is the complex conjugate of A(j, i)). *Used for:* Operators of the form A†A are Hermitian: number operators a†a, measurement operators K†K built from Kraus operators, Gram matrices of state vectors. *Price:* **free**; exact.

763. Sum of Hermitian matrices is Hermitian. For any index set I and all I × I matrices A and B with complex entries (on the complex numbers over the line): if A† = A and B† = B, then (A + B)† = A + B, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* A Hamiltonian that is a sum of Hermitian terms (kinetic, potential and interaction energy) is Hermitian. *Price:* **free**; exact.

764. Identity matrix is Hermitian. For every size n, the n × n identity matrix with complex entries (on the complex numbers over the line) equals its own conjugate transpose: 1† = 1, where X† has entry at (i, j) the complex conjugate of X(j, i). *Used for:* The identity is an observable, reading 1 in every state; it is also the trivial unitary evolution. *Price:* **free**; exact.

765. Conjugate transpose of a sum. For any index sets I and K and all I × K matrices A and B with complex entries (on the complex numbers over the line): (A + B)† = A† + B†, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* Hermitian parts of operators: A + A† is Hermitian, which builds observables such as a + a† from non-Hermitian operators. *Price:* **free**; exact.

766. Conjugate transpose of the zero matrix. For any index sets I and K, the conjugate transpose of the zero I × K matrix with complex entries (on the complex numbers over the line) is the zero K × I matrix. *Used for:* The zero operator is Hermitian, the trivial observable; a switched-off coupling stays zero under adjoints. *Price:* **free**; exact.

767. Conjugate transpose of the negative of a matrix. For any index sets I and K and every I × K matrix A with complex entries (on the complex numbers over the line): (−A)† = −A†, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* Anti-Hermitian generators of unitary evolution (A† = −A): sign changes pass through the adjoint. *Price:* **free**; exact.

768. Conjugate transpose of a difference. For any index sets I and K and all I × K matrices A and B with complex entries (on the complex numbers over the line): (A − B)† = A† − B†, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* Commutators: the adjoint of AB − BA is B†A† − A†B†, so the commutator of two Hermitian observables is anti-Hermitian. *Price:* **free**; exact.

769. Conjugate transpose of a complex multiple. For every complex number c (on the complex numbers over the line), any index sets I and K and every I × K matrix A with complex entries: (c A)† = $\bar{c}$ A†, where c A multiplies every entry by c, $\bar{c}$ is the complex conjugate of c, and A† is the conjugate transpose (its entry at (i, j) is the complex conjugate of A(j, i)). *Used for:* The generator −i H of unitary time evolution is anti-Hermitian when H is Hermitian, since (−i H)† = i H. *Price:* **free**; exact.

770. Conjugating a Hermitian matrix as B†AB keeps it Hermitian. For every natural number m, any index set K, every m × m matrix A and every m × K matrix B with complex entries (on the complex numbers over the line): if A† = A, then (B†AB)† = B†AB, with the product grouped as (B†A)B, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* An observable stays Hermitian under a change of basis or a projection: U†HU in the Heisenberg picture, effective Hamiltonians P†HP on a subspace. *Price:* **free**; exact.

771. Conjugating a Hermitian matrix as BAB† keeps it Hermitian. For every natural number m, any index set I, every m × m matrix A and every I × m matrix B with complex entries (on the complex numbers over the line): if A† = A, then (BAB†)† = BAB†, with the product grouped as (BA)B†, where X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* A density matrix stays Hermitian under unitary evolution ρ ↦ UρU† and under a Kraus operation ρ ↦ KρK†. *Price:* **free**; exact.

772. Conjugate transpose of an outer product. For any index sets I and K, every vector w indexed by I and every vector v indexed by K with complex entries (on the complex numbers over the line): $(wv^{T})^{\dagger} = \bar{v}\bar{w}^{T}$, where xy^{T} is the outer product with entry x(i)y(j), the bar conjugates every entry, and X†

is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)). *Used for:* The adjoint of a transition operator from one state to another is the reverse transition (raising and lowering operators); a pure-state projector $\psi\psi\dagger$ is Hermitian. *Price:* **free**; exact.

773. A complex vector of zero norm is zero. For every length n and every vector v of length n with complex entries (on the complex numbers over the line): Σ_i conj(v(i))·v(i) = 0 exactly when v = 0, where conj is complex conjugation. *Used for:* Positive definiteness of the quantum inner product: the only state vector of zero norm is the zero vector. *Price:* **free**; exact.

774. Mixed product of Kronecker products. For all natural numbers k and k′, all index sets I, J, I′, J′ and all matrices with entries on the line, A of shape I × k, B of shape k × J, A′ of shape I′ × k′ and B′ of shape k′ × J′: (AB) ⊗ (A′B′) = (A ⊗ A′)(B ⊗ B′). Here X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′), and the product on the right sums over all k·k′ index pairs. *Used for:* Composite systems: independent operations on two subsystems compose part by part, $(U_1 \otimes V_1)(U_2 \otimes V_2) = U_1U_2 \otimes V_1V_2$, as in two-qubit gate circuits and in the transition matrices of two independent Markov chains. *Price:* **free**; exact.

775. Trace of a Kronecker product. For all sizes m and n, every m × m matrix A and every n × n matrix B with entries on the line: tr(A ⊗ B) = tr A · tr B. Here A ⊗ B is the Kronecker product, with entry A(i, j)·B(i′, j′) at row (i, i′) and column (j, j′), and each trace is the sum of the diagonal entries (m·n of them for A ⊗ B). *Used for:* Product observables in product states: with the mixed-product rule, tr((ρ ⊗ σ)(A ⊗ B)) = tr(ρA)·tr(σB); the dimension of a composite system is the product of the dimensions of its parts. *Price:* **free**; exact.

776. Kronecker product of two identity matrices. For any two index sets I and J (finite or not) on which equality of indices is decidable: the Kronecker product of the identity matrix on I with the identity matrix on J, entries on the line, is the identity matrix on the pairs (i, j), that is 1 ⊗ 1 = 1. The Kronecker product X ⊗ Y has entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Doing nothing to each part does nothing to the whole: the identity operator of a composite quantum system is the product of the identities of its parts. *Price:* **free**; exact.

777. Kronecker product of diagonal matrices. For any index sets I and J on which equality of indices is decidable, every family a of numbers on the line indexed by I and every family b indexed by J: diag(a) ⊗ diag(b) = diag(c), where c(i, j) = a(i)·b(j). Here diag(a) is the diagonal matrix with a(i) at position (i, i) and zeros elsewhere, and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Independent subsystems: diagonal density matrices with probabilities p(i) and q(j) combine to the diagonal matrix of joint probabilities p(i)q(j); the Boltzmann weights of non-interacting parts multiply. *Price:* **free**; exact.

778. Kronecker product with the identity on the right. For any index sets I and J, any index set O on which equality of indices is decidable, and every I × J matrix A with entries on the line: A ⊗ 1, with 1 the identity matrix on O, is the block-diagonal matrix with one copy of A in each diagonal block. Entry by entry: A ⊗ 1 has entry A(i, j) at row (i, o) and column (j, o′) when o = o′, and 0 when o ≠ o′. The Kronecker product X ⊗ Y has entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Local operators: an observable or gate acting on the first subsystem alone, A ⊗ 1, written as a block-diagonal matrix with one block per state of the second subsystem. *Price:* **free**; exact.

779. Kronecker product with the identity on the left. For any index sets I and J, any index set O on which equality of indices is decidable, and every I × J matrix B with entries on the line: 1 ⊗ B, with 1 the identity matrix on O, is the block-diagonal matrix with one copy of B in each diagonal block after the two parts of every row pair and every column pair are swapped. Entry by entry: 1 ⊗ B has at row (o, i) and column (o′, j) the entry of that block-diagonal matrix at row (i, o) and column (j, o′), which is B(i, j) when o = o′ and 0 when o ≠ o′. The Kronecker product X ⊗ Y has entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Local operators on the second subsystem, 1 ⊗ B, such as a single-qubit gate applied to the second qubit of a two-qubit register. *Price:* **free**; exact.

780. Transpose of a Kronecker product. For any index sets I, J, I′, J′, every I × J matrix A and every I′ × J′ matrix B with entries on the line: $A^T \otimes B^T = (A \otimes B)^T$, where ^{T} is the transpose and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Adjoints of real operators on composite systems (over the reals the adjoint is the transpose), for example undoing real two-qubit gates or local rotations factor by factor. *Price:* **free**; exact.

781. Kronecker product distributes over a sum on the left. For any index sets I, J, I′, J′, all I × J matrices A_1 and A_2 and every I′ × J′ matrix B with entries on the line: $(A_1 + A_2) \otimes B = A_1 \otimes B + A_2 \otimes B$. Here X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Linearity in the first factor: an operator on one subsystem that is a sum of terms gives a composite operator that splits term by term, $(H_1 + H_2) \otimes 1 = H_1 \otimes 1 + H_2 \otimes 1$. *Price:* **free**; exact.

782. Kronecker product distributes over a sum on the right. For any index sets I, J, I′, J′, every I × J matrix A and all I′ × J′ matrices B_1 and B_2 with entries on the line: $A \otimes (B_1 + B_2) = A \otimes B_1 + A \otimes B_2$. Here X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Linearity in the second factor: expanding an operator on a composite system into a sum of product terms, as in decompositions of two-qubit operators into Pauli products. *Price:* **free**; exact.

783. Kronecker product is associative. For any index sets I, J, I′, J′, I″, J″ and matrices with entries on the line, A of shape I × J, B of shape I′ × J′ and C of shape I″ × J″: (A ⊗ B) ⊗ C and A ⊗ (B ⊗ C) agree once every index triple is regrouped, that is, for all indices the entry of (A ⊗ B) ⊗ C at row ((i, i′), i″) and column ((j, j′), j″) equals the entry of A ⊗ (B ⊗ C) at row (i, (i′, i″)) and column (j, (j′, j″)). Here X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Systems of three or more parts: the operator on a multi-part system does not depend on how the parts are grouped, as for qubit registers and spin chains. *Price:* **free**; exact.

784. Kronecker product with a zero matrix on the left. For any index sets I, J, I′, J′ and every I′ × J′ matrix B with entries on the line: 0 ⊗ B = 0, where the first 0 is the zero I × J matrix, the result is the zero matrix on the index pairs, and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* A vanishing operator on the first subsystem makes every product term containing it vanish: zero coupling terms drop out of a composite Hamiltonian. *Price:* **free**; exact.

785. Kronecker product with a zero matrix on the right. For any index sets I, J, I′, J′ and every I × J matrix A with entries on the line: A ⊗ 0 = 0, where the first 0 is the zero I′ × J′ matrix, the result is the zero matrix on the index pairs, and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Switching off one side of a coupling A ⊗ B removes the whole product term from a composite operator. *Price:* **free**; exact.

786. Scalar factor in the first Kronecker factor. For every set of scalars S acting on the line with (r·a)·b = r·(a·b) for all r in S and all a, b on the line (for example, multiplication by a number on the line), every r in S, any index sets I, J, I′, J′, every I × J matrix A and every I′ × J′ matrix B with entries on the line: (r A) ⊗ B = r(A ⊗ B), where r A multiplies every entry by r and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Coupling constants in front of product operators: (J A) ⊗ B = J (A ⊗ B) for an exchange coupling of strength J between two spins. *Price:* **free**; exact.

787. Scalar factor in the second Kronecker factor. For every set of scalars S acting on the line with a·(r·b) = r·(a·b) for all r in S and all a, b on the line (for example, multiplication by a number on the line), every r in S, any index sets I, J, I′, J′, every I × J matrix A and every I′ × J′ matrix B with entries on the line: A ⊗ (r B) = r(A ⊗ B), where r B multiplies every entry by r and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Moving a coupling strength or a normalisation factor out of the second factor of a product operator on a composite system. *Price:* **free**; exact.

788. Conjugate transpose of a Kronecker product. For any index sets I, J, I′, J′, every I × J matrix A and every I′ × J′ matrix B with complex entries (on the complex numbers over the line): (A ⊗ B)† = A† ⊗ B†. Here X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)) and X ⊗ Y is the Kronecker product, with entry X(i, j)·Y(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Adjoints of operators on composite quantum systems; a product A ⊗ B of Hermitian observables on two subsystems is Hermitian. *Price:* **free**; exact.

789. Kronecker product of unitary matrices is unitary. For all sizes n and m, every n × n matrix U and every m × m matrix V with complex entries (on the complex numbers over the line): if U†U = 1 and UU† = 1, and V†V = 1 and VV† = 1, then (U ⊗ V)†(U ⊗ V) = 1 and (U ⊗ V)(U ⊗ V)† = 1, where 1 is the identity matrix on the n·m index pairs. Here X† is the conjugate transpose (its entry at (i, j) is the complex conjugate of X(j, i)) and U ⊗ V is the Kronecker product, with entry U(i, j)·V(i′, j′) at row (i, i′) and column (j, j′). *Used for:* Independent closed evolutions of two quantum systems form a closed evolution of the pair; gates applied in parallel to a quantum register are unitary. *Price:* **free**; exact.

790. Exponential series of a matrix converges, with a rate. For every size n and every complex n × n matrix X (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), the exponential series $\Sigma_m X^m/m!$ converges entrywise to a matrix E, with an explicit rate: there is a function M on the natural numbers such that for every j and every N ≥ M(j), each entry of the partial sum $X^0/0! + X^1/1! + \ldots + X^{N-1}/(N-1)!$ is within 1/(j+1) of the corresponding entry of E, in its real part and in its imaginary part. One rate M serves every entry. Convergence is read as the limit of the partial sums taken in order. *Used for:* Computing the propagator $e^{-i\,t\,H}$ of a finite quantum system, or the solution matrix $e^{t\,A}$ of linear equations dx/dt = Ax, by truncating the series with a guaranteed error at each stage. *Price:* **free**; exact.

791. Matrix exponential is well defined. For

every size n and every complex n × n matrix X (entries in the complex numbers over the line), there is exactly one matrix E such that the exponential series Σ_m $X^m/m!$ converges entrywise to E. So exp X is a single, definite matrix. *Used for:* Gives the propagator $e^{-i\,t\,H}$ and the Gibbs factor $e^{-\beta\,H}$ one definite value, so every identity about them refers to a single matrix. *Price:* **free**; exact.

792. Exponential of the zero matrix is the identity. For every size n and every complex n × n matrix E (entries in the complex numbers over the line): if the exponential series Σ_m $0^m/m!$ of the zero matrix converges entrywise to E, then E is the identity matrix. That is, exp 0 = 1. *Used for:* The initial condition of quantum time evolution: at time zero the propagator is the identity, $U(0) = e^0 = 1$. *Price:* **free**; exact.

793. Exponential of the conjugate transpose. For every size n and all complex n × n matrices X and E (entries in the complex numbers over the line): if the exponential series Σ_m $X^m/m!$ converges entrywise to E, then the exponential series of the conjugate transpose X† converges entrywise to E†. That is, exp(X†) = (exp X)†. *Used for:* Taking the adjoint of a propagator, $(e^{-i\,t\,H})^\dagger = e^{i\,t\,H}$ for Hermitian H, used to evolve bras and to write observables in the Heisenberg picture, A(t) = U† A U. *Price:* **free**; exact.

794. Exponential of a Hermitian matrix is Hermitian. For every size n and all complex n × n matrices H and E (entries in the complex numbers over the line): if H is Hermitian (H† = H) and the exponential series Σ_m $H^m/m!$ converges entrywise to E, then E is Hermitian (E† = E). *Used for:* Thermal states: for a Hamiltonian H and real β the Gibbs factor $e^{-\beta H}$ is Hermitian, so the density matrix $e^{-\beta H}/Z$ of a system in equilibrium is Hermitian. *Price:* **free**; exact.

795. Exponential of minus a matrix is its inverse. For every size n and all complex n × n matrices X, E and F (entries in the complex numbers over the line): if the exponential series of X converges entrywise to E and the exponential series of –X converges entrywise to F, then EF = 1 and FE = 1. So exp(–X) is the two-sided inverse of exp X. *Used for:* Running quantum evolution backward: $e^{i\,t\,H}$ undoes $e^{-i\,t\,H}$, so the state at time t determines the state at time zero. *Price:* **free**; exact.

796. Matrix exponential is invertible. For every size n and all complex n × n matrices X and E (entries in the complex numbers over the line): if the exponential series Σ_m $X^m/m!$ converges entrywise to E, then E has a two-sided inverse: there is a matrix F with EF = 1 and FE = 1. *Used for:* Every propagator $e^{-i\,t\,H}$ and every fundamental matrix $e^{t\,A}$ of a linear system dx/dt = Ax is invertible, so solutions can be run forward and backward in time. *Price:* **free**; exact.

797. Exponential commutes with what commutes with its argument. For every size n and all complex n × n matrices X, Q and E (entries in the complex numbers over the line): if XQ = QX and the exponential series Σ_m $X^m/m!$ converges entrywise to E, then EQ = QE. So exp X commutes with every matrix that commutes with X. *Used for:* Conservation laws in quantum mechanics: an observable Q that commutes with the Hamiltonian H commutes with the evolution $e^{-i\,t\,H}$, so its expectation value stays constant in time. *Price:* **free**; exact.

798. Exponentials of commuting matrices commute. For every size n and all complex n × n matrices X, Y, E and F (entries in the complex numbers over the line): if XY = YX, the exponential series of X converges entrywise to E and the exponential series of Y converges entrywise to F, then EF = FE. *Used for:* Commuting symmetry operations: a rotation $e^{-i\,\theta\,Jz}$ about the z axis commutes with the time evolution $e^{-i\,t\,H}$ when H commutes with the angular momentum component Jz, and commuting gauge transformations can be applied in either order. *Price:* **free**; exact.

799. Exponential of –i t H is unitary for Hermitian H. For every size n, every Hermitian complex n × n matrix H (H† = H, entries in the complex numbers over the line) and every real number t on the line (the real numbers constructed from distinctions): if the exponential series of –i t H converges entrywise to U, then U†U = 1 and UU† = 1. That is, $e^{-i\,t\,H}$ is unitary. *Used for:* Conservation of probability: the time evolution $e^{-i\,t\,H}$ of a finite quantum system (qubits, spins, few-level atoms) preserves the norm of every state vector. *Price:* **free**; exact.

800. Unitary time evolution of a finite quantum system. For every size n and every Hermitian complex n × n matrix H (H† = H, entries in the complex numbers over the line) there is a function U from the real numbers on the line to complex n × n matrices such that: for every real t the exponential series of –i t H converges entrywise to U(t); U(0) = 1; U(t) U(u) = U(t + u) for all real t and u; and every U(t) is unitary, U(t)† U(t) = 1 and U(t) U(t)† = 1. *Used for:* The Schrödinger evolution of a finite quantum system as a one-parameter group of unitary operators U(t) = $e^{-i\,t\,H}$ in time. *Price:* **free**; exact.

801. Exponential of a sum of commuting matrices. For every size n and all complex n × n matrices A and B (entries in the complex numbers over the line) with AB = BA: if the exponential series of A, of B and of A + B converge entrywise to E, F and G respectively, then G = EF. That is, $e^{A+B} = e^A\,e^B$ for commuting matrices. *Used for:* Splitting a Hamiltonian into commuting parts, $e^{-i\,t\,(H_0 + V)}$ =

$e^{-i\,t\,H_0}\,e^{-i\,t\,V}$ when $H_0\,V = V\,H_0$, and factoring the Gibbs state of non-interacting subsystems into a product. *Price:* **free**; exact.

802. Orthogonal matrix: one product test, $A\,A^T = 1$. For every size n and every real n × n matrix A (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: A is orthogonal if and only if $AA^T = 1$. So orthonormal rows already give orthonormal columns. *Used for:* Building a rotation from an orthonormal set of row vectors, such as a rigid body's frame or the principal axes of an inertia tensor: one product check suffices and the columns are then orthonormal too. *Price:* **free**; exact.

803. Orthogonal matrix: one product test, $A^T\,A = 1$. For every size n and every real n × n matrix A (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: A is orthogonal if and only if $A^TA = 1$. So orthonormal columns already give orthonormal rows. *Used for:* Changing between orthonormal bases: a matrix whose columns are an orthonormal basis (normal modes, principal axes) is a rotation or reflection, and its rows are orthonormal as well. *Price:* **free**; exact.

804. Product of orthogonal matrices is orthogonal. For every size n and all real n × n matrices A and B (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: if A and B are orthogonal, then AB is orthogonal. *Used for:* Composing rotations and reflections of space, for example successive Euler-angle rotations of a rigid body or two symmetry operations of a crystal. *Price:* **free**; exact.

805. Identity matrix is orthogonal. For every size n, the n × n identity matrix 1 (entries on the line) is orthogonal: $1^T1 = 1$ and $11^T = 1$. *Used for:* The trivial symmetry: the identity is the neutral element of every rotation group and crystallographic point group. *Price:* **free**; exact.

806. Transpose of an orthogonal matrix is orthogonal. For every size n and every real n × n matrix A (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: if A is orthogonal, then its transpose A^T is orthogonal. *Used for:* Undoing a rotation: the inverse rotation A^T is again a rotation or reflection, used to switch between the body frame and the space frame of a rigid body. *Price:* **free**; exact.

807. Inverse of an orthogonal matrix is its transpose. For every size n and all real n × n matrices A and B (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: if A is orthogonal and AB = 1, then $B = A^T$. Every right inverse of an orthogonal matrix is its transpose. *Used for:* Inverting a rotation by transposing it, with no matrix inversion, when converting vectors and tensors between rotated frames. *Price:* **free**; exact.

808. Orthogonal matrix satisfies $A^T\,A = 1$. For every size n and every real n × n matrix A (entries on the line), where a square matrix A is orthogonal when $A^TA = 1$ and $AA^T = 1$: if A is orthogonal, then $A^TA = 1$. *Used for:* Orthonormal columns of a rotation matrix, used when expanding vectors in a rotated orthonormal basis. *Price:* **free**; exact.

809. Orthogonal matrices preserve the dot product. For every size n, every real n × n matrix A (entries on the line) that is orthogonal ($A^TA = 1$ and $AA^T = 1$), and all vectors x and y with n real entries: $(Ax) \cdot (Ay) = x \cdot y$, where $u \cdot v = u_1v_1 + \ldots + u_nv_n$. *Used for:* Rotations and reflections preserve angles and lengths: scalar products of positions, velocities and forces, and hence work and energy, are unchanged in every rotated frame. *Price:* **free**; exact.

810. Orthogonal matrices preserve length. For every size n, every real n × n matrix A (entries on the line) that is orthogonal ($A^TA = 1$ and $AA^T = 1$), and every vector x with n real entries: $(Ax) \cdot (Ax) = x \cdot x$, where $u \cdot v = u_1v_1 + \ldots + u_nv_n$. That is, $\|Ax\|^2 = \|x\|^2$. *Used for:* Rotations preserve lengths and distances: the kinetic energy $\tfrac{1}{2}m\|v\|^2$ and the distance between two points are unchanged in every rotated frame. *Price:* **free**; exact.

811. Product of determinant-one matrices has determinant one. For every size n and all real n × n matrices A and B (entries on the line): if $\det A = 1$ and $\det B = 1$, then $\det(AB) = 1$. So the special linear group SL(n), the matrices of determinant 1, is closed under products. *Used for:* Composing volume-preserving linear maps: phase-space maps of a Hamiltonian system with one degree of freedom (Liouville's theorem), ray-transfer (ABCD) matrices of optical systems between media of equal refractive index, deformations of an incompressible material. *Price:* **free**; exact.

812. Inverse in SL(n) is the adjugate. For every size n and every real n × n matrix A (entries on the line) with $\det A = 1$, the adjugate adj A (the transposed matrix of cofactors) satisfies $A\,\mathrm{adj}\,A = 1$ and $\mathrm{adj}\,A \cdot A = 1$, and $\det(\mathrm{adj}\,A) = 1$. So the inverse of a determinant-one matrix is its adjugate, again of determinant 1. *Used for:* Inverting a volume-preserving map exactly, with no division: for a 2 × 2 ray-transfer or phase-space matrix (a b; c d) of determinant 1 the inverse is (d −b; −c a). *Price:* **free**; exact.

813. Transpose of a determinant-one matrix has determinant one. For every size n and every real n × n matrix A (entries on the line): if $\det A = 1$, then

$\det A^T = 1$. So SL(n) is closed under transposition. *Used for:* Covectors such as momenta and gradients transform with the inverse transpose of a linear change of coordinates; for a volume-preserving change the transpose again has determinant one. *Price:* **free**; exact.

814. Product of rotations is a rotation (SO(n)). For every size n and all real n × n matrices A and B (entries on the line), where A is in SO(n) when it is orthogonal ($A^TA = 1$ and $AA^T = 1$) and $\det A = 1$: if A and B are in SO(n), then AB is in SO(n). *Used for:* Composing proper rotations of rigid bodies and molecules: two rotations give a rotation, never a reflection. *Price:* **free**; exact.

815. Inverse of a rotation is a rotation (SO(n)). For every size n and every real n × n matrix A (entries on the line), where A is in SO(n) when it is orthogonal ($A^TA = 1$ and $AA^T = 1$) and $\det A = 1$: if A is in SO(n), then A^T is in SO(n). Since A^T is the inverse of A, SO(n) is closed under inverses. *Used for:* Rotating a rigid body or a reference frame back: the reverse of a proper rotation is a proper rotation. *Price:* **free**; exact.

816. Product of invertible matrices is invertible. For every size n and all real n × n matrices A and B (entries on the line): if A has a two-sided inverse (some A' with $AA' = 1$ and $A'A = 1$) and B has a two-sided inverse, then AB has a two-sided inverse. *Used for:* Composing invertible changes of coordinates or of basis, such as transfer matrices of layered optical or acoustic media and conversions between crystal lattice bases. *Price:* **free**; exact.

817. Reflection of one axis is orthogonal with determinant −1. For every n, the real (n+1) × (n+1) diagonal matrix R = diag(−1, 1, ..., 1) (entries on the line), which reverses the first coordinate, is orthogonal ($R^TR = 1$ and $RR^T = 1$) and has determinant −1. *Used for:* Mirror reflections and the parity operation on one axis: an orthogonal map that reverses orientation, used to separate proper from improper symmetry operations of crystals and molecules. *Price:* **free**; exact.

818. Every orthogonal matrix is a rotation or a reflected rotation. For every n and every real (n+1) × (n+1) matrix A (entries on the line) with $A^TA = 1$ and $AA^T = 1$: either A is in SO(n+1) (orthogonal with $\det A = 1$), or RA is in SO(n+1) and A = R(RA), where R = diag(−1, 1, ..., 1) reflects the first axis. Which case holds is decided without any omniscience principle. *Used for:* Every rigid symmetry of a crystal or molecule is a proper rotation or a mirror reflection followed by a proper rotation, which sorts point-group operations into proper and improper. *Price:* **free**; exact.

819. Entries of a 2 × 2 rotation matrix. For every real 2 × 2 matrix M = (a b; c d) (entries on the line): M is in SO(2) ($M^TM = 1$, $MM^T = 1$ and $\det M = 1$) if and only if $a = d$, $b = -c$ and $a^2 + b^2 = 1$. *Used for:* Recognizing a plane rotation from its entries, in planar rigid-body motion and in the rotation of linear polarization by optical elements. *Price:* **free**; exact.

820. Rotation matrix (c −s; s c) and the unit circle. For all real numbers c and s on the line: the matrix R = (c −s; s c) is in SO(2) ($R^TR = 1$, $RR^T = 1$ and $\det R = 1$) if and only if $c^2 + s^2 = 1$. *Used for:* Describing a plane rotation by a cosine and sine pair (c, s) on the unit circle, without choosing an angle, as in planar mechanics and polarization optics. *Price:* **free**; exact.

821. Plane rotations compose by adding angles. For all real numbers c_1, s_1, c_2, s_2 on the line with ${c_1}^2 + {s_1}^2 = 1$ and ${c_2}^2 + {s_2}^2 = 1$, writing R(c, s) for the matrix (c −s; s c): $R(c_1, s_1)\,R(c_2, s_2) = R(c_1c_2 - s_1s_2, s_1c_2 + c_1s_2)$, and $(c_1c_2 - s_1s_2)^2 + (s_1c_2 + c_1s_2)^2 = 1$. *Used for:* Composing planar rotations by adding angles (the cosine and sine addition formulas), as in planar rigid-body kinematics and rotations of the polarization plane. *Price:* **free**; exact.

822. Lorentz condition is two-sided. For every n and every real (n+1) × (n+1) matrix Λ (entries on the line), where η = diag(−1, 1, ..., 1) is the Minkowski metric in 1 + n dimensions and a matrix L is a Lorentz transformation when $L^T\eta L = \eta$: $\Lambda^T\eta\Lambda = \eta$ if and only if $\Lambda\eta\Lambda^T = \eta$. (n = 3 is spacetime.). *Used for:* Special relativity: a Lorentz transformation can be recognized from either form of the defining condition, and its transpose is again one. *Price:* **free**; exact.

823. Product of Lorentz transformations is a Lorentz transformation. For every n and all real (n+1) × (n+1) matrices Λ and M (entries on the line), where η = diag(−1, 1, ..., 1) is the Minkowski metric in 1 + n dimensions and a matrix L is a Lorentz transformation when $L^T\eta L = \eta$: if Λ and M are Lorentz transformations, then ΛM is a Lorentz transformation. *Used for:* Composing changes of inertial frame in special relativity: successive boosts and rotations give a Lorentz transformation. *Price:* **free**; exact.

824. Identity is a Lorentz transformation. For every n, the (n+1) × (n+1) identity matrix 1 (entries on the line) satisfies $1^T\eta 1 = \eta$, where η = diag(−1, 1, ..., 1) is the Minkowski metric in 1 + n dimensions. So the identity is a Lorentz transformation. *Used for:* Staying in the original inertial frame: the identity is the neutral element of the Lorentz group of special relativity. *Price:* **free**; exact.

825. Inverse of a Lorentz transformation is $\eta\,\Lambda^T\,\eta$. For every n and every real (n+1) × (n+1) matrix Λ (entries on the line), where η = diag(−1, 1, ..., 1) is the

Minkowski metric in 1 + n dimensions and a matrix L is a Lorentz transformation when $L^T\eta L = \eta$: if Λ is a Lorentz transformation, then the matrix $\eta\Lambda^T\eta$ satisfies $\Lambda(\eta\Lambda^T\eta) = 1$ and $(\eta\Lambda^T\eta)\Lambda = 1$, and $\eta\Lambda^T\eta$ is again a Lorentz transformation. *Used for:* Changing back between inertial frames in special relativity: the inverse transformation is $\eta\Lambda^T\eta$, obtained with no matrix inversion (for a boost it reverses the velocity). *Price:* **free**; exact.

826. Transpose of a Lorentz transformation is a Lorentz transformation. For every n and every real (n+1) × (n+1) matrix Λ (entries on the line), where η = diag(−1, 1, ..., 1) is the Minkowski metric in 1 + n dimensions and a matrix L is a Lorentz transformation when $L^T\eta L = \eta$: if Λ is a Lorentz transformation, then Λ^T is a Lorentz transformation. *Used for:* Covectors such as gradients of fields and four-momenta with a lowered index transform with the inverse transpose of a Lorentz transformation; the transpose itself stays in the Lorentz group. *Price:* **free**; exact.

827. Lorentz transformations have determinant 1 or −1. For every n and every real (n+1) × (n+1) matrix Λ (entries on the line), where η = diag(−1, 1, ..., 1) is the Minkowski metric in 1 + n dimensions and a matrix L is a Lorentz transformation when $L^T\eta L = \eta$: if Λ is a Lorentz transformation, then $\det \Lambda = 1$ or $\det \Lambda = -1$. Which of the two holds is decided without any omniscience principle. *Used for:* Separating proper Lorentz transformations (determinant 1: boosts and rotations) from improper ones (determinant −1: those including a parity or time reversal). *Price:* **free**; exact.

828. Boost matrix in 1 + 1 dimensions. For all real numbers c and s on the line: the matrix B = (c s; s c) satisfies $B^T\eta B = \eta$, with η = diag(−1, 1) the Minkowski metric in 1 + 1 dimensions, if and only if $c^2 - s^2 = 1$. *Used for:* Boosts along one axis in special relativity: with $c = \gamma$ and $s = \gamma v$ (units with the speed of light 1) the matrix is a Lorentz transformation exactly when $\gamma^2(1 - v^2) = 1$. *Price:* **free**; exact.

829. Collinear boosts compose by adding rapidities. For all real numbers c_1, s_1, c_2, s_2 on the line with ${c_1}^2 - {s_1}^2 = 1$ and ${c_2}^2 - {s_2}^2 = 1$, writing B(c, s) for the matrix (c s; s c): $B(c_1, s_1)\,B(c_2, s_2) = B(c_1c_2 + s_1s_2, s_1c_2 + c_1s_2)$, and $(c_1c_2 + s_1s_2)^2 - (s_1c_2 + c_1s_2)^2 = 1$. *Used for:* Relativistic velocity addition: two boosts along one axis make one boost, with rapidities adding (the cosh and sinh addition formulas), which gives $w = (u + v)/(1 + uv)$. *Price:* **free**; exact.

830. Unitary matrix: one product test, U U† = 1. For every size n and every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): U is unitary if and only if UU† = 1. *Used for:* Checking that a quantum gate or a scattering matrix is unitary with a single product: orthonormal rows already give orthonormal columns. *Price:* **free**; exact.

831. Unitary matrix: one product test, U† U = 1. For every size n and every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): U is unitary if and only if U†U = 1. *Used for:* A matrix whose columns are orthonormal quantum states (the images of a basis under an evolution or a beam splitter) is unitary, so its rows are orthonormal too. *Price:* **free**; exact.

832. Product of unitary matrices is unitary. For every size n and all complex n × n matrices U and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): if U and V are unitary, then UV is unitary. *Used for:* Quantum circuits and time steps: a sequence of unitary gates or of short evolutions is again a unitary evolution. *Price:* **free**; exact.

833. Identity matrix is unitary. For every size n, the complex n × n identity matrix 1 (entries in the complex numbers over the line) is unitary: 1†1 = 1 and 11† = 1. *Used for:* The identity gate, doing nothing to a quantum state, is a unitary evolution: the neutral element of quantum gate sets and gauge groups. *Price:* **free**; exact.

834. Conjugate transpose of a unitary matrix is unitary. For every size n and every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): if U is unitary, then U† is unitary. *Used for:* Reversing a quantum evolution: the adjoint U† of a unitary gate is the inverse gate, used to uncompute in quantum algorithms and to move observables to the Heisenberg picture. *Price:* **free**; exact.

835. Inverse of a unitary matrix is its conjugate transpose. For every size n and all complex n × n matrices U and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): if U is unitary and UV = 1, then V = U†. Every right inverse of a unitary matrix is its conjugate transpose. *Used for:* Inverting a quantum gate or a scattering matrix by taking its conjugate transpose, with no matrix inversion. *Price:* **free**; exact.

836. Unitary matrix satisfies U† U = 1. For every size n and every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where a square complex matrix U is unitary when U†U = 1 and UU† = 1 (U† is the conjugate transpose): if U is unitary, then U†U = 1. *Used for:* Conservation of total probability: for a unitary evolution or S-matrix the outcome probabilities from any normalized input state sum to one. *Price:* **free**; exact.

837. Unitary matrices preserve the inner product. For every size n, every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is unitary (U†U = 1 and UU† = 1), and all vectors u and v with n complex entries: $\langle Uu, Uv\rangle = \langle u, v\rangle$, where $\langle u, v\rangle = \bar{u}_1 v_1 + \ldots + \bar{u}_n v_n$ (conjugate-linear in the first vector). *Used for:* Transition amplitudes $\langle \varphi, \psi\rangle$ and the probabilities $\|\langle \varphi, \psi\rangle\|^2$ are unchanged when both states undergo one common time evolution or one common change of basis. *Price:* **free**; exact.

838. Product of special unitary matrices is special unitary. For every size n and all complex n × n matrices U and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where U is in SU(n) when it is unitary (U†U = 1 and UU† = 1) and det U = 1: if U and V are in SU(n), then UV is in SU(n). *Used for:* Composing gauge transformations of the weak interaction (SU(2)) and the strong interaction (SU(3), color), and composing spin rotations. *Price:* **free**; exact.

839. Conjugate transpose of a special unitary matrix is special unitary. For every size n and every complex n × n matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), where U is in SU(n) when it is unitary (U†U = 1 and UU† = 1) and det U = 1: if U is in SU(n), then U† is in SU(n). Since U† is the inverse of U, SU(n) is closed under inverses. *Used for:* The inverse of an SU(2) or SU(3) gauge transformation, or of a spin rotation, is its adjoint and lies in that group too. *Price:* **free**; exact.

840. Special unitary 2 × 2 matrices as unit quaternions. For every complex 2 × 2 matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): U is in SU(2) (U†U = 1, UU† = 1 and det U = 1) if and only if there are complex numbers a and b with U = (a −b̄; b ā) and āa + b̄b = 1, that is $\|a\|^2 + \|b\|^2 = 1$. *Used for:* Spin-½ rotations and single-qubit gates of determinant 1: each is described by two Cayley–Klein parameters (a, b) with $\|a\|^2 + \|b\|^2 = 1$, a unit quaternion. *Price:* **free**; exact.

841. Product law of 2 × 2 special unitary matrices. For all complex numbers a, b, c, d (in the complex numbers over the line) with āa + b̄b = 1 and c̄c + đd = 1, writing S(a, b) for the matrix (a −b̄; b ā): S(a, b) S(c, d) = S(ac − b̄d, bc + ād), and $\|ac - \bar{b}d\|^2 + \|bc + \bar{a}d\|^2 = 1$. *Used for:* Composing spin-½ rotations and single-qubit gates through their Cayley–Klein parameters, the matrix form of quaternion multiplication. *Price:* **free**; exact.

842. Commuting square root of a positive semidefinite matrix. For every size n and every n × n matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line) with $A \succeq 0$, there is an n × n complex matrix B with B† = B, $B \succeq 0$ and BB = A such that every n × n complex matrix Q that commutes with A (QA = AQ) also commutes with B (QB = BQ). Here a square complex matrix G is positive semidefinite, $G \succeq 0$, when G† = G and the real part of $\langle x, Gx\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Square roots of density matrices in the fidelity $F(\rho, \sigma) = (\mathrm{tr}\,\sqrt{(\sqrt{\rho}\,\sigma\,\sqrt{\rho})})^2$ and in the Petz recovery map; the root $\sqrt{\rho}$ commutes with every conserved charge that commutes with ρ, so it keeps the state's symmetries. *Price:* **free**; exact.

843. Polar decomposition of a square complex matrix. For every size n and every n × n matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line), there are n × n complex matrices W and P with W†W = 1 (W unitary), $P \succeq 0$ and A = WP. A is not assumed to be invertible. Here a square complex matrix P is positive semidefinite, $P \succeq 0$, when P† = P and the real part of $\langle x, Px\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Splitting a quantum measurement operator into a unitary and a positive part, $M = W\cdot\sqrt{(M^\dagger M)}$, including rank-deficient measurement operators such as projectors, to describe the back-action of a generalized measurement. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

844. Orthogonal vectors as a scaled orthonormal basis. For every size n, every list of n complex vectors $m_1, \ldots, m_n$ with n entries each (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every list of real numbers $\sigma_1, \ldots, \sigma_n \geq 0$ such that $\langle m_k, m_k\rangle = \sigma_k^2$ for every k and $\langle m_j, m_k\rangle = 0$ whenever j ≠ k: there are vectors $u_1, \ldots, u_n$ with $\langle u_j, u_k\rangle = 1$ when j = k and 0 when j ≠ k (an orthonormal basis) and $\sigma_k \cdot u_k = m_k$ for every k. Here $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. Where $\sigma_k = 0$ the vector u_k is not fixed by m_k and has to be found orthogonal to all the others; the statement does not say which σ_k vanish. *Used for:* Completing the left singular vectors of a rank-deficient matrix, and extending a set of mutually orthogonal states or optical modes of known norms, some possibly zero, to a full orthonormal basis. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

845. Polar decomposition of an invertible complex matrix. For every size n, every n × n matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number e with det(A)·e = 1 (an explicit inverse of the determinant): there are n × n complex matrices W and P with W†W = 1 (W unitary), P ⪰ 0 and A = WP. Here a square complex matrix P is positive semidefinite, P ⪰ 0, when P† = P and the real part of ⟨x, Px⟩ is ≥ 0 for every complex vector x, with ⟨x, y⟩ = $\bar{x}_1y_1$ + … + $\bar{x}_ny_n$. *Used for:* Löwdin symmetric orthogonalisation: the unitary polar factor W = A(A†A)$^{-1/2}$ of a matrix of overlapping orbitals is the orthonormal set closest to them, used in quantum chemistry and in building Wannier functions. *Price:* **free**; exact.

846. Schmidt decomposition of a bipartite pure state. For every size n and every n × n matrix C with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line), there are n × n complex matrices U and V with U†U = 1 and V†V = 1 and real numbers s_1, …, s_n ≥ 0 with C = U·diag(s_1, …, s_n)·V†. Read C as the coefficient matrix of a pure state ψ = Σ C_{ij} e_i⊗e_j of two n-level systems (e_1, …, e_n the standard basis): then ψ = s_1 a_1⊗b_1 + … + s_n a_n⊗b_n with orthonormal vectors a_k (the columns of U) and orthonormal vectors b_k (the complex conjugates of the columns of V), and the s_k are the Schmidt coefficients of ψ. *Used for:* Entanglement of a pure state of two subsystems: the Schmidt coefficients s_k give the spectrum s_k^2 of each reduced density matrix, the entanglement entropy −Σ s_k^2 ln s_k^2 and the Schmidt rank. *Price:* **LLPO + AC**$_\omega$; exact.

847. Polar factor of a complex vector. For every size n ≥ 1 and every complex vector m with n entries (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), there are a complex vector u with ⟨u, u⟩ = 1 and a real number r ≥ 0 with ⟨m, m⟩ = r^2 and r·u = m, where ⟨x, y⟩ = $\bar{x}_1y_1$ + … + $\bar{x}_ny_n$. So m = ‖m‖·u with u a unit vector. The vector m is not assumed to be nonzero. *Used for:* Renormalising a quantum state after a projective measurement or an imaginary-time step, ψ = ‖ψ‖·u, when the unnormalised result may vanish. *Price:* **LLPO + AC**$_\omega$; exact.

848. Determinant of the adjugate matrix. For every size n and every n × n matrix A on the line (real entries): det(adj(A)) = det(A)$^{n-1}$, where adj(A) is the adjugate, whose (i, j) entry is $(-1)^{i+j}$ times the determinant of A with row j and column i deleted. At size 0 both sides are 1. A is not assumed to be invertible. *Used for:* Nanson's formula in continuum mechanics: the cofactor (area-change) matrix of a 3 × 3 deformation gradient F has determinant det(F)^2, so the area and volume changes of a deformed body stay consistent. *Price:* **free**; exact.

849. Adjugate of the adjugate matrix. For every size n other than 1 and every n × n matrix A on the line (real entries): adj(adj(A)) = det(A)$^{n-2}$·A, where adj(A) is the adjugate, whose (i, j) entry is $(-1)^{i+j}$ times the determinant of A with row j and column i deleted. At size 0 the exponent n − 2 is read as 0 and both sides are the empty matrix. A is not assumed to be invertible. *Used for:* Recovering a 3 × 3 matrix from its cofactor matrix: for a deformation gradient F in nonlinear elasticity, adj(adj(F)) = det(F)·F, so the area-change map fixes F up to its volume change. *Price:* **free**; exact.

850. Chebyshev series of a Hermitian matrix, coefficients with representatives. For every size n, every n × n Hermitian matrix H with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line; H† = H) with −1 ⪯ H ⪯ 1 (both 1 − H and 1 + H positive semidefinite), and every sequence of real coefficients a_0, a_1, a_2, … on the line that is given together with representatives (for each k, a sequence of rationals q_0, q_1, … with $|q_i - q_l| \le 1/(i+1) + 1/(l+1)$ for all i and l, whose limit is a_k) and has an explicit tail modulus for Σ $|a_k|$ (a function K such that $|a_p| + |a_{p+1}| + \dots + |a_{p+m-1}| \le 1/(j+1)$ for every j, every p ≥ K(j) and every m): the partial sums of $a_0T_0(H) + a_1T_1(H) + a_2T_2(H) + \dots$ converge entry by entry to a matrix F with F† = F and FH = HF; and for every n × n matrix V with V†V = 1 and real numbers λ_1, …, λ_n and μ_1, …, μ_n such that HV = V·diag(λ_1, …, λ_n) and, for each k, the scalar series $a_0T_0(\lambda_k) + a_1T_1(\lambda_k) + \dots$ converges to μ_k, FV = V·diag(μ_1, …, μ_n). So F = f(H) for the function $f(t) = \Sigma\, a_kT_k(t)$. Here $T_0(H) = 1$, $T_1(H) = H$ and $T_{j+2}(H) = 2H\cdot T_{j+1}(H) - T_j(H)$, and $T_j(t)$ for a number t follows this recursion with t in place of H; and a matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, with ⟨x, y⟩ = $\bar{x}_1y_1$ + … + $\bar{x}_ny_n$. *Used for:* Chebyshev expansions of the thermal operator $e^{-\beta H}$ (modified Bessel-function coefficients) and of cos(Ht) and sin(Ht), the real and imaginary parts of the Chebyshev propagator, for a Hamiltonian rescaled to spectrum in [−1, 1]; explicit coefficient formulas come with representatives. *Price:* **free**; exact.

851. Unitary dilation of a Hermitian contraction. For every size n and every n × n Hermitian matrix H with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line; H† = H) with −1 ⪯ H ⪯ 1 (both 1 − H and 1 + H positive semidefinite), there is an n × n complex matrix U with U†U = 1 and UU† = 1 that commutes with H (UH = HU), with H = (U + U†)/2 and $T_k(H) = (U^k + (U\dagger)^k)/2$ for every k ≥ 0. Here $T_0(H) = 1$, $T_1(H) = H$ and $T_{k+2}(H) = 2H\cdot T_{k+1}(H) - T_k(H)$ are the

Chebyshev polynomials, and a matrix G is positive semidefinite when $G\dagger = G$ and the real part of $\langle x, Gx\rangle$ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Qubitization and quantum walks: a Hamiltonian rescaled into $[-1, 1]$ is the average of a unitary walk operator and its inverse, so k steps of the walk produce the Chebyshev polynomial $T_k(H)$, the matrix form of $T_k(\cos\theta) = \cos k\theta$. *Price:* **free**; exact.

852. Chebyshev polynomials of a Hermitian contraction are contractions. For every size n, every $n \times n$ Hermitian matrix H with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line; $H\dagger = H$) with $-1 \preceq H \preceq 1$ (both $1 - H$ and $1 + H$ positive semidefinite), and every $k \geq 0$: $\|T_k(H)x\|^2 \leq \|x\|^2$ for every complex vector x, where $\|x\|^2 = \langle x, x\rangle = \bar{x}_1 x_1 + \ldots + \bar{x}_n x_n$. So the operator norm of $T_k(H)$ is at most 1. Here $T_0(H) = 1$, $T_1(H) = H$ and $T_{k+2}(H) = 2H\cdot T_{k+1}(H) - T_k(H)$ are the Chebyshev polynomials, and a matrix G is positive semidefinite when $G\dagger = G$ and the real part of $\langle x, Gx\rangle$ is ≥ 0 for every complex vector x. *Used for:* Error control in Chebyshev expansions: each term $T_k(H)$ of a rescaled Hamiltonian has norm at most 1, so cutting $\Sigma\, a_k T_k(H)$ after N terms errs by at most Σ over $k \geq N$ of $|a_k|$, in the kernel polynomial method and Chebyshev propagators. *Price:* **free**; exact.

853. Spectral projection below a gap of a Hermitian matrix. For every size n, every $n \times n$ Hermitian matrix H with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line; $H\dagger = H$), and all real numbers c and $r > 0$ such that H has a gap of half-width r around c, that is $\|(H - c)x\|^2 \geq r^2\|x\|^2$ for every complex vector x, so that no eigenvalue of H lies strictly between $c - r$ and $c + r$: there is an $n \times n$ matrix P with $P\dagger = P$, $P^2 = P$ and $PH = HP$ such that, for every $n \times n$ matrix V with $V\dagger V = 1$ and real numbers $\lambda_1, \ldots, \lambda_n$ with $HV = V\cdot\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$, and every k, $Pv_k = v_k$ when $\lambda_k \leq c - r$ and $Pv_k = 0$ when $\lambda_k \geq c + r$, where v_k is the k-th column of V. Here $\|x\|^2 = \langle x, x\rangle = \bar{x}_1 x_1 + \ldots + \bar{x}_n x_n$. P is obtained without naming any eigenbasis. *Used for:* Fermi-sea projector of a gapped insulator or gapped ground state: the projection onto all states below the gap, used for ground-state density matrices, Berry phases, Chern numbers and Wannier functions. *Price:* **free**; exact.

854. Positive definite matrices are uniformly positive. For every size n and every $n \times n$ matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line) that is literally positive definite, meaning $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$: there is a real number $\varepsilon > 0$ such that the real part of $\langle x, Ax\rangle$ is at least $\varepsilon\cdot\langle x, x\rangle$ for every complex vector x. Here $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$. *Used for:* Stability margins: a positive definite Hessian, stiffness matrix or mass-weighted force-constant matrix has a uniform positive curvature ε, which gives a minimum restoring force and a strictly positive lowest normal-mode frequency. *Price:* **free**; exact.

855. Singular value decomposition of square complex matrices. For every size n and every $n \times n$ matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line), there are $n \times n$ complex matrices U and V with $U\dagger U = 1$ and $V\dagger V = 1$ and real numbers $s_1, \ldots, s_n \geq 0$ with $AV = U\cdot\mathrm{diag}(s_1, \ldots, s_n)$. So $A = U\cdot\mathrm{diag}(s_1, \ldots, s_n)\cdot V\dagger$ with U and V unitary; the s_k are the singular values of A, in no prescribed order. *Used for:* Truncating matrix-product states in DMRG and other tensor-network simulations by keeping the largest singular values, and low-rank approximation of response and correlation matrices. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

856. Determinant of a matrix exponential (Jacobi's formula). For every size n and every $n \times n$ matrix A with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line): if the exponential series $1 + A + A^2/2! + A^3/3! + \ldots$ converges entrywise to a matrix E, and the exponential series of the complex number $\mathrm{tr}(A) = A_{11} + \ldots + A_{nn}$ converges to a number e, then $\det(E) = e$. So $\det(\exp A) = \exp(\mathrm{tr}\, A)$. *Used for:* Liouville's theorem for linear flows: a phase-space volume carried by $\dot{x} = A\cdot x$ scales by $\det(e^{t\cdot A}) = e^{t\cdot \mathrm{tr}\, A}$; for a quantum evolution, $\det(e^{-i\cdot H\cdot t}) = e^{-i\cdot t\cdot \mathrm{tr}\, H}$, so traceless generators give special unitary evolutions. *Price:* **free**; exact.

857. Simultaneous diagonalization of commuting Hermitian matrices. For every size n and every two $n \times n$ Hermitian matrices H and K with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line; $H\dagger = H$ and $K\dagger = K$) that commute ($HK = KH$), there are an $n \times n$ complex matrix V with $V\dagger V = 1$ and real numbers $\lambda_1, \ldots, \lambda_n$ and $\kappa_1, \ldots, \kappa_n$ with $HV = V\cdot\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ and $KV = V\cdot\mathrm{diag}(\kappa_1, \ldots, \kappa_n)$. So the columns of V form one orthonormal basis of joint eigenvectors of H and K. *Used for:* Labelling energy eigenstates by a commuting symmetry: a common eigenbasis of a Hamiltonian and a conserved quantity such as parity, momentum or angular momentum, as in a complete set of commuting observables. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

858. Spectral theorem for normal matrices. For every size n and every $n \times n$ matrix N with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line) that is normal, $NN\dagger = N\dagger N$: there are an $n \times n$ complex matrix V with $V\dagger V = 1$ and complex numbers $\mu_1, \ldots,$

μ_n with $NV = V\cdot\mathrm{diag}(\mu_1, \ldots, \mu_n)$. So $N = V\cdot\mathrm{diag}(\mu_1, \ldots, \mu_n)\cdot V\dagger$ with V unitary: an orthonormal basis of eigenvectors with complex eigenvalues. *Used for:* Normal non-Hermitian operators with complex eigenvalues: circulant couplings such as a non-reciprocal (Hatano–Nelson) ring with periodic boundary conditions, diagonalised by plane waves, and operators $A + i\cdot B$ built from commuting observables A and B. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

859. Spectral theorem for unitary matrices. For every size n and every $n \times n$ matrix U with complex entries (on the complex numbers over the line, whose real and imaginary parts lie on the line) with $U\dagger U = 1$: there are an $n \times n$ complex matrix V with $V\dagger V = 1$ and complex numbers $\mu_1, \ldots, \mu_n$ with $\bar{\mu}_k\mu_k = 1$ for every k and $UV = V\cdot\mathrm{diag}(\mu_1, \ldots, \mu_n)$. So $U = V\cdot\mathrm{diag}(\mu_1, \ldots, \mu_n)\cdot V\dagger$ with every eigenvalue on the unit circle. *Used for:* Floquet quasi-energies and quantum gates: the eigenphases of a one-period evolution operator or of a quantum circuit, with an orthonormal basis of Floquet states or gate eigenstates. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

860. Positive definite implies positive semidefinite. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then A is positive semidefinite. Here a square complex matrix A is positive semidefinite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, and positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Strict positivity includes positivity: a full-rank density matrix, a nondegenerate covariance matrix or a mass matrix is in particular positive semidefinite, so every result proved for semidefinite matrices applies to it. *Price:* **free**; exact.

861. Positive definite plus positive semidefinite. For every size n and all complex $n \times n$ matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite and B is positive semidefinite, then $A + B$ is positive definite. Here a square complex matrix A is positive semidefinite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, and positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Regularisation and added couplings: adding a positive semidefinite term (springs with zero modes, a penalty, a coupling) to a positive definite mass, stiffness or covariance matrix keeps it positive definite; ridge regularisation $K + \lambda\cdot 1$ with $\lambda > 0$ is this statement with the roles of the two terms exchanged. *Price:* **free**; exact.

862. Positive multiple of a positive definite matrix. For every size n, every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number c that is a positive real (real part > 0, imaginary part 0): if A is positive definite, then $c\cdot A$ is positive definite. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Changing units or temperature: a positive multiple of a positive definite mass, inertia or metric matrix, such as a unit conversion or the factor $1/(k\cdot T)$ in a Boltzmann weight $\exp(-x^{\mathrm{T}}Ax/(k\cdot T))$, with Boltzmann's constant k and the temperature T„ stays positive definite. *Price:* **free**; exact.

863. Diagonal entries of a positive definite matrix are positive. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then every diagonal entry A_{ii} is a positive real number (real part > 0, imaginary part 0). Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Variances, masses and self-overlaps: each diagonal entry of a nondegenerate covariance matrix (a variance), of a mass matrix (a mass) and of the overlap matrix of independent states ($\langle\varphi_i, \varphi_i\rangle$) is positive. *Price:* **free**; exact.

864. Trace of a positive definite matrix is positive. For every size $n \geq 1$ and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then its trace $A_{11} + \ldots + A_{nn}$ is a positive real number (real part > 0, imaginary part 0). Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Total variance and normalisation: the trace of a nondegenerate covariance matrix (the total variance), of a positive definite inertia tensor (the sum of the principal moments) and of an unnormalised full-rank density matrix is a positive real, so dividing by it is allowed. *Price:* **free**; exact.

865. Congruence $B\dagger AB$ keeps positive definiteness. For all sizes n and m, every complex n

× n matrix A and every complex n × m matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite and B is injective (Bx = By implies x = y, for complex vectors x and y of length m), then the m × m matrix B†AB is positive definite. Here a square complex matrix A is positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries of x and y); x ≠ 0 means only that x is not the zero vector (the negation of x = 0). *Used for:* Restricting a positive energy to coordinates or a subspace: with positions x = Bq given by independent generalised coordinates q, the kinetic-energy matrix $B^T M B$ is positive definite; Rayleigh–Ritz projection of a positive definite operator onto an independent trial basis. *Price:* **free**; exact.

866. Inverse of a positive definite matrix is positive definite. For every size n and all complex n × n matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite and B is a two-sided inverse of A (AB = 1 and BA = 1), then B is positive definite. Here a square complex matrix A is positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). *Used for:* Inverse metric and inverse mass matrix: the inverse metric g^{-1} used to raise indices, the inverse mass matrix M^{-1} that gives velocities from momenta in Hamilton's equations, and a Gaussian's covariance as the inverse of its precision matrix are positive definite. *Price:* **free**; exact.

867. Eigenvalues of a positive definite matrix are positive. For every size n, every complex n × n matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), every complex n × n matrix V with V†V = 1, and all real numbers $\lambda_1, \ldots, \lambda_n$ on the line with HV = V diag($\lambda_1, \ldots, \lambda_n$) (the columns of V are an orthonormal eigenbasis of H with these eigenvalues): if H is positive definite, then every $\lambda_k > 0$. Here a square complex matrix A is positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The eigenbasis is given, not constructed. *Used for:* Stable normal modes: the eigenvalues ω^2 of a positive definite stiffness matrix in mass-weighted coordinates are positive, so every mode oscillates with a real frequency; a positive definite quadratic Hamiltonian has positive mode energies. *Price:* **free**; exact.

868. Identity matrix is positive definite. For every size n, the complex n × n identity matrix 1 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) is positive definite: for every complex vector x ≠ 0, $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2 > 0$. Here a square complex matrix A is positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The hypothesis says only that x is not the zero vector; turning that into a positive length is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already at size 1 the statement asks $r^2 > 0$ for every real r ≠ 0. *Used for:* The Euclidean metric δ_{ij} and the overlap matrix of an orthonormal basis are positive definite: every vector that is not zero has positive length, the property that makes the dot product an inner product. *Price:* **MP**; exact.

869. Positive semidefinite with trivial kernel is positive definite. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive semidefinite and Ax = 0 only for x = 0 (for every complex vector x, Ax = 0 implies x = 0), then A is positive definite. Here a square complex matrix A is positive semidefinite when A† = A and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x, and positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). For x ≠ 0 the hypotheses give only that the real part of $\langle x, Ax\rangle$ is ≥ 0 and is not zero; concluding that it is > 0 is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Ruling out zero modes: a positive semidefinite Hessian, stiffness or overlap matrix whose only null vector is zero is positive definite, so an equilibrium with no zero modes is a strict minimum. *Price:* **MP**; exact.

870. A†A is positive definite for injective A. For all sizes m and n and every complex m × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is injective (Ax = Ay implies x = y, for complex vectors x and y of length n), then the n × n matrix A†A is positive definite. Here a square complex matrix A is positive definite when A† = A and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector x ≠ 0, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). For x ≠ 0 injectivity gives only that Ax is not the zero vector; concluding $\langle x, A^\dagger Ax\rangle = \|Ax\|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly

that a real number that is not zero has an inverse. *Used for:* Least squares and induced metrics: the normal-equations matrix $A^{T}A$ of a fit whose design matrix A has independent columns is positive definite, so the fit has a unique best solution; and the metric $J^{T}J$ induced by an embedding with injective Jacobian J is positive definite for the reason just given. *Price:* **MP**; exact.

871. Determinant of a positive definite matrix is positive. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then det(A) is a positive real number (real part > 0, imaginary part 0). Here a square complex matrix A is positive definite when A† = A and the real part of ⟨x, Ax⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). *Used for:* Gaussian integrals and volume elements: the normalisation $\sqrt{((2\pi)^n/\det A)}$ of $\exp(-\tfrac{1}{2}\, x^{T}Ax)$, Gaussian prefactors in partition functions and path integrals, and the Riemannian volume element √(det g) all need det > 0. *Price:* **free**; exact.

872. A positive definite matrix is invertible. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then A has a two-sided inverse, a matrix B with AB = 1 and BA = 1. Here a square complex matrix A is positive definite when A† = A and the real part of ⟨x, Ax⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). *Used for:* Solving with a positive definite matrix: accelerations from Mẍ = F with a mass matrix M, raising indices with the inverse metric, and inverting a covariance matrix to write a Gaussian density. *Price:* **free**; exact.

873. Positive definite exactly when A = B†B with B invertible. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): A is positive definite if and only if A = B†B for some complex n × n matrix B that has a two-sided inverse (BC = 1 and CB = 1 for some C). Here a square complex matrix A is positive definite when A† = A and the real part of ⟨x, Ax⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). From left to right no principle is needed (B can be taken as the positive square root of A). From right to left, x ≠ 0 gives only that Bx is not the zero vector; concluding ⟨x, Ax⟩ = $\|Bx\|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Factoring a positive energy or metric: writing a mass matrix, metric or covariance as B†B (a Cholesky factor or a square root) to pass to mass-weighted or whitened coordinates y = Bx, in which the quadratic form becomes $\|y\|^2$. *Price:* **MP**; exact.

874. Positive semidefinite matrix: positive definite exactly when invertible. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is positive semidefinite: A is positive definite if and only if A has a two-sided inverse (AB = 1 and BA = 1 for some B). Here a square complex matrix A is positive semidefinite when A† = A and the real part of ⟨x, Ax⟩ is ≥ 0 for every complex vector x, and positive definite when A† = A and the real part of ⟨x, Ax⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). From left to right no principle is needed. From right to left, x ≠ 0 gives only that the real part of ⟨x, Ax⟩ is ≥ 0 and is not zero; concluding that it is > 0 is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Nondegeneracy tests: a positive semidefinite Fisher information, overlap or covariance matrix is strictly positive exactly when it can be inverted, which decides whether parameters are identifiable or a basis is free of redundancy. *Price:* **MP**; exact.

875. Positive definite exactly when all eigenvalues are positive. For every size n, every complex n × n matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with H† = H, every complex n × n matrix V with V†V = 1, and all real numbers $\lambda_1, \ldots, \lambda_n$ on the line with HV = V diag($\lambda_1, \ldots, \lambda_n$) (the columns of V are an orthonormal eigenbasis of H with these eigenvalues): H is positive definite if and only if every $\lambda_k > 0$. Here a square complex matrix A is positive definite when A† = A and the real part of ⟨x, Ax⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\bar{x}_1y_1 + \ldots + \bar{x}_ny_n$; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The eigenbasis is given, not constructed. From left to right no principle is needed. From right to left, x ≠ 0 gives only that the coefficient vector c = V†x is not zero; concluding ⟨x, Hx⟩ = $\lambda_1|c_1|^2 + \ldots + \lambda_n|c_n|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Stability read from the spectrum: an equilibrium of a potential is a strict minimum exactly when every eigenvalue of its Hessian is positive, and a quadratic Hamiltonian is strictly

positive exactly when every mode energy is, once the eigenbasis is known. *Price:* **MP**; exact.

876. Diagonal matrix positive definite exactly when entries are positive. For every size n and all complex numbers $d_1, \ldots, d_n$ (in the complex numbers over the line, whose real and imaginary parts lie on the line): the diagonal matrix $\mathrm{diag}(d_1, \ldots, d_n)$ is positive definite if and only if every d_i is a positive real number (real part > 0, imaginary part 0). Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). From left to right no principle is needed. From right to left, $x \neq 0$ gives only that x is not the zero vector; concluding $d_1|x_1|^2 + \ldots + d_n|x_n|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Principal axes: a diagonal inertia tensor, mass matrix, covariance of independent variables or diagonal metric $\mathrm{diag}(a^2, b^2, c^2)$ is positive definite exactly when every principal moment, mass, variance or diagonal entry is positive. *Price:* **MP**; exact.

877. LDL factorisation of a positive definite matrix. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then $A = L \cdot \mathrm{diag}(d_1, \ldots, d_n) \cdot L\dagger$ for some complex $n \times n$ matrix L that is lower triangular with ones on the diagonal ($L_{ii} = 1$, and $L_{ij} = 0$ whenever $i < j$) and some real numbers $d_1, \ldots, d_n$ on the line, all > 0. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Cholesky and LDL solves: factoring positive definite stiffness, mass and normal-equation matrices in finite-element and normal-mode computations, and generating correlated Gaussian noise from a covariance matrix. *Price:* **free**; exact.

878. Transpose of a positive definite matrix. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then its transpose A^{T} (entries swapped, $(A^{\mathrm{T}})_{ij} = A_{ji}$, with no complex conjugation) is positive definite. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Transposing a whole quantum state: the full transpose ρ^{T} of a full-rank density matrix is again positive definite (only the partial transpose can fail to be positive, which is what the Peres–Horodecki entanglement test detects); also switching row and column conventions. *Price:* **free**; exact.

879. Conjugate transpose of a positive definite matrix. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite, then its conjugate transpose $A\dagger$ is positive definite. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). *Used for:* Moving a positive operator across an inner product: the adjoint of a positive definite metric, Hamiltonian or density matrix is again positive definite (it is the operator itself), so the bra and ket forms of a quadratic expression agree. *Price:* **free**; exact.

880. Literal and uniform positive definiteness agree. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $A\dagger = A$: A is positive definite if and only if A is uniformly positive: there is a real number $\varepsilon > 0$ on the line such that the real part of $\langle x, Ax\rangle$ is $\geq \varepsilon\|x\|^2$ for every complex vector x, where $\|x\|^2 = \langle x, x\rangle = |x_1|^2 + \ldots + |x_n|^2$. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). From left to right no principle is needed: the margin ε is constructed. From right to left, $x \neq 0$ gives only that x is not the zero vector; concluding $\varepsilon\|x\|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Coercivity: a positive definite Hessian, stiffness or kinetic-energy matrix comes with a uniform margin $\langle x, Ax\rangle \geq \varepsilon\|x\|^2$, the bound behind energy estimates, stability margins, a positive lower bound on the spectrum of a quadratic Hamiltonian, and convergence rates of iterative solvers. *Price:* **MP**; exact.

881. Invertible change of basis preserves positive definiteness. For every size n and all complex $n \times n$ matrices U, W and X (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $UW = 1$ and $WU = 1$ (U is invertible with inverse W): $U\dagger XU$ is positive definite if and only if X is positive definite. Here a square complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the

negation of x = 0). *Used for:* Changing coordinates by any invertible, not necessarily unitary, matrix: positive definiteness of a metric, inertia tensor, kinetic-energy matrix or Hamiltonian does not depend on the basis (the positive definite case of Sylvester's law of inertia). *Price:* **free**; exact.

882. Inverse is positive definite exactly when the matrix is. For every size n and all complex n × n matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with AB = 1 and BA = 1 (B is the inverse of A): B is positive definite if and only if A is positive definite. Here a square complex matrix A is positive definite when $A^\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \bar{x}_1 y_1 + \ldots + \bar{x}_n y_n$; $x \neq 0$ means only that x is not the zero vector (the negation of x = 0). *Used for:* Passing between a matrix and its inverse in both directions: a Lagrangian mass matrix and the Hamiltonian inverse mass matrix, a metric and its inverse, and a Gaussian's covariance and precision matrix are positive definite together. *Price:* **free**; exact.

883. Congruence BAB† keeps positive definiteness. For all sizes n and m, every complex n × n matrix A and every complex m × n matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if A is positive definite and the row-vector map $v \mapsto v\cdot B$ is injective ($v\cdot B = w\cdot B$ implies v = w, for complex row vectors v and w of length m, where $(v\cdot B)_j = v_1 B_{1j} + \ldots + v_m B_{mj}$), then the m × m matrix $BAB^\dagger$ is positive definite. Here a square complex matrix A is positive definite when $A^\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries of x and y); $x \neq 0$ means only that x is not the zero vector (the negation of x = 0). *Used for:* Pushing a nondegenerate covariance or positive operator through a linear map: the covariance $B\Sigma B^\dagger$ of the image of a nondegenerate Gaussian under a map B with independent rows is nondegenerate, so the transformed variables still have a proper joint density. *Price:* **free**; exact.

884. Gram–Schmidt and QR for uniformly independent vectors. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is uniformly independent: there is a real number $\varepsilon > 0$ on the line with $\|c_1 v_1 + \ldots + c_k v_k\|^2 \geq \varepsilon(|c_1|^2 + \ldots + |c_k|^2)$ for all complex numbers $c_1, \ldots, c_k$: there are orthonormal vectors $u_1, \ldots, u_k$ of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and k × k upper triangular matrices R and S (entries below the diagonal are 0) with RS = SR = 1 and every diagonal entry R_{jj} a positive real number, such that $v_j = R_{1j}u_1 + \ldots + R_{kj}u_k$ and $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j. Since R and S are upper triangular, $u_1, \ldots, u_j$ and $v_1, \ldots, v_j$ span one common space for every j: this is Gram–Schmidt orthonormalisation, and the QR factorisation of the n × k matrix whose columns are $v_1, \ldots, v_k$. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. *Used for:* Orthonormalising a basis that comes with a certified overlap bound: Gram–Schmidt and QR on Krylov (Lanczos, Arnoldi) vectors, trial wavefunctions or atomic orbitals whose overlap matrix has its smallest eigenvalue bounded away from zero. *Price:* **free**; exact.

885. Gram–Schmidt for linearly independent vectors. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is linearly independent in the literal sense: whenever $c_1 v_1 + \ldots + c_k v_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is): there are orthonormal vectors $u_1, \ldots, u_k$ of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and k × k upper triangular matrices R and S (entries below the diagonal are 0) with RS = SR = 1 and every diagonal entry R_{jj} a positive real number, such that $v_j = R_{1j}u_1 + \ldots + R_{kj}u_k$ and $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j. Since R and S are upper triangular, $u_1, \ldots, u_j$ and $v_1, \ldots, v_j$ span one common space for every j: this is Gram–Schmidt orthonormalisation, and the QR factorisation of the n × k matrix whose columns are $v_1, \ldots, v_k$. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. The hypothesis is of the 'only zero' kind and gives no positive length; normalising the residual vectors needs a positive length, and getting it is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already one vector (r) with a real $r \neq 0$ is literally independent, and normalising it inverts r. *Used for:* Textbook Gram–Schmidt: orthonormalising states known only to be linearly independent, such as a basis of a degenerate eigenspace, a set of trial wavefunctions or non-orthogonal orbitals, before computing matrix elements. *Price:* **MP**; exact.

886. Löwdin orthonormalisation for uniformly independent vectors. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is uniformly independent: there is a real number $\varepsilon > 0$ on the line with $\|c_1 v_1 + \ldots + c_k v_k\|^2 \geq \varepsilon(|c_1|^2 + \ldots + |c_k|^2)$ for all complex numbers $c_1, \ldots, c_k$: there are orthonormal vectors $u_1, \ldots, u_k$ of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and a k × k matrix S with $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j, S positive semidefinite ($S^\dagger = S$ and

the real part of $\langle x, Sx\rangle$ is ≥ 0 for every complex vector x), SGS = 1 for the Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$), and S invertible (ST = TS = 1 for some T). Then S^2 is the inverse of G, so S is a positive semidefinite square root of G^{-1}: the matrix written $G^{-1/2}$ in Löwdin's symmetric orthonormalisation u = VS. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. *Used for:* Löwdin symmetric orthonormalisation of non-orthogonal atomic orbitals (the orbitals multiplied by the inverse square root of their overlap matrix), used in tight-binding and Hückel models and in Löwdin population analysis, for orbital sets with a certified overlap bound. *Price:* **free**; exact.

887. Löwdin orthonormalisation for linearly independent vectors. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is): there are orthonormal vectors $u_1, \ldots, u_k$ of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and a k × k matrix S with $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j, S positive semidefinite ($S^\dagger = S$ and the real part of $\langle x, Sx\rangle$ is ≥ 0 for every complex vector x), SGS = 1 for the Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$), and S invertible (ST = TS = 1 for some T). Then S^2 is the inverse of G, so S is a positive semidefinite square root of G^{-1}: the matrix written $G^{-1/2}$ in Löwdin's symmetric orthonormalisation u = VS. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. The hypothesis is of the 'only zero' kind and gives no positive lower bound on the overlaps; producing one is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already one vector (r) with a real $r \neq 0$ is literally independent, and normalising it inverts r. *Used for:* Löwdin symmetric orthonormalisation of atomic orbitals under the textbook hypothesis that the orbitals are merely linearly independent. *Price:* **MP**; exact.

888. Gram matrix is positive semidefinite. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the k × k Gram matrix G with $G_{ij} = \langle v_i, v_j\rangle$ is positive semidefinite, where a square complex matrix A is positive semidefinite when $A^\dagger = A$ and the real part of $\langle x, Ax\rangle$ is ≥ 0 for every complex vector x. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. *Used for:* Overlap and correlation matrices: the overlap matrix $\langle \varphi_i, \varphi_j\rangle$ of any set of states, orbitals or coherent states, and the correlation matrix of a set of signals, are positive semidefinite. *Price:* **free**; exact.

889. Positive definite Gram matrix gives linear independence. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if the k × k Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$) is positive definite, then $v_1, \ldots, v_k$ are linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is). Here a square complex matrix A is positive definite when $A^\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries); $x \neq 0$ means only that x is not the zero vector (the negation of x = 0). *Used for:* Certifying a basis: a positive definite overlap matrix shows that a set of basis functions, coherent states or trial wavefunctions has no linear dependence. *Price:* **free**; exact.

890. Gram matrix of independent vectors is positive definite. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if $v_1, \ldots, v_k$ are linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is), then the k × k Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$) is positive definite. Here a square complex matrix A is positive definite when $A^\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries); $x \neq 0$ means only that x is not the zero vector (the negation of x = 0). For a coefficient vector $c \neq 0$ the hypothesis gives only that $c_1v_1 + \ldots + c_kv_k$ is not the zero vector; concluding $\langle c, Gc\rangle = \|c_1v_1 + \ldots + c_kv_k\|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Non-orthogonal bases: the overlap matrix of linearly independent atomic orbitals or tight-binding basis functions is positive definite, so the generalized eigenvalue problem Hc = ESc is well posed. *Price:* **MP**; exact.

891. Gram matrix positive definite exactly when vectors are independent. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the k × k Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$) is positive definite if and only if $v_1, \ldots, v_k$ are linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is). Here a square

complex matrix A is positive definite when $A\dagger = A$ and the real part of $\langle x, Ax\rangle$ is > 0 for every complex vector $x \neq 0$, with $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries); $x \neq 0$ means only that x is not the zero vector (the negation of $x = 0$). From left to right no principle is needed. From right to left, for a coefficient vector c $\neq 0$ the hypothesis gives only that $c_1v_1 + \ldots + c_kv_k$ is not the zero vector; concluding $\langle c, Gc\rangle = \|c_1v_1 + \ldots + c_kv_k\|^2 > 0$ is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* Testing a basis for overcompleteness: a set of Gaussian basis functions or coherent states is linearly independent exactly when its overlap matrix is positive definite, the standard check for near-linear dependence in quantum chemistry codes. *Price:* **MP**; exact.

892. Literal and uniform linear independence agree. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): $v_1, \ldots, v_k$ are linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers $c_1, \ldots, c_k$, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is) if and only if they are uniformly independent: there is a real number $\varepsilon > 0$ on the line with $\|c_1v_1 + \ldots + c_kv_k\|^2 \geq \varepsilon(|c_1|^2 + \ldots + |c_k|^2)$ for all complex numbers $c_1, \ldots, c_k$. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. From right to left no principle is needed. From left to right the hypothesis gives no positive length for any combination; producing the uniform bound ε is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* The two meanings of an independent basis in numerical physics: no nontrivial combination vanishes, versus the smallest eigenvalue of the overlap matrix is bounded away from zero (a finite condition number), which is what solvers and orthonormalisation routines check. *Price:* **MP**; exact.

893. QR decomposition of an invertible matrix. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that has a two-sided inverse ($AB = 1$ and $BA = 1$ for some B): there are complex $n \times n$ matrices Q, R and S with $Q\dagger Q = 1$ and $QQ\dagger = 1$ (Q is unitary), $A = QR$, R and S upper triangular (entries below the diagonal are 0), every diagonal entry R_{jj} a positive real number, and $RS = SR = 1$. *Used for:* The QR factorisation in numerical physics: QR iterations for the eigenvalues of Hamiltonians, stable least-squares solves, and the repeated re-orthonormalisation used to compute Lyapunov exponents of dynamical systems. *Price:* **free**; exact.

894. Columns independent exactly when the matrix is invertible. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the columns of A are linearly independent in the literal sense ($Ac = 0$ for a complex vector c implies $c = 0$) if and only if A has a two-sided inverse ($AB = 1$ and $BA = 1$ for some B). From right to left no principle is needed. From left to right the hypothesis gives no positive lower bound on $\|Ac\|$; building the inverse needs one, and getting it is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already at size 1 this is $A = (r)$ with a real $r \neq 0$. *Used for:* Square linear systems: n equations in n unknowns (normal-mode, circuit or equilibrium equations) have a unique solution for every right-hand side exactly when the columns of the coefficient matrix are independent. *Price:* **MP**; exact.

895. Gram–Schmidt on an arbitrary list of vectors. For all sizes n and k and every list of k complex vectors $f_1, \ldots, f_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), with no independence hypothesis: there are vectors $w_1, \ldots, w_k$ that are pairwise orthogonal ($\langle w_i, w_j\rangle = 0$ for $i \neq j$) and $k \times k$ upper triangular matrices R and S, each with every diagonal entry equal to 1, such that $f_j = R_{1j}w_1 + \ldots + R_{kj}w_k$ and $w_j = S_{1j}f_1 + \ldots + S_{kj}f_k$ for every j. So w_j is f_j minus a combination of $f_1, \ldots, f_{j-1}$, and a vector that is a combination of the earlier ones comes out as 0. Here $\langle x, y\rangle = \sum_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. The construction has to decide at every step whether the remaining residual is zero or not, and that decision is exactly what costs the limited principle of omniscience (LPO); already the two vectors $f_1 = (a)$ and $f_2 = (1)$ of length 1 decide whether the real number a is 0 or apart from 0. *Used for:* Gram–Schmidt on an overcomplete or possibly dependent set: orthogonalising a redundant list of states, functions or measurement vectors, where dependent vectors come out as zero and are pruned. *Price:* **LPO**; exact.

896. Gram–Schmidt output exists exactly for uniform independence. For all sizes n and k and every list of k complex vectors $v_1, \ldots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), the following are equivalent: (a) there are orthonormal vectors $u_1, \ldots, u_k$ of length n ($\langle u_i, u_j\rangle = 1$ if $i = j$ and 0 otherwise) and $k \times k$ upper triangular matrices R and S (entries below the diagonal are 0) with $RS = SR = 1$ and every diagonal entry R_{jj} a positive real number, such that $v_j = R_{1j}u_1 + \ldots + R_{kj}u_k$ and $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for

every j; (b) v_1, ..., v_k are uniformly independent: there is a real number $\varepsilon > 0$ on the line with $\|c_1v_1 + \ldots + c_kv_k\|^2 \geq \varepsilon(|c_1|^2 + \ldots + |c_k|^2)$ for all complex numbers c_1, ..., c_k. Since R and S are upper triangular, u_1, ..., u_j and v_1, ..., v_j span one common space for every j: this is Gram–Schmidt orthonormalisation, and the QR factorisation of the n × k matrix whose columns are v_1, ..., v_k. Here $\langle x, y\rangle = \Sigma_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. *Used for:* What orthonormalisation actually needs: a Gram–Schmidt or QR output exists exactly when the vectors have a uniform overlap bound, the quantity numerical codes monitor as the smallest overlap eigenvalue or the condition number. *Price:* **free**; exact.

897. Löwdin output exists exactly for uniform independence. For all sizes n and k and every list of k complex vectors v_1, ..., v_k of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), the following are equivalent: (a) there are orthonormal vectors u_1, ..., u_k of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and a k × k matrix S with $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j, S positive semidefinite ($S\dagger = S$ and the real part of $\langle x, Sx\rangle$ is ≥ 0 for every complex vector x), SGS = 1 for the Gram matrix G ($G_{ij} = \langle v_i, v_j\rangle$), and S invertible (ST = TS = 1 for some T); (b) v_1, ..., v_k are uniformly independent: there is a real number $\varepsilon > 0$ on the line with $\|c_1v_1 + \ldots + c_kv_k\|^2 \geq \varepsilon(|c_1|^2 + \ldots + |c_k|^2)$ for all complex numbers c_1, ..., c_k. In (a), S^2 is the inverse of G, so S is a positive semidefinite square root of G^{-1}, the matrix written $G^{-1/2}$ in Löwdin's symmetric orthonormalisation u = VS. Here $\langle x, y\rangle = \Sigma_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. *Used for:* What Löwdin orthonormalisation of atomic orbitals needs: exactly a uniform positive lower bound on the overlap matrix of the orbitals, no more and no less. *Price:* **free**; exact.

898. Gram–Schmidt output exists exactly for independent vectors. For all sizes n and k and every list of k complex vectors v_1, ..., v_k of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), the following are equivalent: (a) there are orthonormal vectors u_1, ..., u_k of length n ($\langle u_i, u_j\rangle = 1$ if i = j and 0 otherwise) and k × k upper triangular matrices R and S (entries below the diagonal are 0) with RS = SR = 1 and every diagonal entry R_{jj} a positive real number, such that $v_j = R_{1j}u_1 + \ldots + R_{kj}u_k$ and $u_j = S_{1j}v_1 + \ldots + S_{kj}v_k$ for every j; (b) v_1, ..., v_k are linearly independent in the literal sense: whenever $c_1v_1 + \ldots + c_kv_k = 0$ for complex numbers c_1, ..., c_k, every $c_i = 0$ (only the zero combination vanishes; this says nothing about how long a nonzero combination is). Since R and S are upper triangular, u_1, ..., u_j and v_1, ..., v_j span one common space for every j: this is Gram–Schmidt orthonormalisation, and the QR factorisation of the n × k matrix whose columns are v_1, ..., v_k. Here $\langle x, y\rangle = \Sigma_i \bar{x}_i y_i$ (summed over all entries) and $\|x\|^2 = \langle x, x\rangle$. From (a) to (b) no principle is needed. From (b) to (a) the hypothesis gives no positive length for the residual vectors; normalising them is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. *Used for:* The textbook equivalence: a set of states can be orthonormalised by Gram–Schmidt with a triangular change of basis exactly when the states are linearly independent. *Price:* **MP**; exact.

899. Rows independent exactly when the matrix is invertible. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the rows of A are linearly independent in the literal sense (if c_1 times row 1 plus ... plus c_n times row n is the zero row for complex numbers c_1, ..., c_n, then every $c_i = 0$) if and only if A has a two-sided inverse (AB = 1 and BA = 1 for some B). From right to left no principle is needed. From left to right the hypothesis gives no positive lower bound on the length of a nonzero combination of rows; building the inverse needs one, and getting it is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already at size 1 this is A = (r) with a real $r \neq 0$. *Used for:* Independent equations: n linear constraints or measurement rows on n unknowns determine the unknowns uniquely, through an inverse matrix, exactly when the rows are independent; also invertibility of a change-of-basis matrix read from its rows. *Price:* **MP**; exact.

900. Hermitian block matrix and its Schur complement. For all sizes m and k, every complex m × m matrix A with $A\dagger = A$, every complex m × k matrix B, every complex k × k matrix D and every complex m × m matrix W that is either a two-sided inverse of A (AW = 1 and WA = 1) or the zero matrix (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the block matrix M with rows (A B) and (B† D), of size m + k, is Hermitian ($M\dagger = M$) if and only if the Schur complement D − B†WB is Hermitian. Here X† is the conjugate transpose of X. W stands for A^{-1} in the convention that gives a matrix with no inverse the inverse 0; the statement holds for either value. *Used for:* Löwdin partitioning (Feshbach projection): the effective Hamiltonian of the retained states is a Schur complement D − B†A^{-1}B, with A the eliminated block shifted by a real energy, and it is Hermitian exactly when the full Hamiltonian is. *Price:* **free**; exact.

901. Hermitian block matrix, Schur complement of the second block. For all sizes m

and k, every complex m × m matrix A, every complex m × k matrix B, every complex k × k matrix D with D† = D and every complex k × k matrix W that is either a two-sided inverse of D (DW = 1 and WD = 1) or the zero matrix (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the block matrix M with rows (A B) and (B† D), of size m + k, is Hermitian (M† = M) if and only if the Schur complement A − BWB† is Hermitian. Here X† is the conjugate transpose of X. W stands for D^{-1} in the convention that gives a matrix with no inverse the inverse 0; the statement holds for either value. *Used for:* Low-energy effective Hamiltonians: eliminating a high-energy block D (shifted by a real energy) leaves A − $BD^{-1}B$† acting on the low-energy states, and that operator is Hermitian exactly when the full Hamiltonian is. *Price:* **free**; exact.

902. Positive semidefinite block matrix and its Schur complement. For all sizes m and k, every positive definite complex m × m matrix A, every complex m × k matrix B, every complex k × k matrix D and every complex m × m matrix W with AW = 1 and WA = 1 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the block matrix M with rows (A B) and (B† D), of size m + k, is positive semidefinite if and only if the Schur complement D − B†WB is positive semidefinite. Here X† is the conjugate transpose of X; a square complex matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, and positive definite when G† = G and the real part of ⟨x, Gx⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = Σ_i $\bar{x}_i y_i$ summed over all entries; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The inverse W of A is given. *Used for:* Gaussian conditioning in statistical physics and estimation: a joint covariance matrix with blocks A, B, B†, D is a valid covariance (positive semidefinite) exactly when the conditional covariance D − B†A^{-1}B is. *Price:* **free**; exact.

903. Positive semidefinite block matrix, Schur complement of the second block. For all sizes m and k, every complex m × m matrix A, every complex m × k matrix B, every positive definite complex k × k matrix D and every complex k × k matrix W with DW = 1 and WD = 1 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the block matrix M with rows (A B) and (B† D), of size m + k, is positive semidefinite if and only if the Schur complement A − BWB† is positive semidefinite. Here X† is the conjugate transpose of X; a square complex matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, and positive definite when G† = G and the real part of ⟨x, Gx⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = Σ_i $\bar{x}_i y_i$ summed over all entries; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The inverse W of D is given. *Used for:* Eliminating stiff or fast coordinates from a quadratic energy (static condensation, adiabatic elimination): with a positive definite block D, the full stiffness or Hessian matrix is positive semidefinite exactly when the effective stiffness A − $BD^{-1}B$† of the remaining coordinates is. *Price:* **free**; exact.

904. Positive definite block matrix and its Schur complement. For all sizes m and k, every positive definite complex m × m matrix A, every complex m × k matrix B, every complex k × k matrix D and every complex m × m matrix W with AW = 1 and WA = 1 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the block matrix M with rows (A B) and (B† D), of size m + k, is positive definite if and only if the Schur complement D − B†WB is positive definite. Here X† is the conjugate transpose of X; a square complex matrix G is positive definite when G† = G and the real part of ⟨x, Gx⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = Σ_i $\bar{x}_i y_i$ summed over all entries; x ≠ 0 means only that x is not the zero vector (the negation of x = 0). The inverse W of A is given. No principle beyond the hypotheses is needed: a positive definite matrix with at least one row already supplies the step from 'not zero' to 'positive' (Markov's principle), and when m = k = 0 there is nothing to prove. *Used for:* Stability of coupled systems: the Hessian of a two-block energy, such as strain coupled to an order parameter or two coupled sets of oscillators, is positive definite (a strict minimum, a stable equilibrium) exactly when one block and its Schur complement are; this test also decides convergence of a Gaussian integral over a block-partitioned quadratic form. *Price:* **free**; exact.

905. Finite sum of positive semidefinite matrices. For every size n, every number of terms N and all complex n × n matrices X(1), X(2), ..., X(N) (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that are each positive semidefinite: the sum X(1) + X(2) + ... + X(N) is positive semidefinite (for N = 0 the sum is the zero matrix). Here a square complex matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, with ⟨x, y⟩ = $\bar{x}_1 y_1$ + ... + $\bar{x}_n y_n$. *Used for:* Mixtures and noise sums: a density matrix written as a weighted sum of pure-state projectors, a Kraus sum Σ $K_i \rho K_i$† whose terms are each positive semidefinite, and a noise covariance summed over independent sources are positive semidefinite. *Price:* **free**; exact.

906. Resolvent of a Hermitian matrix off the real axis. For every size n, every complex n × n matrix H with H† = H (entries in the complex

numbers over the line, whose real and imaginary parts lie on the line) and every complex number z with $(\mathrm{Im}\ z)^2 > 0$, which holds whenever $\mathrm{Im}\ z > 0$ or $\mathrm{Im}\ z < 0$: the matrix $z - H$ (that is, $z \cdot 1 - H$) has a two-sided inverse, a complex $n \times n$ matrix R with $(z - H)R = 1$ and $R(z - H) = 1$. R is the resolvent $(z - H)^{-1}$. The hypothesis is a positive bound on Im z, not merely that Im z is not zero. *Used for:* Retarded and advanced Green's functions $G(E \pm i\eta) = (E \pm i\eta - H)^{-1}$ of a finite Hamiltonian exist for every real energy E and every broadening $\eta > 0$: spectral functions, local densities of states and Green's-function transport calculations at finite η. *Price:* **free**; exact.

907. Resolvent when the imaginary part is not zero. For every size n, every complex $n \times n$ matrix H with $H\dagger = H$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number z with $\mathrm{Im}\ z \neq 0$: the matrix $z - H$ (that is, $z \cdot 1 - H$) has a two-sided inverse, a complex $n \times n$ matrix R with $(z - H)R = 1$ and $R(z - H) = 1$. The hypothesis $\mathrm{Im}\ z \neq 0$ says only that $\mathrm{Im}\ z = 0$ is false, the negation of an equation; obtaining an inverse from it is the step that costs Markov's principle, which on the line says exactly that a real number that is not zero has an inverse. Already at size 1 with $H = 0$ the statement says that $i \cdot r$ has an inverse for every real $r \neq 0$. *Used for:* The textbook form of 'a Hermitian Hamiltonian has a Green's function $(z - H)^{-1}$ at every complex energy off the real axis', with off the axis stated as $\mathrm{Im}\ z \neq 0$, as in complex-energy contour integrals and the analytic continuation of Green's functions. *Price:* **MP**; exact.

908. Points of the spectrum of a Hermitian matrix are real. For every size n, every complex $n \times n$ matrix H with $H\dagger = H$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number z: if $z - H$ (that is, $z \cdot 1 - H$) has no two-sided inverse, then $\mathrm{Im}\ z = 0$. So every point of the spectrum of H, where $z - H$ fails to be invertible, lies on the real axis. *Used for:* Energies of a closed quantum system are real: the poles of the Green's function $(z - H)^{-1}$ of a Hermitian Hamiltonian lie on the real energy axis, and complex poles (resonances with a finite lifetime) need a non-Hermitian effective Hamiltonian. *Price:* **free**; exact.

909. Resolvent formula with a real positive denominator. For every size n, every complex $n \times n$ matrix H with $H\dagger = H$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), every complex number z and every complex $n \times n$ matrix W that is a two-sided inverse of $Q = (H - \mathrm{Re}\ z)^2 + (\mathrm{Im}\ z)^2 \cdot 1$ ($QW = 1$ and $WQ = 1$): the matrix $(\bar{z} - H)W$ is a two-sided inverse of $z - H$, where $\bar{z}$ is the complex conjugate of z and $z - H$ means $z \cdot 1 - H$. So $(z - H)^{-1} = (\bar{z} - H)((H - \mathrm{Re}\ z)^2 + (\mathrm{Im}\ z)^2)^{-1}$; the inverse W is given. *Used for:* Lorentzian broadening: with $z = E + i\eta$ the formula gives the anti-Hermitian part of $G(E + i\eta)$ as $-i\eta((H - E)^2 + \eta^2)^{-1}$, the matrix Lorentzian behind spectral functions and broadened densities of states. *Price:* **free**; exact.

910. First resolvent identity. For every size n, every complex $n \times n$ matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line; H need not be Hermitian), all complex numbers z and w, and all complex $n \times n$ matrices R(z) and R(w) such that R(z) is a two-sided inverse of $z - H$ and R(w) is a two-sided inverse of $w - H$ ($z - H$ meaning $z \cdot 1 - H$): $R(z) - R(w) = (w - z) \cdot R(z)R(w)$. Both resolvents are given. *Used for:* Green's functions at two complex energies: $G(z) - G(w) = (w - z)G(z)G(w)$ shows that the derivative of G with respect to z is $-G^2$, and gives the analytic structure of G used in spectral sum rules and many-body perturbation theory. *Price:* **free**; exact.

911. Resolvent norm bound by the imaginary part. For every size n, every complex $n \times n$ matrix H with $H\dagger = H$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), every complex number z and every complex $n \times n$ matrix R with $(z - H)R = 1$ and $R(z - H) = 1$ ($z - H$ meaning $z \cdot 1 - H$): $(\mathrm{Im}\ z)^2 \cdot \|Rx\|^2 \le \|x\|^2$ for every complex vector x, where $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. So the resolvent $(z - H)^{-1}$ has operator norm at most $1/|\mathrm{Im}\ z|$, here written without division. *Used for:* A broadening η bounds the response of a finite system: $\|G(E + i\eta)\| \le 1/\eta$ at every real energy E, the basic a priori estimate in linear-response theory and in Green's-function numerics at finite broadening. *Price:* **free**; exact.

912. Resolvent at a real energy inside a spectral gap. For every size n, every complex $n \times n$ matrix H with $H\dagger = H$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and all real numbers c and r on the line such that H has a spectral gap of half-width r around c, meaning $r > 0$ and $r^2\|x\|^2 \le \|(H - c)x\|^2$ for every complex vector x (so no eigenvalue lies strictly between $c - r$ and $c + r$): the matrix $c - H$ (that is, $c \cdot 1 - H$) has a two-sided inverse R, and $r^2\|Rx\|^2 \le \|x\|^2$ for every complex vector x. Here $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. So the resolvent $(c - H)^{-1}$ at the real number c exists and has operator norm at most $1/r$. *Used for:* Green's function at an energy inside a band gap: it exists and is bounded by one over the distance to the spectrum, which controls gap-energy Green's functions and evanescent states in insulators, perturbation theory around a gapped ground state and Riesz projections onto isolated bands. *Price:* **free**; exact.

913. Difference of two inverse matrices. For every size n and all complex $n \times n$ matrices A, B, W

and W′ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) such that either W is a two-sided inverse of A and W′ is a two-sided inverse of B (AW = WA = 1 and BW′ = W′B = 1), or W = 0 and W′ = 0: W − W′ = W(B − A)W′. When A and B are invertible this is $A^{-1} - B^{-1} = A^{-1}(B - A)B^{-1}$; the second case covers the convention that assigns the inverse 0 to a matrix with none, as when A and B are both singular. *Used for:* Dyson's equation in difference form: with A = E − H_0 − V and B = E − H_0 the identity reads G − G_0 = G V G_0, relating full and unperturbed propagators; it also gives the first-order change of any inverted response matrix. *Price:* **free**; exact.

914. Kronecker product of positive semidefinite matrices. For all sizes n and m, every positive semidefinite complex n × n matrix A and every positive semidefinite complex m × m matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the Kronecker product A ⊗ B is positive semidefinite. Here A ⊗ B is indexed by the n·m pairs (i, i′) and has entry A(i, j)·B(i′, j′) at row (i, i′) and column (j, j′); a square complex matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, with ⟨x, y⟩ = $\Sigma_p \bar{x}_p y_p$ summed over all pair indices p (respectively all indices of A or B). *Used for:* Uncorrelated composite systems: for density matrices ρ and σ of two independently prepared subsystems, ρ ⊗ σ is positive semidefinite, a valid joint state; separable (Kronecker) covariance models of space-time noise are valid covariances by this theorem. *Price:* **free**; exact.

915. Kronecker product of positive definite matrices. For all sizes n and m, every positive definite complex n × n matrix A and every positive definite complex m × m matrix B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the Kronecker product A ⊗ B is positive definite. Here A ⊗ B is indexed by the n·m pairs (i, i′) and has entry A(i, j)·B(i′, j′) at row (i, i′) and column (j, j′); a square complex matrix G is positive definite when G† = G and the real part of ⟨x, Gx⟩ is > 0 for every complex vector x ≠ 0, with ⟨x, y⟩ = $\Sigma_p \bar{x}_p y_p$ summed over all pair indices p (respectively all indices of A or B); x ≠ 0 means only that x is not the zero vector (the negation of x = 0). No principle beyond the hypotheses is needed: a positive definite A with at least one row already supplies the step from 'not zero' to 'positive' (Markov's principle), and when n = 0 there is nothing to prove. *Used for:* Thermal states of non-interacting subsystems: the product $e^{-\beta H_1}/Z_1 \otimes e^{-\beta H_2}/Z_2$ of two full-rank Gibbs states is positive definite, so the joint state is faithful and its logarithm and relative entropies are defined; and a tensor product of positive definite metrics is a positive definite metric on the tensor-product space. *Price:* **free**; exact.

916. Woodbury identity for a low-rank update. For all sizes n and k, every complex n × n matrix A with a given two-sided inverse A^{-1}, every complex n × k matrix U, every complex k × k matrix C with a given two-sided inverse C^{-1}, every complex k × n matrix V, and every complex k × k matrix S that is a two-sided inverse of $C^{-1} + VA^{-1}U$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the matrix $Y = A^{-1} - A^{-1}USVA^{-1}$ is a two-sided inverse of A + UCV, and every left or right inverse of A + UCV equals Y. So $(A + UCV)^{-1} = A^{-1} - A^{-1}U(C^{-1} + VA^{-1}U)^{-1}VA^{-1}$, with each inverse on the right given as a two-sided inverse. *Used for:* Dyson equation for a rank-k perturbation: the Green's function of H_0 plus a rank-k coupling follows from that of H_0 and one k × k inversion (T-matrix of a separable potential, impurity Green's functions, Lippmann–Schwinger equations with finite-rank interactions); also the covariance update of the Kalman filter. *Price:* **free**; exact.

917. Binomial inverse theorem for a low-rank update. For all sizes n and k, every complex n × n matrix A with a given two-sided inverse A^{-1}, every complex n × k matrix U, every complex k × k matrix C (not assumed invertible), every complex k × n matrix V, and every complex k × k matrix T that is a two-sided inverse of $C + CVA^{-1}UC$ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): the matrix $Y = A^{-1} - A^{-1}UCTCVA^{-1}$ is a two-sided inverse of A + UCV, and every left or right inverse of A + UCV equals Y. So $(A + UCV)^{-1} = A^{-1} - A^{-1}UC(C + CVA^{-1}UC)^{-1}CVA^{-1}$, with each inverse on the right given as a two-sided inverse. *Used for:* Rank-k Green's-function and covariance updates, as with the Woodbury identity (impurity and separable-potential T-matrices, Kalman-type updates), arranged so that only the k × k matrix $C + C{\cdot}V{\cdot}A^{-1}{\cdot}U{\cdot}C$ is inverted and the inverse of C never appears. *Price:* **free**; exact.

918. Matrix Chebyshev series with coefficients given as numbers. For every size n, every complex n × n matrix H with H† = H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and $-1 \preceq H \preceq 1$ (both 1 − H and 1 + H positive semidefinite), and every sequence of real coefficients $a_0, a_1, a_2, \ldots$ on the line, given only as numbers, with an explicit tail modulus for $\Sigma\,|a_k|$ (a function K such that $|a_p| + |a_{p+1}| + \ldots + |a_{p+m-1}| \le 1/(j+1)$ for every j, every $p \ge K(j)$ and every m): there is a complex n × n matrix F such that the partial sums of $a_0T_0(H) + a_1T_1(H) + a_2T_2(H) + \ldots$ converge entry by entry to F (real and imaginary parts), F† = F and FH =

HF; and for every n × n matrix V with V†V = 1 and real numbers $\lambda_1, \ldots, \lambda_n$ and $\mu_1, \ldots, \mu_n$ such that HV = V·diag($\lambda_1, \ldots, \lambda_n$) and, for each k, the scalar series $a_0T_0(\lambda_k) + a_1T_1(\lambda_k) + \ldots$ converges to μ_k, FV = V·diag($\mu_1, \ldots, \mu_n$). So F = f(H) for f(t) = $\Sigma\, a_kT_k(t)$ on every orthonormal eigenbasis. Here $T_0(H) = 1$, $T_1(H) = H$ and $T_{j+2}(H) = 2H\cdot T_{j+1}(H) - T_j(H)$, and $T_j(t)$ for a number t follows this recursion with t in place of H; a matrix G is positive semidefinite when G† = G and the real part of ⟨x, Gx⟩ is ≥ 0 for every complex vector x, with $\langle x, y\rangle = \bar{x}_1y_1 + \ldots + \bar{x}_ny_n$. Because the coefficients are given only as numbers, forming the limit uses the completeness of the line (a Cauchy sequence of points with a modulus has a limit), and the statement implies that completeness: at size 1 with H = 1 it says that every real series with an explicit tail modulus for $\Sigma\, |a_k|$ has a sum. *Used for:* Kernel polynomial method and Chebyshev propagators: $e^{-\beta H}$, cos(Ht), sin(Ht) or a Fermi function of a Hamiltonian rescaled into [−1, 1] is computed as the limit of $\Sigma\, a_kT_k(H)$, with no decision about the spectrum of H, here for coefficient sequences specified only as numbers. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

919. Moore–Penrose pseudoinverse of any square matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), with no rank hypothesis: there is an n × n matrix B, the Moore–Penrose pseudoinverse A^+, with ABA = A, BAB = B, (AB)† = AB and (BA)† = BA, where M† is the conjugate transpose of M. The construction runs Gram–Schmidt on the columns of A and of A† and must decide, for each column, whether its residual length (the pivot) is zero or apart from zero; that decision is exactly what costs the limited principle of omniscience (LPO). Already the 1 × 1 matrix A = (a) with a real forces it: ABA = A gives a(ar − 1) = 0 for the real part r of B, and that decides whether a is 0 or apart from 0. No countable choice is used. *Used for:* Inverting a matrix that may be singular: least-squares fits to a redundant or degenerate model, effective operators and response matrices with zero modes, and the pseudoinverse of a singular Fisher or covariance matrix in data analysis. *Price:* **LPO**; exact.

920. Generalized inverse of any square matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), with no rank hypothesis: there is an n × n matrix B with ABA = A (a generalized inverse, also called an inner inverse of A). Building B decides, for each column of A, whether its Gram–Schmidt residual length (the pivot) is zero or apart from zero, and that decision is exactly what costs the limited principle of omniscience (LPO). The lower bound is the 1 × 1 matrix A = (a) with a real: ABA = A gives a(ar − 1) = 0 for the real part r of B, which decides whether a is 0 or apart from 0. No countable choice is used. *Used for:* Solving a consistent linear system Ax = y whose matrix may be singular: if y = Ax_0 for some x_0, then x = By solves it, since A(By) = $ABAx_0 = Ax_0$ = y; used for constraint equations with gauge freedom and for linear response in redundant coordinates. *Price:* **LPO**; exact.

921. Normal equations of least squares are solvable. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex vector b of length n, with no rank hypothesis on A: the normal equations A†Ax = A†b have a solution x, where A† is the conjugate transpose of A. These are the equations of the least-squares problem of making ‖Ax − b‖ as small as possible; the row asserts only that they can be solved. Solving them decides, for each column of A, whether its Gram–Schmidt residual length (the pivot) is zero or apart from zero, and that decision is exactly what costs the limited principle of omniscience (LPO): already A = (a) with a real and b = (1) give $a^2x = a$, so a(ar − 1) = 0 for the real part r of the solution, which decides whether a is 0 or apart from 0. No countable choice is used. *Used for:* Linear least-squares fitting of measurements to a model that may be degenerate or over-parametrised: the fitted parameters solve the normal equations, as in detector calibration, spectral unmixing and linearised parameter estimation. *Price:* **LPO**; exact.

922. Orthogonal projector onto the range of a matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), with no rank hypothesis: there is an n × n matrix P that is Hermitian (P† = P) and idempotent ($P^2 = P$), with PA = A and Px = 0 for every complex vector x with A†x = 0. So P is the orthogonal projector onto the range (column space) of A: it fixes every column of A and kills every vector orthogonal to all the columns. The price is the weak limited principle of omniscience (WLPO) together with countable choice. The upper bound takes a singular value decomposition A = U diag($s_1, \ldots, s_n$) V† (which costs LLPO with countable choice, and WLPO gives LLPO) and decides only whether each singular value is zero or not zero, never an inverse of it, setting P = U diag($e_1, \ldots, e_n$) U† with each e_j equal to 0 or 1. The lower bound, with no choice, is the 1 × 1 matrix A = (a) with a real: P = (p) has p real, $p^2 = p$, pa = a and p = 0 when a = 0, and comparing p with 0 and 1 decides whether a = 0 or a ≠ 0. *Used for:* The projector onto

the column space of a design or measurement matrix (the hat matrix of least squares), the signal subspace in subspace methods of spectroscopy and array processing, and restriction to the states reachable through a given coupling, all without knowing the rank in advance. *Price:* **WLPO + AC$_\omega$**; exact.

923. Orthogonal projector onto the kernel of a matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), with no rank hypothesis: there is an n × n matrix K that is Hermitian (K† = K) and idempotent (K² = K), with AK = 0 and Kx = x for every complex vector x with Ax = 0. So K is the orthogonal projector onto the kernel (null space) of A: its range is exactly the set of zero modes of A. The price is the weak limited principle of omniscience (WLPO) together with countable choice. The upper bound is K = 1 − Q, with Q the orthogonal projector onto the range of A†, which comes from a singular value decomposition (LLPO with countable choice; WLPO gives LLPO) by deciding only whether each singular value is zero or not zero. The lower bound, with no choice, is the 1 × 1 matrix A = (a) with a real: K = (k) has k real, $k^2 = k$, ak = 0 and k = 1 when a = 0, and comparing k with 0 and 1 decides whether a = 0 or a ≠ 0. *Used for:* Isolating zero modes without knowing how many there are: gauge directions of a constraint matrix, translational and rotational zero modes of a Hessian or stiffness matrix, and the zero-energy subspace of a Hamiltonian. *Price:* **WLPO + AC$_\omega$**; exact.

924. Pseudoinverse of a matrix with invertible determinant. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex number e with det(A)·e = 1 (an inverse of the determinant is given): there is an n × n matrix B with AB = 1 and BA = 1 that also satisfies the four Penrose equations ABA = A, BAB = B, (AB)† = AB and (BA)† = BA, where M† is the conjugate transpose of M. So for a matrix of full rank, given through an invertible determinant, the Moore–Penrose pseudoinverse is the ordinary inverse; the proof takes B = e·adj(A), with adj(A) the adjugate of A, and needs no decision. *Used for:* Matrices certified nonsingular by an explicit inverse of the determinant, such as a nondegenerate metric, a normal-mode matrix with no zero frequency or the Jacobian of a change of variables: inverse and pseudoinverse coincide and cost nothing. *Price:* **free**; exact.

925. Pseudoinverse with uniformly independent columns. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) whose columns are uniformly independent, meaning there is a real number ε > 0 on the line with $\|Ac\|^2 \geq \varepsilon\|c\|^2$ for every complex vector c, where $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$: there is an n × n matrix B with AB = 1 and BA = 1 that satisfies the four Penrose equations ABA = A, BAB = B, (AB)† = AB and (BA)† = BA, where M† is the conjugate transpose of M. So for a square matrix of full rank, given as a certified lower bound on $\|Ac\|$, the Moore–Penrose pseudoinverse is the two-sided inverse, and finding it needs no decision. *Used for:* Inverting a well-conditioned square system whose smallest singular value has a known positive lower bound, as for a calibrated detector response or a transfer matrix with a certified gap above zero: the pseudoinverse is the inverse and costs nothing. *Price:* **free**; exact.

926. Least squares with uniformly independent vectors. For all sizes n and k, every list of k complex vectors $v_1, \dots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is uniformly independent, meaning there is a real number ε > 0 on the line with $\|c_1v_1 + \dots + c_kv_k\|^2 \geq \varepsilon(|c_1|^2 + \dots + |c_k|^2)$ for all complex numbers $c_1, \dots, c_k$, and every complex vector b of length n: the equations Gc = $(\langle v_1, b\rangle, \dots, \langle v_k, b\rangle)$ have exactly one solution c = $(c_1, \dots, c_k)$, where G is the k × k Gram matrix with entries $G_{ij} = \langle v_i, v_j\rangle$. For the n × k matrix A whose columns are $v_1, \dots, v_k$, these are the normal equations A†Ac = A†b of fitting b by $c_1v_1 + \dots + c_kv_k$ in least squares. Here $\langle x, y\rangle = \bar{x}_1y_1 + \dots + \bar{x}_ny_n$ and $\|x\|^2 = \langle x, x\rangle$. No decision is needed: G has a two-sided inverse. *Used for:* Fitting data to k known templates or basis functions with a certified non-degenerate overlap: the coefficients of a spectral fit with known line shapes, or of a state expanded in a non-orthogonal basis, exist and are unique. *Price:* **free**; exact.

927. Projection onto the span of independent vectors. For all sizes n and k and every list of k complex vectors $v_1, \dots, v_k$ of length n (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is uniformly independent, meaning there is a real number ε > 0 on the line with $\|c_1v_1 + \dots + c_kv_k\|^2 \geq \varepsilon(|c_1|^2 + \dots + |c_k|^2)$ for all complex numbers $c_1, \dots, c_k$: there is an n × n matrix P that is Hermitian (P† = P) and idempotent ($P^2 = P$), fixes every v_i ($Pv_i = v_i$) and kills every vector orthogonal to all of them (if $\langle v_i, x\rangle = 0$ for every i, then Px = 0). So P is the orthogonal projection onto the span of $v_1, \dots, v_k$. Here $\langle x, y\rangle = \bar{x}_1y_1 + \dots + \bar{x}_ny_n$ and $\|x\|^2 = \langle x, x\rangle$. No decision is needed: the proof orthonormalises the vectors and adds up the projectors onto the results. *Used for:* Projecting onto a model space spanned by known independent states: a set of non-orthogonal atomic orbitals in quantum

chemistry, the model space of an effective Hamiltonian, or the span of independent signal templates. *Price:* **free**; exact.

928. Logarithm of a uniformly positive matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian ($A\dagger = A$) and uniformly positive, meaning there is a real number $s > 0$ on the line with $\mathrm{Re}\langle x, Ax\rangle \geq s\|x\|^2$ for every complex vector x: there is an n × n matrix L, the logarithm $\log A$, that is Hermitian ($L\dagger = L$), commutes with A ($LA = AL$) and has $\exp(L) = A$, where $\exp(X) = E$ means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E. L acts as the ordinary logarithm on every eigenbasis: whenever V is an n × n matrix with $V\dagger V = 1$ and $AV = V\,\mathrm{diag}(\lambda_1, \dots, \lambda_n)$ for real numbers $\lambda_1, \dots, \lambda_n$, and $\mu_1, \dots, \mu_n$ are real numbers with $\exp(\mu_k) = \lambda_k$, then $LV = V\,\mathrm{diag}(\mu_1, \dots, \mu_n)$. No eigenbasis is used to build L: it comes from the series $\log(1 - Y) = -(Y + Y^2/2 + Y^3/3 + \dots)$ applied to $Y = 1 - A/K$ for a suitable real number $K > 0$. Here $\langle x, y\rangle = \bar{x}_1 y_1 + \dots + \bar{x}_n y_n$ and $\|x\|^2 = \langle x, x\rangle$. *Used for:* The logarithm of a positive operator: the modular (entanglement) Hamiltonian $-\log \rho$ of a faithful state, the relative entropy $\mathrm{tr}\,\rho(\log \rho - \log \sigma)$, and an effective Hamiltonian read off as the logarithm of a positive transfer matrix. *Price:* **free**; exact.

929. Real powers of a uniformly positive matrix. For every size n and every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian ($A\dagger = A$) and uniformly positive, meaning there is a real number $s > 0$ on the line with $\mathrm{Re}\langle x, Ax\rangle \geq s\|x\|^2$ for every complex vector x: there are a Hermitian n × n matrix L that commutes with A and has $\exp(L) = A$, and a matrix P(t) for every real number t on the line with $P(t) = \exp(t \cdot L)$, such that every P(t) is Hermitian and commutes with A, $P(0) = 1$, $P(1) = A$, $P(t)P(u) = P(t + u)$ for all real numbers t and u, and $P(1/2)$ is positive semidefinite (Hermitian with $\mathrm{Re}\langle x, P(1/2)x\rangle \geq 0$ for every x) with $P(1/2)^2 = A$. So $P(t) = A^t = \exp(t \log A)$ are the real powers of A, negative powers included, and $P(1/2)$ is a positive square root of A. Here $\exp(X) = E$ means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\langle x, y\rangle = \bar{x}_1 y_1 + \dots + \bar{x}_n y_n$ and $\|x\|^2 = \langle x, x\rangle$. *Used for:* Real powers of a positive operator: $\rho^{1/2}$ in the fidelity and in purifications, ρ^{α} in Rényi entropies, $S^{-1/2}$ for an overlap matrix S in Löwdin orthogonalisation, and interpolations between two positive metrics. *Price:* **free**; exact.

930. Entropy sign for a state bounded by the identity. For every size n and every complex n × n matrix ρ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian, uniformly positive (there is a real number $s > 0$ on the line with $\mathrm{Re}\langle x, \rho x\rangle \geq s\|x\|^2$ for every complex vector x) and below the identity, $\rho \preceq 1$ ($\mathrm{Re}\langle x, \rho x\rangle \leq \|x\|^2$ for every x): there is an n × n matrix L, the logarithm of ρ, that is Hermitian, commutes with ρ, has $\exp(L) = \rho$, and satisfies $LV = V\,\mathrm{diag}(\mu_1, \dots, \mu_n)$ whenever $V\dagger V = 1$, $\rho V = V\,\mathrm{diag}(\lambda_1, \dots, \lambda_n)$ with real numbers λ_k, and μ_k are real numbers with $\exp(\mu_k) = \lambda_k$; and the real part of $\mathrm{tr}(\rho L)$ is ≤ 0. So the von Neumann entropy $S(\rho) = -\mathrm{tr}(\rho \log \rho)$ is nonnegative (stated for its real part). Here $\exp(X) = E$ means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\langle x, y\rangle = \bar{x}_1 y_1 + \dots + \bar{x}_n y_n$ and $\|x\|^2 = \langle x, x\rangle$. *Used for:* Nonnegativity of the von Neumann entropy of a full-support state given with the operator bound $\rho \preceq 1$, as for a reduced density matrix of a subsystem: the base case of entropy inequalities for finite quantum systems. *Price:* **free**; exact.

931. Entropy sign for a full-rank density matrix. For every size n and every complex n × n matrix ρ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian, uniformly positive (there is a real number $s > 0$ on the line with $\mathrm{Re}\langle x, \rho x\rangle \geq s\|x\|^2$ for every complex vector x) and of trace 1 (the real part of $\rho_{11} + \dots + \rho_{nn}$ is 1, which for a Hermitian matrix is the whole trace): there is an n × n matrix L, the logarithm of ρ, that is Hermitian, commutes with ρ, has $\exp(L) = \rho$, and satisfies $LV = V\,\mathrm{diag}(\mu_1, \dots, \mu_n)$ whenever $V\dagger V = 1$, $\rho V = V\,\mathrm{diag}(\lambda_1, \dots, \lambda_n)$ with real numbers λ_k, and μ_k are real numbers with $\exp(\mu_k) = \lambda_k$; and the real part of $\mathrm{tr}(\rho L)$ is ≤ 0. So the von Neumann entropy $S(\rho) = -\mathrm{tr}(\rho \log \rho)$ of a density matrix of full rank is nonnegative (stated for its real part). The row covers only density matrices bounded below by a positive multiple of the identity: a density matrix with a zero eigenvalue, such as a pure state, is outside it. Here $\exp(X) = E$ means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\langle x, y\rangle = \bar{x}_1 y_1 + \dots + \bar{x}_n y_n$ and $\|x\|^2 = \langle x, x\rangle$. *Used for:* The von Neumann entropy of a mixed state with full support is nonnegative, for example a thermal state $\exp(-\beta H)/Z$ at finite temperature: the entropy S in the free energy $F = E - TS$ and in the second law. *Price:* **free**; exact.

932. Lie–Trotter product formula with its error bound. For every size n, all complex n × n matrices H_1 and H_2 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that are Hermitian ($H_1\dagger = H_1$, $H_2\dagger = H_2$), every real number t on the line, every real number $c \geq 0$ that bounds the commutator in operator norm ($\|(H_1H_2 - H_2H_1)x\| \leq c\|x\|$ for every complex vector x) and every

number of steps $M = m + 1 \geq 1$: if $E = \exp(-it(H_1 + H_2))$, $E_1 = \exp(-itH_1/M)$ and $E_2 = \exp(-itH_2/M)$, then $\|(E - (E_1E_2)^M)x\| \leq (t^2c/(2M))\|x\|$ for every complex vector x. So alternating the two evolutions in M short steps reproduces the full evolution with operator-norm error at most $t^2\|[H_1, H_2]\|/(2M)$. Here $\exp(X) = E$ means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$. *Used for:* Trotterised time evolution: split-operator integration of the Schrödinger equation, Suzuki–Trotter steps in digital quantum simulation and time slicing in path integrals, with the number of steps for a target accuracy read off from $t^2\|[H_1, H_2]\|/(2M)$. *Price:* **free**; exact.

933. Every complex matrix has an eigenvector. For every size $n \geq 1$ and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): there are a complex vector v with $\langle v, v\rangle = 1$ and a complex number μ with $Av = \mu v$, where $\langle x, y\rangle = \bar{x}_1y_1 + \dots + \bar{x}_ny_n$. So every complex square matrix has a unit eigenvector. Already 2×2 Hermitian matrices force LLPO, with no choice. With no principle at all, the statement gives an exact root of every monic complex polynomial of degree at least 1, through its companion matrix. *Used for:* Existence of a normal mode or stationary state for any finite linear dynamics, Hermitian or not: damped oscillators, non-Hermitian effective Hamiltonians of open systems, transfer and Floquet matrices, and rate matrices of Markov processes. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact: the statement implies LLPO with no choice; conversely, under LLPO and countable choice the statement holds exactly when the approximate fundamental theorem of algebra holds (every monic complex polynomial p of degree at least 1 has, for every k, a point z with $|p(z)|^2 \leq 1/(k+1)$), and the exact fundamental theorem of algebra, which is free (row 482), gives the approximate one.

934. Schur triangularization of a complex matrix. For every size n and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): there are $n \times n$ matrices U and T with $U\dagger U = 1$ (U is unitary), T upper triangular (every entry below the diagonal is 0) and $AU = UT$, that is $A = UTU\dagger$. With no principle, this is equivalent to the statement that every complex $n \times n$ matrix with $n \geq 1$ has a unit eigenvector (row 933): the first column of U is such an eigenvector, and conversely unit eigenvectors triangularise A one column at a time. *Used for:* Triangularising a non-normal matrix by a unitary change of basis: the Schur form behind numerically stable eigenvalue algorithms, the analysis of non-Hermitian Hamiltonians and Liouvillians of open quantum systems, and transient growth in hydrodynamic stability. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact: through the equivalence above it has the price of row 933, which rests on the free fundamental theorem of algebra (row 482); the statement implies LLPO with no choice.

935. Operator norm of a complex matrix exists. For every size $n \geq 1$ and every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): there is a real number c on the line that is the operator norm of A and also the operator norm of $A\dagger$, and whose square c^2 is the operator norm of $A\dagger A$, where $A\dagger$ is the conjugate transpose of A. So $\|A\|$, the supremum of $\|Ax\|$ over unit vectors x, exists as a number, with $\|A\dagger\| = \|A\|$ and $\|A\dagger A\| = \|A\|^2$ (the C*-identity). Here a real number c is the operator norm of a matrix M when $c \geq 0$, $\|Mx\|^2 \leq c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j + 1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \geq c^2 - 1/(j + 1)$; $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$. The construction finds c^2 as the top value of $\|Ax\|^2$ over unit vectors without deciding any comparison. The size must be at least one: the empty 0×0 matrix has no unit vector, so no number meets the last clause. *Used for:* The largest factor by which an operator can amplify a state: the norm in every perturbation and error bound of quantum dynamics ($\|H_1 - H_2\|$, $\|[A, B]\|$), the spectral norm behind condition numbers and numerical stability, and the size of a coupling or of a gate error. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

936. Operator norm is unique. For every size n, every complex $n \times n$ matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and all real numbers a and b on the line: if a and b are both operator norms of A, then $a = b$. Here a real number c is the operator norm of a matrix M when $c \geq 0$, $\|Mx\|^2 \leq c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j + 1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \geq c^2 - 1/(j + 1)$; $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$. So the operator norm, defined by its properties, names a single number. *Used for:* Lets the operator norm be used as a definite quantity: two computations of the largest amplification of one operator, for example by power iteration and from an eigenvalue bound, must agree on its value. *Price:* **free**; exact.

937. Submultiplicativity of the operator norm. For every size n, all complex $n \times n$ matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and all real numbers a, b and c on the line: if a is the operator norm of A, b is the operator norm of B and c is the operator norm of the product AB, then $c \leq ab$. So $\|AB\|$

$\le \|A\|\|B\|$. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Error growth through a sequence of operations: a product of time steps, gates or transfer matrices is bounded by the product of their norms, as in stability estimates for time-stepping schemes and in the growth of perturbations along a chain of transfer matrices. *Price:* **free**; exact.

938. Triangle inequality for the operator norm. For every size n, all complex n × n matrices A and B (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and all real numbers a, b and c on the line: if a is the operator norm of A, b is the operator norm of B and c is the operator norm of A + B, then $c \le a + b$. So $\|A + B\| \le \|A\| + \|B\|$. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Adding up error sources: a Hamiltonian $H_0 + V_1 + V_2$ with two perturbations has $\|V_1 + V_2\| \le \|V_1\| + \|V_2\|$, the step that combines separate error terms in perturbation bounds and in Trotter error budgets. *Price:* **free**; exact.

939. Operator norm is unchanged by unitary factors. For every size n, all complex n × n matrices U and A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $U\dagger U = 1$ and $UU\dagger = 1$ (U is unitary; U† is its conjugate transpose), and every real number a on the line: if a is the operator norm of A, then a is also the operator norm of UA and of AU. So $\|UA\| = \|AU\| = \|A\|$. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Norms do not depend on the basis or the picture: an operator keeps its norm after any change of orthonormal basis and in the interaction picture, so error bounds survive unitary frame changes such as the rotating frames of NMR and qubit control. *Price:* **free**; exact.

940. Norm of a diagonalized Hermitian matrix from its eigenvalues. For every size n, all complex n × n matrices H and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $V\dagger V = 1$ and $VV\dagger = 1$ (V is unitary; V† is its conjugate transpose), all real numbers $\lambda_1, \ldots, \lambda_n$ on the line with $HV = V\cdot\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ (a given orthonormal diagonalization of H, which makes H Hermitian), and every real number c that is the operator norm of H: $|\lambda_k| \le c$ for every k, and for every tolerance $1/(j+1)$ some index k has $\lambda_k^2 \ge c^2 - 1/(j+1)$. So $\|H\| = \max|\lambda_k|$, stated without naming an index where the maximum is reached. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* The norm of a Hamiltonian or an observable is its largest eigenvalue in absolute value: $\|H\| = \max|E_k|$ sets the stable time step of explicit integrators, the spectral window of Chebyshev and Krylov propagators, and the strength of a perturbation in energy units. *Price:* **free**; exact.

941. Operator norm compared with the Frobenius norm. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every real number c on the line that is the operator norm of A: $c^2 \le \mathrm{Re}\,\mathrm{tr}(A\dagger A) \le n\cdot c^2$, where A† is the conjugate transpose of A and $\mathrm{tr}(A\dagger A) = \Sigma\,|A_{il}|^2$, summed over all entries, is the squared Frobenius norm $F(A)^2$. So $\|A\| \le F(A) \le \sqrt{n}\cdot\|A\|$. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Cheap, computable bounds on the operator norm: the Frobenius norm, the square root of the sum of all squared matrix elements, brackets $\|A\|$ within a factor $\sqrt{n}$, used to bound coupling strengths and errors in large numerical problems where the largest eigenvalue is too expensive to find. *Price:* **free**; exact.

942. Matrix entries and the operator norm bound each other. For every size n, every complex n × n matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every real number c on the line that is the operator norm of A: $|A_{il}|^2 \le c^2$ for every entry A_{il}; and $c \le n\cdot K$ for every real number $K \ge 0$ with $|A_{il}|^2 \le K^2$ for every entry. So no entry exceeds $\|A\|$ in absolute value, and $\|A\| \le n\cdot\max|A_{il}|$. Here a real number c is the operator norm of a matrix M when $c \ge 0$, $\|Mx\|^2 \le c^2\|x\|^2$ for every complex vector x, and for every tolerance $1/(j+1)$ some unit vector x ($\|x\|^2 = 1$) has $\|Mx\|^2 \ge c^2 - 1/(j+1)$; $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Estimating the strength of a Hamiltonian from its matrix elements: a tight-binding or spin Hamiltonian on n states whose couplings are all at most K in size has $\|H\| \le n\cdot K$, and one large matrix element forces a large norm; used for quick bounds on energy ranges and time steps. *Price:* **free**; exact.

943. Moore–Penrose pseudoinverse of any rectangular matrix. For all sizes n and m and every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary

parts lie on the line), with no rank hypothesis: there is a complex m × n matrix B, the Moore–Penrose pseudoinverse A^+, with ABA = A, BAB = B, (AB)† = AB and (BA)† = BA, where M† is the conjugate transpose of M. The price is exactly the limited principle of omniscience (LPO), with no countable choice. The upper bound places A in the top-left corner of a square matrix of size n + m, filled with zeros elsewhere, takes the square pseudoinverse (which costs LPO) and keeps its m × n corner block. The lower bound is already the 1 × 1 case A = (a) with a real: ABA = A gives a(ar − 1) = 0 for the real part r of B, and that decides whether a is 0 or apart from 0. *Used for:* Fitting m model parameters to n measurements when the design matrix may be rank-deficient: the pseudoinverse gives the minimum-norm least-squares estimate in detector unfolding, tomographic reconstruction and the calibration of over- or under-determined linear models. *Price:* **LPO**; exact.

944. Normal equations of a rectangular least-squares problem are solvable. For all sizes n and m, every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every complex vector b of length n, with no rank hypothesis on A: the normal equations A†Ax = A†b have a solution x, a complex vector of length m, where A† is the conjugate transpose of A. These are the equations of the least-squares problem of making $\|Ax - b\|$ as small as possible (n measurements, m parameters); the row asserts only that they can be solved. The price is exactly the limited principle of omniscience (LPO), with no countable choice. The upper bound takes x = A^+b with the Moore–Penrose pseudoinverse A^+, since $A†AA^+ = A†(AA^+)† = (AA^+A)† = A†$. The lower bound is already A = (a) with a real and b = (1): $a^2x = a$ gives a(ar − 1) = 0 for the real part r of x, which decides whether a is 0 or apart from 0. *Used for:* Linear least-squares fitting with more measurements than parameters or a degenerate model: the fitted parameters of a calibration curve, a spectral decomposition or a linearised orbit determination solve the normal equations, whatever the rank of the design matrix. *Price:* **LPO**; exact.

945. Pseudoinverse of a matrix with uniformly independent columns. For all sizes n and m and every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) whose columns are uniformly independent, meaning there is a real number ε > 0 on the line with $\|Ax\|^2 \geq \varepsilon\|x\|^2$ for every complex vector x of length m, where $\|x\|^2 = |x_1|^2 + \ldots + |x_m|^2$: there is a complex m × n matrix B with BA = 1 (the m × m identity) that also satisfies the four Penrose equations ABA = A, BAB = B, (AB)† = AB and (BA)† = BA, where M† is the conjugate transpose of M. So B is both the Moore–Penrose pseudoinverse and a left inverse of A. It is B = $(A†A)^{-1}A†$, where the inverse of A†A is a convergent series with an explicit rate, so no decision is needed. *Used for:* Overdetermined fits with a certified non-degenerate design, where every parameter direction moves the predictions by a definite amount, as in a well-conditioned calibration or a fit to known line shapes: the estimator $(A†A)^{-1}A†b$ then costs nothing. *Price:* **free**; exact.

946. Pseudoinverse of a matrix with uniformly independent rows. For all sizes n and m and every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) whose rows are uniformly independent, meaning there is a real number ε > 0 on the line with $\|A†y\|^2 \geq \varepsilon\|y\|^2$ for every complex vector y of length n, where A† is the conjugate transpose of A and $\|y\|^2 = |y_1|^2 + \ldots + |y_n|^2$: there is a complex m × n matrix B with AB = 1 (the n × n identity) that also satisfies the four Penrose equations ABA = A, BAB = B, (AB)† = AB and (BA)† = BA. So B is both the Moore–Penrose pseudoinverse and a right inverse of A. It is B = $A†(AA†)^{-1}$, built with no decision. *Used for:* Underdetermined linear systems with independent constraints, more unknowns than equations: distributing a required field or force over redundant coils or actuators, or reconstructing a source from fewer sensors than unknowns; the right inverse $A†(AA†)^{-1}$ meets every target exactly. *Price:* **free**; exact.

947. Minimum-norm solution of an underdetermined system. For all sizes n and m and every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) whose rows are uniformly independent (there is a real number ε > 0 on the line with $\|A†y\|^2 \geq \varepsilon\|y\|^2$ for every complex vector y of length n, where A† is the conjugate transpose of A): the n × n matrix AA† has a two-sided inverse W (AA†W = 1 and WAA† = 1), and for every complex vector b of length n the vector x = A†Wb has three properties: Ax = b; x is the only solution of Ax = b of the form A†w for a complex vector w (the only solution in the range of A†); and every solution x′ of Ax′ = b satisfies $\|x'\|^2 = \|x\|^2 + \|x' - x\|^2$, so x is the solution of least norm. Here $\|x\|^2 = |x_1|^2 + \ldots + |x_m|^2$. *Used for:* Choosing the least-effort solution when the constraints leave freedom: minimum-energy control inputs, minimum-norm current estimates in magnetoencephalography and EEG source imaging, and the smallest correction that meets a set of linear constraints in beam steering. *Price:* **free**; exact.

948. Least-squares Pythagorean identity. For all

sizes n and m, every complex n × m matrix A (entries in the complex numbers over the line, whose real and imaginary parts lie on the line), every complex vector b of length n and every complex vector x_0 of length m that solves the normal equations $A\dagger Ax_0 = A\dagger b$, where $A\dagger$ is the conjugate transpose of A, with no rank hypothesis: for every complex vector x of length m, $\|Ax - b\|^2 = \|Ax_0 - b\|^2 + \|A(x - x_0)\|^2$, where $\|y\|^2 = |y_1|^2 + \ldots + |y_k|^2$ for a vector of length k. So every solution of the normal equations makes $\|Ax - b\|$ as small as possible, and any other x is worse by exactly $\|A(x - x_0)\|^2$. *Used for:* The geometry of a least-squares fit: the residual of the best fit is orthogonal to everything the model can predict, which splits the total squared error into the best-fit residual plus the model-space part, the decomposition behind χ^2 goodness-of-fit tests and the analysis of variance. *Price:* **free**; exact.

949. Truncation error of a given singular value decomposition. For every size n, all complex n × n matrices A, U and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with $U\dagger U = 1$, $V\dagger V = 1$ and $AV = U\cdot\mathrm{diag}(s_1, \ldots, s_n)$ for real numbers $s_1, \ldots, s_n$ on the line (a given singular value decomposition $A = U\cdot\mathrm{diag}(s_1, \ldots, s_n)\cdot V\dagger$; the s_k need not be ordered or nonnegative), and every set S of indices among 1, ..., n (given by a yes-or-no value for each index): let $E = A - \sum_k s_k u_k v_k\dagger$, the sum running over the indices k not in S, where u_k and v_k are the k-th columns of U and V. Then the real part of $\mathrm{tr}(E\dagger E)$ equals $\sum_k s_k{}^2$, the sum running over the indices k in S. So dropping a set of singular triples leaves a squared Frobenius error equal to the sum of the squares of the dropped singular values. Here $M\dagger$ is the conjugate transpose of M and tr(M) the sum of its diagonal entries. *Used for:* Low-rank compression with a known error: truncating a Schmidt decomposition or a matrix product state in DMRG and tensor-network simulations, where the discarded weight $\Sigma\, s_k{}^2$ is exactly the squared error, and principal component analysis of data. *Price:* **free**; exact.

950. Evolution depends Lipschitz-continuously on the Hamiltonian. For every size n, all complex n × n matrices H_1 and H_2 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that are Hermitian ($H_1\dagger = H_1$ and $H_2\dagger = H_2$), all real numbers t and c ≥ 0 on the line such that c bounds the difference in operator norm ($\|(H_1 - H_2)x\|^2 \le c^2\|x\|^2$ for every complex vector x): if $E_1 = \exp(-itH_1)$ and $E_2 = \exp(-itH_2)$, then $\|(E_1 - E_2)x\|^2 \le (|t|c)^2\|x\|^2$ for every complex vector x. So $\|e^{-itH_1} - e^{-itH_2}\| \le |t|\|H_1 - H_2\|$ in operator norm. The proof replaces Duhamel's integral formula by many short time steps and needs no integral. Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \ldots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Comparing two models of one system: the true Hamiltonian and an approximation of it (a truncated basis, an effective or mean-field Hamiltonian) give evolutions that differ by at most $|t|\|H_1 - H_2\|$ at time t, the bound used for error budgets in Hamiltonian simulation and quantum control. *Price:* **free**; exact.

951. Evolved state under a perturbed Hamiltonian. For every size n, all complex n × n matrices H and V (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that are Hermitian ($H\dagger = H$ and $V\dagger = V$), all real numbers t and v ≥ 0 on the line such that v bounds V in operator norm ($\|Vx\|^2 \le v^2\|x\|^2$ for every complex vector x), and every complex vector ψ of length n: if $E_1 = \exp(-i\cdot t\cdot(H + V))$ and $E_2 = \exp(-i\cdot t\cdot H)$, then $\|E_1\psi - E_2\psi\|^2 \le (|t|v)^2\|\psi\|^2$. So adding a perturbation V to the Hamiltonian moves the state evolved for a time t by at most $|t|\|V\|\|\psi\|$. Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \ldots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* Robustness of quantum dynamics to an unknown or neglected term: a stray field, a residual coupling or a calibration error V shifts the evolved state by at most $|t|\|V\|\|\psi\|$, which sets how long a quantum simulation or a gate sequence stays faithful to the intended Hamiltonian. *Price:* **free**; exact.

952. Short-time evolution stays close to the identity. For every size n, every complex n × n matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian ($H\dagger = H$), every real number τ on the line and every real number K ≥ 0 that bounds H in operator norm ($\|Hx\|^2 \le K^2\|x\|^2$ for every complex vector x): if $E = \exp(-i\tau H)$, then $\|(E - 1)x\|^2 \le (|\tau|K)^2\|x\|^2$ for every complex vector x. So the evolution over a time τ differs from the identity by at most $|\tau|\|H\|$ in operator norm. Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \ldots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \ldots + |x_n|^2$. *Used for:* A Hamiltonian of strength $\|H\|$ acting for a time τ moves any state ψ by at most $|\tau|\|H\|\|\psi\|$: the short-time estimate behind step-size control in numerical quantum dynamics, and a crude limit on how fast a quantum state can change under a bounded Hamiltonian. *Price:* **free**; exact.

953. Unitary evolution is Lipschitz in time. For every size n, every complex n × n matrix H (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is Hermitian ($H\dagger = H$), all real numbers t and s on the line and every real number K ≥ 0 that bounds H in operator norm ($\|Hx\|^2 \le K^2\|x\|^2$ for every complex vector x): if $E_t = \exp(-i\cdot t\cdot H)$ and $E_s = \exp(-i\cdot s\cdot H)$, then $\|(E_t - E_s)x\|^2 \le (|t$

$- s|K)^2\|x\|^2$ for every complex vector x. So $\|e^{-i\cdot t\cdot H} - e^{-i\cdot s\cdot H}\| \le |t - s|\|H\|$: the evolution is Lipschitz in time with constant $\|H\|$. Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$. *Used for:* Timing errors in quantum dynamics: a state read out or stored at time s instead of t differs by at most $|t - s|\|H\|\|\psi\|$, which bounds the effect of timing jitter in pulse sequences and the error of interpolating between saved time steps of a simulation. *Price:* **free**; exact.

954. Strang splitting with its error bound. For every size n, all complex n × n matrices H_1 and H_2 (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that are Hermitian ($H_1\dagger = H_1$ and $H_2\dagger = H_2$), every real number t on the line, all real numbers $c_1 \ge 0$ and $c_2 \ge 0$ that bound the double commutators in operator norm ($\|[H_1, [H_1, H_2]]x\|^2 \le {c_1}^2\|x\|^2$ and $\|[H_2, [H_1, H_2]]x\|^2 \le {c_2}^2\|x\|^2$ for every complex vector x, where [X, Y] = XY − YX), and every number of steps M = m + 1 ≥ 1: put $\tau = t/M$, $E = \exp(-it(H_1 + H_2))$, $A = \exp(-i\tau H_1/2)$ and $B = \exp(-i\tau H_2)$. Then $\|(E - (ABA)^M)x\|^2 \le r^2\|x\|^2$ for every complex vector x, with $r = |t|^3(c_1/8 + c_2/12)/M^2$. So the Strang step (half a step of H_1, a full step of H_2, another half step of H_1), repeated M times, reproduces the full evolution with operator-norm error at most $|t|^3(\|[H_1, [H_1, H_2]]\|/8 + \|[H_2, [H_1, H_2]]\|/12)/M^2$. Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E, and $\|x\|^2 = |x_1|^2 + \dots + |x_n|^2$. *Used for:* Second-order splitting of quantum dynamics: the split-step Fourier method for the Schrödinger equation (half a kinetic step, a full potential step, half a kinetic step), second-order Trotter–Suzuki circuits in digital quantum simulation and symmetric time slicing of path integrals, with the number of steps for a target accuracy read off from the $1/M^2$ error. *Price:* **free**; exact.

955. Von Neumann entropy of every density matrix. For every size n and every complex n × n matrix ρ (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is a density matrix, meaning positive semidefinite ($\rho\dagger = \rho$ and the real part of $\langle x, \rho x\rangle$ is ≥ 0 for every complex vector x) with trace 1 (the real part of $\rho_{11} + \dots + \rho_{nn}$ is 1), pure states and other singular ρ included: there is a real number $S \ge 0$ on the line, the von Neumann entropy $S(\rho) = -\mathrm{tr}(\rho \log \rho)$, such that $S = -(\lambda_1\ell_1 + \dots + \lambda_n\ell_n)$ whenever V is a complex n × n matrix with $V\dagger V = 1$, $\lambda_1, \dots, \lambda_n$ are real numbers with $\rho V = V\cdot\mathrm{diag}(\lambda_1, \dots, \lambda_n)$ (an orthonormal eigenbasis of ρ with its eigenvalues), and $\ell_1, \dots, \ell_n$ are real numbers such that, for each k, either $\lambda_k = 0$ or $\exp(\ell_k) = \lambda_k$. So $S = -\sum_k \lambda_k \log \lambda_k$ on every eigenbasis, with 0 log 0 = 0: a zero eigenvalue contributes nothing, whatever ℓ_k is. Building S needs no eigenbasis and no decision about which eigenvalues vanish: with Y = 1 − ρ, S is the limit of the increasing numbers $S(N) = \mathrm{Re}\,\mathrm{tr}(\rho(Y + Y^2/2 + \dots + Y^N/N))$, and the terms from N on add at most n/(N + 1). Here $\langle x, y\rangle = \bar{x}_1y_1 + \dots + \bar{x}_ny_n$, and $\exp(\ell) = \lambda$ means that the exponential series of ℓ converges to λ. *Used for:* The entropy of any quantum state of a finite system, mixed or pure, full rank or not: the entanglement entropy of a subsystem, the thermodynamic entropy of a Gibbs state, and the optimal rate of quantum data compression. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

956. Exponential of a traceless anti-Hermitian matrix is special unitary. For every size n and all complex n × n matrices X and E (entries in the complex numbers over the line, whose real and imaginary parts lie on the line): if X is anti-Hermitian ($X\dagger = -X$, where X† is the conjugate transpose), traceless ($X_{11} + \dots + X_{nn} = 0$) and E = exp(X), then $E\dagger E = 1$, $EE\dagger = 1$ and $\det E = 1$. So the exponential maps the Lie algebra su(n) into the special unitary group SU(n). Here exp(X) = E means that the partial sums of the series $1 + X + X^2/2! + X^3/3! + \dots$ converge entrywise to E. *Used for:* The exponential map from generators to symmetry transformations: every exp(X) with X in su(n) is special unitary, as used for SU(2) spin rotations, SU(3) colour transformations in quantum chromodynamics and quantum gates written as $\exp(-i\cdot H)$ with a traceless H. *Price:* **free**; exact.

957. One-parameter group of a traceless anti-Hermitian matrix is special unitary. For every size n, every complex n × n matrix X (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) that is anti-Hermitian ($X\dagger = -X$, where X† is the conjugate transpose) and traceless ($X_{11} + \dots + X_{nn} = 0$), every real number t on the line and every complex n × n matrix E: if $E = \exp(t\cdot X)$, then $E\dagger E = 1$, $EE\dagger = 1$ and $\det E = 1$. So the whole one-parameter group $t \mapsto \exp(t\cdot X)$ lies in the special unitary group SU(n). Here $\exp(t\cdot X) = E$ means that the partial sums of the series $1 + t\cdot X + t^2X^2/2! + t^3X^3/3! + \dots$ converge entrywise to E. *Used for:* Evolution under a traceless Hamiltonian $H = i\cdot X$: $\exp(-i\cdot t\cdot H) = \exp(t\cdot X)$ is special unitary at every time t, so spin precession (SU(2)) and flavour or colour rotations (SU(3)) stay in the special unitary group, with unit determinant at every time. *Price:* **free**; exact.

958. Exponential of a real skew-symmetric matrix is a rotation. For every size n, every n × n matrix A with real entries on the line (the real numbers constructed from distinctions) that is skew-symmetric ($A^T = -A$), and every complex n × n

matrix E (entries in the complex numbers over the line) with E = exp(A), meaning that the partial sums of the series 1 + A + $A^2/2!$ + $A^3/3!$ + … converge entrywise to E: every entry of E is real, so E = R for a real n × n matrix R, and R is a proper rotation: R^TR = 1, RR^T = 1 and det R = 1. So the exponential maps the real skew-symmetric matrices, the Lie algebra so(n), into the rotation group SO(n). *Used for:* Rotations generated by angular velocities: a constant angular velocity, written as a skew-symmetric matrix, integrates to a proper rotation with no reflection, as in rigid-body kinematics and the precession of a classical magnetic moment in a constant field. *Price:* **free**; exact.

959. Exponential of a matrix whose square is a scalar. For every size n, all complex n × n matrices X and E (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) and every real number s on the line: if $X^2 = -s\cdot 1$ and E = exp(X), then E = C(s)·1 + S(s)·X, where $C(s) = \sum_j (-s)^j/(2j)!$ and $S(s) = \sum_j (-s)^j/(2j+1)!$, both sums over j = 0, 1, 2, and so on. For $s = \omega^2 \geq 0$ these are cos ω and (sin ω)/ω; for $s = -\kappa^2 \leq 0$ they are cosh κ and (sinh κ)/κ. No square root of s and no decision about the sign of s is needed. Here exp(X) = E means that the partial sums of the series 1 + X + $X^2/2!$ + $X^3/3!$ + … converge entrywise to E. *Used for:* Closed-form exponentials of 2 × 2 generators: every traceless 2 × 2 matrix squares to −det(X)·1, so the spin-1/2 rotations and Rabi oscillations of a two-level system (cos and sin) and boosts in one space dimension (cosh and sinh) come out in closed form. *Price:* **free**; exact.

960. Spin-1/2 rotation formula with Pauli matrices. For all real numbers a, b, c and w on the line (the real numbers constructed from distinctions) with $a^2 + b^2 + c^2 = 1$, and every complex 2 × 2 matrix E (entries in the complex numbers over the line): if E = exp(−iw(aσ₁ + bσ₂ + cσ₃)), then E = cos w·1 − i sin w·(aσ₁ + bσ₂ + cσ₃), where σ_1 = (0 1; 1 0), σ_2 = (0 −i; i 0) and σ_3 = (1 0; 0 −1) are the Pauli matrices, cos w = $\sum_j (-1)^j w^{2j}/(2j)!$ and sin w = $\sum_j (-1)^j w^{2j+1}/(2j+1)!$. Here exp(X) = E means that the partial sums of the series 1 + X + $X^2/2!$ + $X^3/3!$ + … converge entrywise to E. *Used for:* Rotating a spin-1/2: the rotation by angle θ about the unit axis n̂ = (a, b, c) acts on spinors as exp(−i(θ/2)n̂·σ) = cos(θ/2) − i sin(θ/2)n̂·σ, the formula behind single-qubit gates, NMR and ESR pulses, and the sign change of a spinor under a full 2π turn. *Price:* **free**; exact.

961. Rodrigues rotation formula. For all real numbers a, b, c and θ on the line (the real numbers constructed from distinctions) with $a^2 + b^2 + c^2 = 1$, and every complex 3 × 3 matrix E (entries in the complex numbers over the line): if E = exp(θK), where K = (0 −c b; c 0 −a; −b a 0) is the cross-product matrix of the unit axis n̂ = (a, b, c) (Kv = n̂ × v for every vector v), then E = 1 + sin θ·K + (1 − cos θ)·K^2, with sin θ = $\sum_j (-1)^j \theta^{2j+1}/(2j+1)!$ and cos θ = $\sum_j (-1)^j \theta^{2j}/(2j)!$. So exp(θK) sends v to v cos θ + (n̂ × v) sin θ + n̂(n̂·v)(1 − cos θ). Here exp(X) = E means that the partial sums of the series 1 + X + $X^2/2!$ + $X^3/3!$ + … converge entrywise to E. *Used for:* The rotation by angle θ about a unit axis in three-dimensional space, in closed form: attitude of rigid bodies and spacecraft, rotation of molecular and crystal coordinates, and the rotation operators of classical mechanics. *Price:* **free**; exact.

962. Rotation generated by a cross-product matrix lies in SO(3). For all real numbers a, b, c and θ on the line (the real numbers constructed from distinctions), the axis (a, b, c) not necessarily of length one, and every complex 3 × 3 matrix E (entries in the complex numbers over the line): if E = exp(θK), where K = (0 −c b; c 0 −a; −b a 0) is the cross-product matrix of (a, b, c), then every entry of E is real, so E = R for a real 3 × 3 matrix R, and R^TR = 1, RR^T = 1 and det R = 1. So exp(θK) is a proper rotation of space. Here exp(X) = E means that the partial sums of the series 1 + X + $X^2/2!$ + $X^3/3!$ + … converge entrywise to E. *Used for:* Every constant angular velocity generates a proper rotation: the attitude update of a gyroscope or spacecraft over one time step, and rotations of molecules and crystals, stay in SO(3) with no reflection. *Price:* **free**; exact.

963. Every unit complex number is a phase $e^{i\theta}$. For every complex number u (in the complex numbers over the line, whose real and imaginary parts lie on the line) with $(\mathrm{Re}\ u)^2 + (\mathrm{Im}\ u)^2 = 1$: there is a real number θ on the line with exp(iθ) = u, the exponential taken of the 1 × 1 matrix (iθ), meaning that the partial sums of 1 + iθ + $(i\theta)^2/2!$ + $(i\theta)^3/3!$ + … converge to u. So every element of the circle group U(1) is the exponential of a purely imaginary number, an element of its Lie algebra. No window is required for θ: the row does not ask for the principal value in (−π, π]. *Used for:* Phases of quantum amplitudes: every unit complex number is a phase factor $e^{i\theta}$, as in U(1) gauge transformations of electromagnetism, the global phase of a wave function and the phase of a plane wave or a coherent state. *Price:* **free**; exact.

964. Every SU(2) matrix is the exponential of an su(2) matrix. For every complex 2 × 2 matrix U (entries in the complex numbers over the line, whose real and imaginary parts lie on the line) with U†U = 1 and det U = 1 (U is in SU(2); U† is its conjugate transpose): there is a complex 2 × 2 matrix X with X† = −X (anti-Hermitian) and $X_{11} + X_{22} = 0$ (traceless) such that U = exp(X), meaning that the partial sums of 1 + X + $X^2/2!$ + $X^3/3!$ + … converge entrywise to U. The price is exactly the lesser limited principle of omniscience (LLPO) together with countable choice.

The upper bound diagonalizes U by a unitary V (the spectral theorem for unitary matrices, which costs LLPO with countable choice), writes the eigenvalues as $e^{i\theta}$ and $e^{-i\theta}$ with an angle θ that costs nothing, and takes $X = V \cdot \mathrm{diag}(i\theta, -i\theta) \cdot V\dagger$. The lower bound, with no choice, uses test matrices near -1, the 2π rotation: for a real number y, a logarithm of an SU(2) matrix built from y decides whether $y \geq 0$ or $y \leq 0$, and that sign decision is LLPO. *Used for:* Every spin-1/2 rotation or single-qubit gate in SU(2) is generated by some traceless Hamiltonian $H = i \cdot X$ acting for unit time, $U = \exp(-i \cdot H)$; finding that generator, for instance to implement a gate as a single pulse or to interpolate between two rotations, costs a sign decision near the 2π rotation $U = -1$. *Price:* **LLPO + $\mathbf{AC}_{\omega}$**; exact.

Q.7 Spectra, lattice models and thermodynamic limits

965. Fekete's subadditive lemma. If $u(m + n) \leq u(m) + u(n)$ for all m, n and u(n)/n is bounded below for $n \geq 1$, then u(n)/n converges to a limit no larger than any u(n)/n. *Used for:* thermodynamic limit of free energy or ground energy per site. *Price:* **LPO**; exact (the converse is monotone convergence, row 1302). Proved in Proposition 28.63(1).

966. Fekete's lemma, bounded-defect case. If $|u(m + n) - u(m) - u(n)| \leq C$ for all m, n, there is a point L with $|u(n)/n - L| \leq C/n$ for every $n \geq 1$. *Used for:* energy per site of a chain whose halves interact through a bounded boundary term. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Proposition 28.63(2).

967. Top level value of a symmetric matrix. Every symmetric $n \times n$ matrix A on the line, $n \geq 1$, has a value λ with $x \cdot Ax \leq \lambda(x \cdot x)$ for every x, and unit vectors x with $x \cdot Ax$ within every tolerance of λ. *Used for:* highest energy of a finite real Hamiltonian; highest normal-mode frequency. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

968. Ground level value of a symmetric matrix. Every symmetric $n \times n$ matrix A on the line, $n \geq 1$, has a value λ with $\lambda(x \cdot x) \leq x \cdot Ax$ for every x, and unit vectors x with $x \cdot Ax$ within every tolerance of λ. *Used for:* ground-state energy of a finite real Hamiltonian by the variational principle. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

969. Spectral theorem at every finite precision. Every symmetric $n \times n$ matrix A on the line, $n \geq 1$, has at every precision ε an exactly orthonormal basis of vectors v with values μ such that every coordinate of $Av - \mu v$ is at most ε in size. *Used for:* diagonalizing finite Hamiltonians and normal-mode problems to any finite precision. *Price:* **free**; exact.

970. Thermodynamic limit over boxes in any dimension. A translation-invariant function F of boxes in the n-dimensional lattice that changes by at most C times the area of the cut when any side is split has a value f with $|F/\text{volume} - f| \leq C(1/L_1 + \ldots + 1/L_n)$ for every box with sides $L_1, \ldots, L_n \geq 1$. *Used for:* free energy per site of a system with surface interactions in any dimension, with its finite-size correction. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Theorem 28.62.

971. Every energy level of a symmetric matrix. Every symmetric $n \times n$ matrix on the line has levels $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_n$ such that, for a fixed constant K, the j-th largest value of every diagonalization accurate to ε lies within $K\varepsilon$ of λ_j. *Used for:* the full spectrum of a finite Hamiltonian: every energy level, each to any stated precision. *Price:* **free**; exact.

972. Ground energy of a lattice model splits over boxes. For a nearest-neighbour model on boxes of the n-dimensional lattice, with finitely many states per site and bond energies at most J_0 in size, splitting a box changes its ground energy by at most J_0 times the area of the cut. *Used for:* the ground energy per site of lattice magnets and lattice gases, with its finite-size correction. *Price:* **free**; exact.

973. Spectral theorem when the levels are known and apart. A symmetric $n \times n$ matrix on the line with n values that are pairwise apart, each of which has approximate unit eigenvectors at every precision, has an exactly orthonormal basis of eigenvectors with exactly those values. *Used for:* energy eigenstates of a nondegenerate finite Hamiltonian; Born probabilities for observables with distinct outcomes. *Price:* **free**; exact (no choice at all). Proved in Theorem 28.67.

974. Eigenvector of a simple energy level. For a symmetric $n \times n$ matrix on the line, $n \geq 1$, a level that is apart from every other level has an exact unit eigenvector with that level as its eigenvalue. *Used for:* the ground state of a gapped finite Hamiltonian; eigenstates of nondegenerate energy levels. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

975. Free energy of a lattice model splits over boxes. For a nearest-neighbour model on boxes of

the n-dimensional lattice with bond energies at most J_0 in size, at every inverse temperature $\beta \geq 0$ the free energy $-\log Z$ changes by at most βJ_0 times the area of the cut when a box is split. *Used for:* free energy per site of lattice magnets and lattice gases at every temperature, with its finite-size correction. *Price:* **free**; exact.

976. Determinant as the product of the energy levels. For every real symmetric $n \times n$ matrix A on the line, $n \geq 1$, $\det(t \cdot 1 - A)$ equals the product of $t - \lambda_j$ over its levels λ_j for every t, so $\det A$ is the product of the levels. *Used for:* characteristic polynomials of finite Hamiltonians; Gaussian integrals and partition functions as products over normal modes. *Price:* **free**; exact.

977. Spectral projector onto a gapped window of levels. For a symmetric $n \times n$ matrix on the line, $n \geq 1$, and a run of consecutive levels separated by gaps from the levels above and below it, there is an orthogonal projector P commuting with the matrix whose trace is the number of levels in the run and whose range has energies between the lowest and highest level of the run. *Used for:* the probability of finding the energy in a gapped window, even when levels inside the window coincide. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

978. Free energy of a finite-range lattice model splits. For a lattice model on boxes in n dimensions with finitely many pair interactions of range at most R, each at most J_0 in size, splitting a box changes the free energy $-\log Z$ by at most $\beta\, J_0\, r\, R$ times the area of the cut, where r is the number of interaction terms and $\beta \geq 0$. *Used for:* free energy per site of lattice systems with interactions beyond nearest neighbours, at every temperature. *Price:* **free**; exact.

979. Functions of a symmetric matrix. For a symmetric $n \times n$ matrix A on the line, $n \geq 1$, and a Lipschitz function f, the matrix f(A) exists: it is symmetric, commutes with A, is the limit of $\Sigma\, f(\mu)\, v\, v^{T}$ over diagonalizations, and its trace is the sum of f over the levels of A. *Used for:* Gibbs matrices $e^{-\beta H}$ and partition functions as sums over energy levels, with the exponential made constant outside an interval that contains every level (f(A) depends only on the values of f near the levels); time evolution of finite quantum systems. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

980. Weyl's bound for energy levels. If two symmetric $n \times n$ matrices on the line, $n \geq 1$, have Rayleigh quotients that differ by at most $e(x \cdot x)$ for every vector x, then each level of one is within e of the corresponding level of the other. *Used for:* stability of energy levels under a bounded perturbation; error bounds in perturbation theory. *Price:* **free**; exact.

981. Energies of non-interacting systems add. For symmetric matrices A and B on the line with level lists, the levels of the combined system $A \otimes 1 + 1 \otimes B$ are the sums of one level of A and one level of B, sorted from the largest; two level lists of one matrix always agree. *Used for:* energies of independent subsystems; partition functions of non-interacting systems multiply. *Price:* **free**; exact.

982. Partition function of two coupled blocks. For symmetric matrices A and B on the line and a symmetric coupling E that changes every Rayleigh quotient by at most e times the squared length, the partition function of $A \otimes 1 + 1 \otimes B + E$ at inverse temperature $\beta \geq 0$ lies within a factor $e^{\beta\, e}$ of the product of the partition functions of A and B. *Used for:* almost additivity of the free energy of quantum systems; surface terms in the thermodynamic limit. *Price:* **free**; exact.

983. Quantum lattice free energy is almost additive. For symmetric matrices indexed by boxes of the d-dimensional lattice that split across every cut into the two halves side by side plus a coupling of size at most J per unit of cut area, the free energy, minus the logarithm of the partition function at inverse temperature $\beta \geq 0$, changes by at most β J times the cut area when a box is split. *Used for:* thermodynamic limit of the free energy per site of quantum spin lattice models. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Theorem 28.64(1).

984. Functions of a symmetric matrix multiply. For a symmetric $n \times n$ matrix A on the line, $n \geq 1$, and Lipschitz functions f and g, the matrix f(A) times the matrix g(A) is the matrix of the product function f g at A. *Used for:* composing functions of a Hamiltonian, each made Lipschitz by a cut-off outside an interval that contains every level; products of observables that are functions of the energy. *Price:* **free**; exact.

985. Time evolution of a finite quantum system is unitary. For a symmetric $n \times n$ matrix A on the line, $n \geq 1$, and Lipschitz functions c and s with $c^2 + s^2 = 1$, the matrices $C = c(A)$ and $S = s(A)$ commute and $C^2 + S^2$ is the identity matrix; with c and s the cosine and sine of t times the energy, the evolution C minus i times S is unitary. *Used for:* unitary time evolution of finite quantum systems; conservation of probability. *Price:* **free**; exact.

986. Gibbs state of a finite quantum system. For a symmetric $n \times n$ matrix A on the line, $n \geq 1$, and inverse temperature $\beta \geq 0$, the Gibbs matrix $\rho = e^{-\beta A}/Z$ exists: it is symmetric, commutes with A, is positive, has trace 1, and $Z\, \rho$ is the limit of the sums

of $e^{-\beta\,\mu}$ v v^{T} over diagonalizations. *Used for:* thermal states and thermal expectation values of finite quantum systems. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

987. Ising chain in a transverse field splits at every cut. For real numbers J and g, the transverse-field Ising chain on n sites with open ends, with nearest-neighbour coupling −J between the spins along one axis and field −g flipping each spin, is on any cut into a left and a right part the two parts side by side plus one bond whose effect on every expectation value is at most |J| times the squared length. *Used for:* surface terms of the quantum Ising chain; locality of quantum spin chain Hamiltonians. *Price:* **free**; exact. Proved in Theorem 28.61.

988. Free energy per site of the quantum Ising chain. For real numbers J and g and inverse temperature $\beta \geq 0$, the free energy of the transverse-field Ising chain on n sites with open ends, minus the logarithm of its partition function (β times the thermodynamic free energy), divided by n, has a limit f, and on n sites it is within $\beta\,|J| / n$ of f. *Used for:* thermodynamic limit of the quantum Ising chain; quantum phase transitions in one dimension. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Corollary 28.65(1).

989. Quantum Ising model splits at every cut. For real numbers J and g and every dimension d, the transverse-field Ising model on a box of the d-dimensional lattice with open boundaries, with coupling −J between neighbouring spins along one axis and field −g flipping each spin, is on any cut of the box into two boxes the two parts side by side plus the bonds across the cut, whose effect on every expectation value is at most |J| times the area of the cut times the squared length. *Used for:* surface terms of quantum spin models; locality of lattice Hamiltonians in every dimension. *Price:* **free**; exact. Proved in Theorem 28.61.

990. Free energy per site of the quantum Ising model. For real numbers J and g, every dimension d and inverse temperature $\beta \geq 0$, the free energy per site of the transverse-field Ising model on boxes of the d-dimensional lattice with open boundaries, the free energy being minus the logarithm of the partition function (β times the thermodynamic free energy), has a limit f, and on a box with sides $L_1, \ldots, L_d$ it is within $\beta\,|J|\,(1/L_1 + \ldots + 1/L_d)$ of f. *Used for:* thermodynamic limit of the quantum Ising model; quantum phase transitions in two and three dimensions. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Corollary 28.65(1).

991. Ground energies of quantum lattice models are almost additive. For symmetric matrices indexed by boxes of the d-dimensional lattice that split across every cut into the two halves side by side plus a coupling of size at most J per unit of cut area, the lowest energy level changes by at most J times the cut area when a box is split. *Used for:* ground-state energy per site of quantum lattice models; surface energies. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Theorem 28.64(2).

992. Ground energy per site of the quantum Ising chain. For real numbers J and g, the lowest energy level of the transverse-field Ising chain on n sites with open ends, divided by n, has a limit, and on n sites it is within $|J| / n$ of that limit. *Used for:* ground-state energy density of the quantum Ising chain; quantum phase transitions at zero temperature. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Corollary 28.65(2).

993. Ground energy per site of the quantum Ising model. For real numbers J and g and every dimension d, the lowest energy level of the transverse-field Ising model on boxes of the d-dimensional lattice with open boundaries, divided by the number of sites, has a limit e_0, and on a box with sides $L_1, \ldots, L_d$, each at least 1, it is within $|J|\,(1/L_1 + \ldots + 1/L_d)$ of e_0. *Used for:* ground-state energy per site of quantum spin models in two and three dimensions; quantum phase transitions at zero temperature. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Corollary 28.65(2).

994. Collecting located points into a sequence. Choosing, for every natural number, the one point that a relation assigns to it, when rational approximations of that point within every tolerance are picked out by a relation that can be decided case by case, is exactly as strong as countable unique choice of yes-or-no answers. The free allowance contains that choice: countable choice at pairs of ratios, applied to the pair (b, b) for the unique bit b. *Used for:* collecting computed physical quantities, one per box or per length, into one function. *Price:* **free**; exact (equivalent, with no other choice, to countable unique choice of yes-or-no answers).

Q.8 Topology, compactness and fixed points

995. Brouwer's fixed point theorem on an interval. On the line, if a function is continuous at every point of an interval [a, b] ($a \le b$) and sends every point of [a, b] into [a, b], then it has a fixed point in [a, b]. *Used for:* equilibria of one-variable maps: a mixed equilibrium of a two-strategy game, a self-consistent solution with one order parameter. *Price:* **LLPO**; exact (the converse goes through the intermediate value theorem, row 1312; its choices, of yes-or-no answers and of representatives of the map's values, are inside the free allowance).

996. Brouwer's fixed point theorem on the unit square. On the line, if a function of two variables is uniformly continuous (with a modulus of continuity) on the unit square $[0, 1] \times [0, 1]$ and sends the square into itself, then it has a fixed point in the square. *Used for:* equilibria of two-variable maps: a Nash equilibrium with two mixing probabilities, a self-consistent solution with two order parameters. *Price:* **LLPO**; exact for uniformly continuous maps: the converse uses weak König's lemma, whose choices are yes-or-no answers, and representatives of the moves of the map at the dyadic corners, all inside the free allowance; for maps that are only continuous at each point see row 1058.

997. Banach's fixed point theorem on a complete invariant set. On the line, let K be a set such that every Cauchy sequence of points of K converges to a point of K, let f send K into K, and let f shrink the distance between any two points of K by a factor q with $0 \le q < 1$. Then for every start x_0 in K the iterates of f converge to a fixed point p in K, and $(1 - q)\cdot|f^n(x_0) - p| \le q^n\cdot|f(x_0) - x_0|$ for every n. *Used for:* iterations confined to a closed region: self-consistent-field and Picard iterations inside a ball or a constraint set. *Price:* **free**; exact.

998. The continuous image of a connected set is connected. On the line, call a set connected when any two open sets that together cover it and each contain a point of it share a point of it. If a set is connected and f is continuous on it, then the set of values of f on it is connected. *Used for:* a continuous quantity on a connected parameter set takes an interval of values, which is the source of every intermediate-value statement. *Price:* **free**; exact.

999. Locally constant integer functions on connected sets are constant. On the line, let K be a connected set (any two open sets that together cover K and each contain a point of K share a point of K) and let c be an integer-valued function that is locally constant on K: near every point of K, c is constant on K. Then c is constant on K: it has one single value at all points of K. *Used for:* quantized invariants such as winding numbers, charges and Chern numbers cannot change along a connected set of parameters. *Price:* **free**; exact.

1000. An integer-valued locally constant function on an interval is constant. On the line, an integer-valued function that is locally constant on a closed interval [a, b] (near every point of [a, b] it is constant on [a, b]) is constant on [a, b]: it has one single value at all points of [a, b]. *Used for:* quantized invariants such as winding numbers, charges and Chern numbers cannot change along a parameter interval. *Price:* $\mathbf{AC}_\omega$; exact.

1001. The line has no nontrivial open and closed sets. On the line, if a set of points is open and its complement is open, then the set is empty or it contains every point. *Used for:* a connected state space cannot be split into two disjoint open parts: no nontrivial superselection sectors. *Price:* **EM** + $\mathbf{AC}_\omega$; exact.

1002. Limit points are limits of sequences of members. On the line, for a set K and a point x: for every tolerance K has a member within that tolerance of x if and only if some sequence of points of K converges to x. *Used for:* every argument that takes the limit of a sequence of allowed states. *Price:* $\mathbf{AC}_\omega$; exact.

1003. A set that contains its limit points is complete. On the line, if a set K contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x), then every Cauchy sequence of points of K converges to a point of K. *Used for:* closed constraint sets and closed subspaces are complete, so iterations that start in them converge inside them. *Price:* **free**; exact (the proof uses the completeness of the line and forms a limit point).

1004. A complete set contains its limit points. On the line, if every Cauchy sequence of points of a set K converges to a point of K, then K contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x). *Used for:* a complete subspace of states is closed under limits. *Price:* $\mathbf{AC}_\omega$; exact.

1005. Cantor's intersection theorem. On the line, let $S_0, S_1, S_2, \ldots$ be sets that each contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x), such that for every N some point lies in the first N + 1 sets at once, and such that for every tolerance, from some index on any two points of one set S_n are within that tolerance of each other. Then some point lies in every S_n. *Used for:* nested-region and bisection arguments: existence of the limiting point. *Price:* **free**; exact (the proof chooses rational approximations of points of the sets, which the free allowance contains, and forms a limit point).

1006. Baire's category theorem on the line. On the line, let U_0, U_1, U_2, ... be open sets (every point of U_n has a tolerance band of points of U_n around it) such that every point has, within every tolerance, a point of each U_n. Then every point has, within every tolerance, a point that lies in all the U_n at once. *Used for:* generic properties of systems; uniform boundedness of operator families in quantum theory. *Price:* **free**; exact (the proof chooses rational intervals inside the open sets, which the free allowance contains, and forms a limit point).

1007. The preimage of a set containing its limit points. On the line, if f is continuous and a set K contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x), then the set of points x with f(x) in K also contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x). *Used for:* level sets and constraint surfaces {F = c} contain their limit points. *Price:* **free**; exact.

1008. Where two continuous functions agree contains its limit points. On the line, if f and g are continuous, then the set of points where f(x) = g(x) contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x). *Used for:* a constraint surface {F = G}: limits of states that satisfy the constraint satisfy it. *Price:* **free**; exact.

1009. A ball contains its limit points. On the line, for any centre c and radius r, the set of points x with $|x - c| \le r$ contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x). *Used for:* closed neighbourhoods: limits of states within a radius stay within it. *Price:* **free**; exact.

1010. The intersection of two sets containing their limit points. On the line, if two sets K and L each contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x), then so does the set of points lying in both. *Used for:* combining two constraints on a state. *Price:* **free**; exact.

1011. The intersection of two open sets is open. On the line, if two sets are open (every point of the set has a tolerance band of points of the set around it), then so is the set of points lying in both. *Used for:* combining two open conditions or two neighbourhoods. *Price:* **free**; exact.

1012. Limit of a sequence in a limit-closed set. On the line, if a set K contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x), and a sequence is eventually in K and converges to L, then L is in K. *Used for:* the limit of states that satisfy a constraint satisfies it. *Price:* **free**; exact.

1013. A closed interval contains its limit points. On the line, for any a and b the interval of points x with $a \le x \le b$ contains every point that its members approach (every point x such that, for every tolerance, the set has a member within that tolerance of x). *Used for:* bounded parameter ranges: limits of parameters in range stay in range. *Price:* **free**; exact.

1014. A compact set has an open complement. On the line, if a set K is compact (every countable cover of K by open intervals with fraction endpoints has a finite subcover made of its first intervals), then every point outside K has a tolerance band around it that contains no point of K. *Used for:* a compact set of allowed states keeps a margin from every excluded state, so small perturbations cannot reach it. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the price is excluded middle).

1015. Where two continuous functions disagree is open. On the line, if f and g are continuous, then every point x with $f(x) \ne g(x)$ has a tolerance band around it in which $f(y) \ne g(y)$ at every point y. *Used for:* a constraint F = G that fails at a state fails at every nearby state: violations are stable. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the statement is free).

1016. The complement of a closed interval is open. On the line, for any a and b, every point x that does not satisfy $a \le x \le b$ has a tolerance band around it containing no point of the interval [a, b]. *Used for:* a parameter out of range stays out of range under small perturbations. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the statement is free).

1017. The complement of a closed ball is open. On the line, for any centre c and radius r, every point x with $|x - c| \le r$ false has a tolerance band around it containing no point of the ball of points y with $|y - c| \le r$. *Used for:* a state outside a ball stays outside under small perturbations. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the statement is free).

1018. The union of two sets with open complements. On the line, if the complements of two sets K and L are open (every point outside K has a tolerance band outside K, and every point outside L has a tolerance band outside L), then the complement of the set of points lying in K or in L is open. *Used for:* two constraints either of which may hold, such as alternative allowed regions. *Price:* **free**; exact.

1019. The intersection of two sets with open complements. On the line, if the complements of two sets K and L are open (every point outside K has a tolerance band outside K, and every point outside L has a tolerance band outside L), then the complement of the set of points lying in both K and L is open. *Used for:* combining two constraints on a state. *Price:* **open**; at most weak excluded middle, and more sharply at most this principle: whenever a property N of natural numbers is stable (if not-not N(k) then N(k)) and persists (N(k) gives N(k+1)), and for a statement A both "A fails" and "A does not fail" lead to some k with N(k), then some k has N(k). With Markov's principle available this statement is exactly equivalent to that principle, and then implies LPO. Without Markov's principle no lower bound is proved: the encodings tried need it, because requiring the single point 0 to be closed already costs Markov's principle. The principle is not one of the letters.

1020. The preimage of a set with open complement. On the line, if f is continuous and the complement of a set K is open, then the complement of the set of points x with f(x) in K is open. *Used for:* level sets of continuous quantities have open complements. *Price:* **free**; exact.

1021. Limit of a sequence in a set with open complement. On the line, if the complement of a set K is open, and a sequence is eventually in K and converges to L, then L is in K. *Used for:* the limit of states that satisfy a constraint satisfies it, for an arbitrary constraint set with open complement. *Price:* **EM**; exact.

1022. A set with open complement is complete. On the line, if the complement of a set K is open, then every Cauchy sequence of points of K converges to a point of K. *Used for:* constraint sets with open complement are complete, so iterations that start in them converge inside them. *Price:* **EM**; exact (the proof uses the completeness of the line).

1023. A complete set has an open complement. On the line, if every Cauchy sequence of points of a set K converges to a point of K, then every point outside K has a tolerance band around it containing no point of K. *Used for:* a complete subspace of states keeps a margin from every excluded state. *Price:* **open**; at least LPO and at most EM + AC_{ω}. With countable choice this statement is exactly equivalent to the conjunction of two principles: Markov's principle for stable persistent properties (if N is stable under double negation, N(k) gives N(k+1), and it is not refuted that some k has N(k), then some k has N(k)) and the double negation shift (if ¬¬Q(n) for every n, then ¬¬(Q(n) for every n)); the lower bound needs only that the line is complete, which the free allowance supplies. The first principle is not one of the letters, so the exact price in the letters is open.

1024. Finitely enumerable sets contain their limit points. On the line, let S be a set given by a list of points, repeated entries allowed. If for every tolerance S has a member within that tolerance of a point x, then x is a member of S. *Used for:* a discrete spectrum, such as the eigenvalues of a finite matrix, is closed: a limit of approximate eigenvalues is an eigenvalue; the price is the degeneracy problem of telling which of two nearly equal levels the limit is. *Price:* **LLPO**; exact.

1025. Finite sets contain their limit points, without repeated points. On the line, let S be a set given by a list of points with no repeated entries. If for every tolerance S has a member within that tolerance of a point x, then x is a member of S. *Used for:* a discrete spectrum of distinct eigenvalues is closed: a limit of approximate eigenvalues is an eigenvalue. *Price:* $\mathbf{MP}^{\vee}$; exact.

1026. A finite set has an open complement. On the line, let S be a set given by a list of points with no repeated entries. Then every point x outside S has a tolerance band around it that contains no point of S. *Used for:* a point outside the spectrum of a finite matrix has a margin free of eigenvalues, so small perturbations cannot reach the spectrum. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, only upper bounds are proved).

1027. A single point contains its limit points. On the line, for any point a and any point x: if for every tolerance the set containing only a has a member within that tolerance of x, that is, if a is within every tolerance of x, then x equals a. *Used for:* a limit of states that all equal a given state equals it. *Price:* **free**; exact.

1028. A single point has an open complement. On the line, for any point a, every point x different from a has a tolerance band around it in which every point differs from a. *Used for:* a state different from a reference state stays different under small perturbations. *Price:* **MP**; exact.

1029. A finite set is compact. On the line, every set given by a list of points is compact: whenever countably many open intervals with fraction endpoints cover the points of the list, finitely many of them, the first N for some N, already cover them. *Used for:* finitely many levels or measured values are covered by finitely many neighbourhoods. *Price:* **free**; exact.

1030. A single point is compact. On the line, for any point a, whenever countably many open intervals with fraction endpoints cover a, finitely many of them, the first N for some N, already cover it. *Used for:* a reference state is covered by finitely many

neighbourhoods of any cover. *Price:* **free**; exact.

1031. Path-connected subsets of the line are connected. On the line, let K be a set containing a point x_0 such that for every point y of K some path, continuous on [0, 1], runs inside K from x_0 to y. Then K is nonempty and connected: any two open sets that together cover K and each contain a point of K share a point of K. *Used for:* a set of parameters that can be moved through continuously cannot be split into two separated parts. *Price:* $\mathbf{AC}_\omega$; exact.

1032. Path-connected subsets of the plane are connected. On the plane of pairs of points of the line with the maximum distance, let K be a set containing a point p_0 such that for every point q of K some path, continuous on [0, 1], runs inside K from p_0 to q. Then K is nonempty and connected: any two open sets of the plane that together cover K and each contain a point of K share a point of K. *Used for:* a region of two parameters that can be moved through continuously cannot be split into two separated parts. *Price:* $\mathbf{AC}_\omega$; exact.

1033. Convex subsets of the line are path-connected. On the line, let K be a nonempty set such that for any points x and y of K and any a and b with $a \geq 0$, $b \geq 0$ and $a + b = 1$, the point $a \cdot x + b \cdot y$ lies in K. Then any two points of K are joined by a path, continuous on [0, 1], that stays in K. *Used for:* convex parameter regions, such as intervals of couplings, can be traversed continuously. *Price:* **free**; exact (the two-point conclusion is stronger than the base-point form of the statement).

1034. Convex subsets of the plane are path-connected. On the plane of pairs of points of the line with the maximum distance, let K be a nonempty set such that for any points p and q of K and any a and b with $a \geq 0$, $b \geq 0$ and $a + b = 1$, the point $a \cdot p + b \cdot q$ lies in K. Then any two points of K are joined by a path, continuous on [0, 1], that stays in K. *Used for:* convex state spaces of two parameters, such as a segment of probability distributions on three outcomes, can be traversed continuously. *Price:* **free**; exact (the two-point conclusion is stronger than the base-point form of the statement).

1035. Convex subsets of the line are connected. On the line, let K be a set such that for any points x and y of K and any a and b with $a \geq 0$, $b \geq 0$ and $a + b = 1$, the point $a \cdot x + b \cdot y$ lies in K. Then any two open sets that together cover K and each contain a point of K share a point of K (and K is nonempty when it contains a point). *Used for:* a convex parameter region cannot be split into two separated parts. *Price:* $\mathbf{AC}_\omega$; exact.

1036. Convex subsets of the plane are connected. On the plane of pairs of points of the line with the maximum distance, let K be a set such that for any points p and q of K and any a and b with $a \geq 0$, $b \geq 0$ and $a + b = 1$, the point $a \cdot p + b \cdot q$ lies in K. Then any two open sets of the plane that together cover K and each contain a point of K share a point of K (and K is nonempty when it contains a point). *Used for:* a convex state space of two parameters cannot be split into two separated parts. *Price:* $\mathbf{AC}_\omega$; exact.

1037. Open intervals are open. On the line, for any a and b, every point x with $a < x < b$ has a tolerance band around it in which every point y also satisfies $a < y < b$. Here $a < x$ means that $x - a$ is at a known positive distance from 0 (the apartness order). *Used for:* an open range of a parameter stays open under small perturbations. *Price:* **free**; exact.

1038. Open half-lines are open (above). On the line, for any a, every point x with $a < x$ has a tolerance band around it in which every point y also satisfies $a < y$. Here $a < x$ means that $x - a$ is at a known positive distance from 0 (the apartness order). *Used for:* a strict lower bound on a quantity is stable under small perturbations. *Price:* **free**; exact.

1039. Open half-lines are open (below). On the line, for any b, every point x with $x < b$ has a tolerance band around it in which every point y also satisfies $y < b$. Here $x < b$ means that $b - x$ is at a known positive distance from 0 (the apartness order). *Used for:* a strict upper bound on a quantity is stable under small perturbations. *Price:* **free**; exact.

1040. Open balls are open. On the line, for any centre c and radius r, every point x with $|x - c| < r$ has a tolerance band around it in which every point y also satisfies $|y - c| < r$. Here the strict inequality is the apartness order: $r - |x - c|$ is at a known positive distance from 0. *Used for:* states within a given distance of a reference state form a neighbourhood: small perturbations stay inside. *Price:* **free**; exact.

1041. Closed half-lines contain their limit points (above). On the line, for any a, the set of points x with $a \leq x$ contains its limit points: if for every tolerance the set has a member within that tolerance of a point x, then $a \leq x$. *Used for:* a limit of quantities that stay above a bound stays above it. *Price:* **free**; exact.

1042. Closed half-lines contain their limit points (below). On the line, for any a, the set of points x with $x \leq a$ contains its limit points: if for every tolerance the set has a member within that tolerance of a point x, then $x \leq a$. *Used for:* a limit of quantities that stay below a bound stays below it. *Price:* **free**; exact.

1043. Closed half-lines have an open complement (above). On the line, for any a, every point x for which $a \leq x$ fails has a tolerance band

around it in which a ≤ y fails for every point y. *Used for:* a quantity that violates a lower bound violates it under every small perturbation. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the statement is free).

1044. Closed half-lines have an open complement (below). On the line, for any a, every point x for which x ≤ a fails has a tolerance band around it in which y ≤ a fails for every point y. *Used for:* a quantity that violates an upper bound violates it under every small perturbation. *Price:* **MP**; exact (with the other reading of closed, containing its limit points, the statement is free).

1045. Open half-lines open under the derived strict order (above). On the line, write x > a for: a ≤ x holds and x ≤ a fails. For any a, every point x with x > a has a tolerance band around it in which every point y also satisfies y > a. *Used for:* a strict lower bound, read as not at most the bound, is stable under small perturbations. *Price:* **MP**; exact.

1046. Open half-lines open under the derived strict order (below). On the line, write x < b for: x ≤ b holds and b ≤ x fails. For any b, every point x with x < b has a tolerance band around it in which every point y also satisfies y < b. *Used for:* a strict upper bound, read as not at least the bound, is stable under small perturbations. *Price:* **MP**; exact.

1047. Closed intervals are totally bounded. On the line, for any a and b and any tolerance, there is a finite list of points such that every point x with a ≤ x ≤ b is within that tolerance of a listed point. *Used for:* a bounded region of a parameter can be discretized by a finite grid at every accuracy. *Price:* **free**; exact.

1048. The rationals are dense in the line. On the line, every point x has, within every tolerance, a fraction z/(d+1) with z an integer and d a natural number. *Used for:* every real quantity is approximated to any accuracy by a fraction: numerical approximation. *Price:* **free**; exact.

1049. The line has a countable dense sequence. On the line, there is a sequence of points such that every point has a member of the sequence within every tolerance. *Used for:* a countable list of trial values suffices to approximate every real value: separability of the line. *Price:* **free**; exact.

1050. Heine–Borel theorem on the unit square. On the line, if countably many open rectangles with fraction endpoints cover the unit square [0, 1] × [0, 1], then finitely many of them, the first N for some N, already cover it. *Used for:* compact parameter regions of two variables: the compactness step behind uniform estimates and fixed-point arguments. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω); the square statement implies the one-variable theorem.

1051. Compact sets are closed and bounded (open-complement reading). On the line, if every cover of a set K by countably many open intervals with fraction endpoints has a finite subcover (the first N intervals), then every point outside K has a tolerance band containing no point of K, and K lies inside some interval [−B, B]. *Used for:* a compact set of allowed states keeps a margin from every excluded state and is bounded. *Price:* **MP**; exact.

1052. Subsets of compact sets with open complement are compact. On the line, let K be compact (every cover of K by countably many open intervals with fraction endpoints has a finite subcover), and let L be a subset of K such that every point outside L has a tolerance band containing no point of L. Then L is compact. *Used for:* a constraint set inside a compact region is compact, so the minimum of a continuous cost over it is attained. *Price:* **open**; at most WEM + MP + AC_ω (and at most EM + AC_ω); no lower bound is proved.

1053. Heine–Borel theorem: compact exactly when closed and bounded. On the line, a set K is compact (every cover by countably many open intervals with fraction endpoints has a finite subcover) if and only if every point outside K has a tolerance band containing no point of K and K lies inside some interval [−B, B]. *Used for:* compactness of the closed bounded parameter regions that physics works with. *Price:* **open**; at least MP and at most WEM + MP + AC_ω.

1054. Closed bounded sets are compact (open-complement reading). On the line, if every point outside a set K has a tolerance band containing no point of K, and K lies inside some interval [−B, B], then every cover of K by countably many open intervals with fraction endpoints has a finite subcover. *Used for:* a closed bounded region of states is compact: the compactness step behind uniform bounds. *Price:* **open**; at most WEM + MP + AC_ω; no lower bound is proved; with MP it gives the one-variable Heine–Borel theorem.

1055. Heine–Borel theorem on the unit cube. On the line, if countably many open boxes with fraction endpoints cover the unit cube [0, 1] × [0, 1] × [0, 1], then finitely many of them, the first N for some N, already cover it. *Used for:* compact three-dimensional regions of positions or parameters: the compactness step behind uniform estimates. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω); the cube statement implies the square and interval statements.

1056. Heine–Borel theorem on the unit cube of every dimension. On the line, for every n, if

countably many open boxes with fraction endpoints cover the unit cube $[0, 1]^n$ (n coordinates, each in [0, 1]), then finitely many of them, the first N for some N, already cover it. *Used for:* compact regions of any number of parameters, such as the configuration space of a finite system: the compactness step behind uniform estimates. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem, in every dimension (so at most LLPO + AC_ω); implies the one-variable theorem.

1057. Heine–Cantor theorem on the unit square. On the line, if a function from the unit square to the plane is continuous at every point of the square, then it is uniformly continuous on the square: for every tolerance there is one distance such that any two points of the square closer than it have images within the tolerance. *Used for:* uniform error estimates for a continuous map of two parameters on a compact region. *Price:* **open**; at least the decidable fan theorem (it implies the interval statement and so the fan theorem); at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives), and at most the full fan theorem with no choice; equivalent, with no choice, to the decidable fan theorem together with a presentation of the local control data by countable covers; under LLPO and countable choice that presentation is equivalent to the statement itself, so whether LLPO with countable choice gives it is the open question.

1058. Brouwer on the unit square, pointwise continuous maps. On the line, if a function from the unit square into itself is continuous at every point of the square (not necessarily uniformly), then it has a fixed point in the square. *Used for:* equilibria of two-variable maps when only pointwise continuity is known. *Price:* **open**; at least LLPO and at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives); the proof reads the modulus of uniform continuity off as a function from yes-or-no questions; for uniformly continuous maps the price is exactly LLPO (row 996).

1059. Order-connected subsets of the line are connected. On the line, let K be a set such that every point between two points of K lies in K (if x and y are in K and $x \le z \le y$ then z is in K). Then any two open sets that together cover K and each contain a point of K share a point of K. *Used for:* a parameter region that is an interval, however it is described, cannot be split into separated parts. *Price:* $\mathbf{AC}_\omega$; exact (equivalent to the connectedness of closed intervals, with no principle).

1060. Connected subsets of the line are order-connected. On the line, let K be a set such that any two open sets that together cover K and each contain a point of K share a point of K. Then every point between two points of K lies in K. *Used for:* a connected set of parameters is an interval: every intermediate value is attained. *Price:* **open**; at most LPO with no choice; at least LPO given countable choice, so exactly LPO in the presence of countable choice; the lower bound without that hypothesis is open.

1061. Connected equals order-connected on the line. On the line, a set K is connected (any two open sets that together cover K and each contain a point of K share a point of K) if and only if every point between two points of K lies in K. *Used for:* connected parameter regions of the line are exactly the intervals. *Price:* **LPO + $\mathbf{AC}_\omega$**; exact.

1062. Intersections of closed sets contain their limit points. On the line, for any family of sets, each of which contains its limit points, the set of points lying in all of them contains its limit points. *Used for:* intersections of constraints: a limit of states that satisfy every constraint satisfies every constraint. *Price:* **free**; exact.

1063. Limit points of a set form a closed set. On the line, for any set S, the set of limit points of S (points with members of S within every tolerance) contains its own limit points. *Used for:* taking limits of limits gives nothing new: the closure of a region is closed. *Price:* **free**; exact.

1064. Limit points lie in every closed superset. On the line, if a set T contains its limit points and contains a set S, then T contains every limit point of S. *Used for:* the closure of a region lies inside every closed region that contains it. *Price:* **free**; exact.

1065. A function on a finite list has a minimizer. On the line, let S be given by a nonempty list of points with no repeated entries (for each pair of positions the entries are not equal), and let f be any function from points to points. Then some member x of S satisfies $f(x) \le f(y)$ for every member y of S ($a \le b$ here means that $b < a$ fails). *Used for:* the lowest-energy configuration among finitely many candidates: a ground state of a system with finitely many configurations. *Price:* **LLPO**; exact (the lower bound uses no choice).

1066. A function on a finite list has a maximizer. On the line, let S be given by a nonempty list of points with no repeated entries (for each pair of positions the entries are not equal), and let f be any function from points to points. Then some member x of S satisfies $f(y) \le f(x)$ for every member y of S ($a \le b$ here means that $b < a$ fails). *Used for:* the most probable outcome or the highest-energy configuration among finitely many candidates. *Price:* **LLPO**; exact (the lower bound uses no choice).

1067. Distinct finitely many reals have a least member. On the line, for a nonempty list of points with no repeated entries, some member x of the list satisfies x ≤ y for every member y (a ≤ b here means that b < a fails). *Used for:* the lowest of finitely many distinct energy levels of a discrete spectrum. *Price:* **MP**$^\vee$; exact (the lower bound uses no choice).

1068. Distinct finitely many reals have a greatest member. On the line, for a nonempty list of points with no repeated entries, some member x of the list satisfies y ≤ x for every member y (a ≤ b here means that b < a fails). *Used for:* the highest of finitely many distinct energy levels of a discrete spectrum. *Price:* **MP**$^\vee$; exact (the lower bound uses no choice).

1069. Finitely many reals with repeats have a least member. On the line, for a nonempty list of points in which entries may repeat, some member x of the list satisfies x ≤ y for every member y (a ≤ b here means that b < a fails). *Used for:* the lowest of finitely many energy levels when levels may coincide (degenerate spectra). *Price:* **LLPO**; exact (the lower bound uses no choice).

1070. Distinct finitely many reals can be sorted. On the line, for every list of points with no repeated entries, some rearrangement of the list has every entry ≤ every later entry (a ≤ b here means that b < a fails). *Used for:* ordering the levels of a finite spectrum from the lowest up, as when filling levels one by one. *Price:* **MP**$^\vee$; exact (the lower bound uses no choice).

1071. Finitely many reals with repeats can be sorted. On the line, for every list of points, entries may repeat, some rearrangement of the list has every entry ≤ every later entry (a ≤ b here means that b < a fails). *Used for:* ordering measured values or levels from the lowest up when values may coincide. *Price:* **LLPO**; exact (the lower bound uses no choice).

1072. Every real has a nearest point in a finite set. On the line, for a nonempty list of points with no repeated entries and any point x, some member y of the list satisfies |x − y| ≤ |x − z| for every member z of the list (a ≤ b here means that b < a fails). *Used for:* rounding a measured value to the nearest allowed level of a finite spectrum: quantization. *Price:* **LLPO**; exact (the lower bound uses no choice).

1073. Finite sets are discrete: every point is isolated. On the line, for every list of points with no repeated entries and every member a of the list there is a tolerance such that any member y of the list within that tolerance of a equals a. *Used for:* a discrete spectrum has a gap around every level: the levels are separated from each other. *Price:* **MP**; exact (the lower bound uses no choice).

1074. Compactness of the space of bit sequences. On the line, if countably many finite strings of bits are given such that every infinite sequence of bits begins with at least one of them, then finitely many of them, the first N for some N, already do: every infinite sequence of bits begins with one of the first N strings. *Used for:* the configuration space of a spin system with two states per site is compact: the compactness step behind limit states of lattice models (a minimizer of a cost function carries its own price). *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω); also equivalent to the one-variable Heine–Borel theorem.

1075. Compactness of the space of sequences with m values. On the line, let m ≥ 2. If countably many finite strings with letters from {0, ..., m − 1} are given such that every infinite sequence of such letters begins with at least one of them, then the first N of them, for some N, already do. *Used for:* the configuration space of a lattice system with m states per site is compact: the compactness step behind limit states of lattice models (a minimizer of a cost function carries its own price). *Price:* **FAN**; exact for every m ≥ 2: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω).

1076. Convex subsets of the line are order-connected. On the line, let K be a set such that for any points x and y of K and any a and b with a ≥ 0, b ≥ 0 and a + b = 1, the point a·x + b·y lies in K. Then every point between two points of K lies in K (if x and y are in K and x ≤ z ≤ y then z is in K). *Used for:* a convex region of one parameter is an interval: every intermediate value between two allowed states is allowed. *Price:* **LLPO**; exact (the converse chooses one yes-or-no answer for each row of a table of numbers, a choice inside the free allowance); also at most LPO with no choice at all.

1077. Order-connected subsets of the line are convex. On the line, let K be a set such that every point between two points of K lies in K (if x and y are in K and x ≤ z ≤ y then z is in K). Then for any points x and y of K and any a and b with a ≥ 0, b ≥ 0 and a + b = 1, the point a·x + b·y lies in K. *Used for:* an interval of allowed values is closed under mixing: any mixture of two allowed states is allowed. *Price:* **LLPO**; exact (no choice anywhere).

1078. Convex equals order-connected on the line. On the line, a set K is convex (for any points x and y of K and any a and b with a ≥ 0, b ≥ 0 and a + b = 1, the point a·x + b·y lies in K) if and only if every point between two points of K lies in K. *Used for:* convex regions of one parameter are exactly the intervals. *Price:* **LLPO**; exact; each direction is exactly LLPO, and the converse of each chooses yes-or-no answers, a choice inside the free allowance.

1079. Order-connected sets of comparable points are convex. On the line, let K be a set such

that every point between two points of K lies in K, and such that any two different points x and y of K satisfy $x \le y$ or $y \le x$. Then for any points x and y of K and any a and b with $a \ge 0$, $b \ge 0$ and $a + b = 1$, the point $a \cdot x + b \cdot y$ lies in K. *Used for:* intervals of allowed values whose points are known to be ordered are closed under mixing. *Price:* **open**; at most LLPO (an order-connected set is convex at LLPO whatever the extra hypothesis); with the disjunctive Markov principle available the statement is exactly LLPO, so it is not free; no lower bound is proved without that principle; a variant that assumes the comparison for every pair, equal points included, is free.

1080. Path-connected subsets of the line are order-connected. On the line, let K be a set containing a point x_0 such that for every point y of K some path, continuous on [0, 1], runs inside K from x_0 to y. Then every point between two points of K lies in K. *Used for:* a set of states connected by continuous deformations is an interval: every intermediate value is attained. *Price:* **LLPO**; exact (the converse chooses yes-or-no answers and representatives of the path's values, both inside the free allowance); with the stronger hypothesis that any two points of K are joined by a path, the price is unchanged.

1081. Path-connected subsets of the line are convex. On the line, let K be a set containing a point x_0 such that for every point y of K some path, continuous on [0, 1], runs inside K from x_0 to y. Then for any points x and y of K and any a and b with $a \ge 0$, $b \ge 0$ and $a + b = 1$, the point $a \cdot x + b \cdot y$ lies in K. *Used for:* a set of states connected by continuous deformations is closed under mixing. *Price:* **LLPO**; exact (the converse chooses yes-or-no answers and representatives of the path's values, both inside the free allowance); with the stronger hypothesis that any two points of K are joined by a path, the price is unchanged.

1082. The join of finitely many reals is one of them. On the line, let S be given by a nonempty list of indices with no repeated entries, and let f give a point for each index. Then the largest of the values (computed pairwise as the larger of two points) f(i), i in S, equals f(i) for some index i in S. *Used for:* the largest energy of a finite spectrum is one of its levels. *Price:* **LLPO**; exact (the lower bound uses no choice); also exact for lists in which entries may repeat.

1083. The meet of finitely many reals is one of them. On the line, let S be given by a nonempty list of indices with no repeated entries, and let f give a point for each index. Then the smallest of the values (computed pairwise as the smaller of two points) f(i), i in S, equals f(i) for some index i in S. *Used for:* the lowest energy of a finite spectrum is one of its levels. *Price:* **LLPO**; exact (the lower bound uses no choice); also exact for lists in which entries may repeat.

1084. Join of finitely many reals is the least upper bound. On the line, for a nonempty list of indices and a point f(i) for each index, each value f(i) is at most the largest of the values (computed pairwise as the larger of two points) f(i), i in the list, and that largest value is at most a point c exactly when every value f(i) is at most c. *Used for:* the largest of finitely many measured values bounds them all and is the smallest such bound. *Price:* **free**; exact.

1085. Meet of finitely many reals is the greatest lower bound. On the line, for a nonempty list of indices and a point f(i) for each index, the smallest of the values (computed pairwise as the smaller of two points) f(i), i in the list, is at most each value f(i), and a point c is at most that smallest value exactly when c is at most every value f(i). *Used for:* the smallest of finitely many measured values is below them all and is the largest such bound. *Price:* **free**; exact.

1086. A finite list has a least member for any function. On the line, for every nonempty list of items, entries may repeat, and every function f from items to points, some member m of the list satisfies $f(m) \le f(a)$ for every member a of the list ($a \le b$ here means that $b < a$ fails). *Used for:* the lowest-cost configuration in a finite enumeration of candidates. *Price:* **LLPO**; exact (the lower bound uses no choice); the mirror statement for a greatest member has an equal price.

1087. A finite list has a first member of least value. On the line, for every nonempty list of items, entries may repeat, and every function f from items to points, some member m of the list satisfies $f(m) \le f(a)$ for every member a and, for every member a with $f(a) \le f(m)$, the first occurrence of m comes no later in the list than the first occurrence of a ($a \le b$ here means that $b < a$ fails). *Used for:* naming the first of the lowest-cost configurations in a fixed enumeration: ties must be decided. *Price:* **WLPO**; exact (the lower bound uses no choice); the mirror statement for the first greatest member has an equal price.

1088. Heine–Cantor theorem on the unit cube. On the line, if a function from the unit cube $[0, 1] \times [0, 1] \times [0, 1]$ to the line is continuous at every point of the cube (a distance for every point and tolerance, with closeness meaning every coordinate within the distance), then it is uniformly continuous on the cube: for every tolerance there is one distance that serves all pairs of points of the cube. *Used for:* one mesh serves a whole compact three-dimensional region: uniform error estimates for a field that is only known to be continuous at each point. *Price:* **open**; at least the decidable fan theorem; at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives),

and at most the full fan theorem with no choice; equivalent, with no choice, to the decidable fan theorem together with a presentation of the local control data by countable covers.

1089. Heine–Cantor theorem on the unit cube of every dimension. On the line, for every $n \geq 1$, if a function from the unit cube $[0, 1]^n$ (n coordinates, each in $[0, 1]$) to the line is continuous at every point of the cube, then it is uniformly continuous on the cube: for every tolerance there is one distance that serves all pairs of points of the cube. *Used for:* one mesh for a compact region of any number of parameters, such as the configuration space of a finite system. *Price:* **open**; at least the decidable fan theorem in every dimension; at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives), and at most the full fan theorem with no choice; equivalent, with no choice, to the decidable fan theorem together with a presentation of the local control data by countable covers, in every dimension.

1090. Arzelà–Ascoli with a common modulus, uniformly Cauchy form. On the line, let $f_0, f_1, f_2, \ldots$ be functions on $[0, 1]$ that are all bounded by one natural number M, and suppose that for every tolerance there is one distance such that every function f_n changes by at most the tolerance between any two points of $[0, 1]$ within that distance. Then some strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ makes the functions $f(\varphi(0)), f(\varphi(1)), \ldots$ uniformly Cauchy on $[0, 1]$: for every tolerance, from some m on, any two of them are within the tolerance at every point of $[0, 1]$. *Used for:* a bounded family with one common modulus of continuity has a uniformly Cauchy subfamily: a step toward limiting profiles in variational and evolution problems. *Price:* **LPO**; exact: the lower bound LPO uses no choice (constant functions); the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance.

1091. Arzelà–Ascoli for sequences equicontinuous at each point. On the line, let $f_0, f_1, f_2, \ldots$ be functions on $[0, 1]$ that are all bounded by one natural number M, and suppose that at every point x of $[0, 1]$, for every tolerance there is a distance such that every function f_n changes by at most the tolerance between x and any point of $[0, 1]$ within that distance. Then some strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ makes the functions $f(\varphi(0)), f(\varphi(1)), \ldots$ uniformly Cauchy on $[0, 1]$: for every tolerance, from some m on, any two of them are within the tolerance at every point of $[0, 1]$. *Used for:* limiting profiles exist when continuity is only known at each point, to one common degree for every profile of the family. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance; it goes through row 1090 and the Heine–Cantor theorem for a sequence of functions.

1092. A tuple of reals can be sorted by a permutation. On the line, for every n and every list of n points $f(0), \ldots, f(n-1)$, repeats allowed, some permutation σ of the places $0, \ldots, n-1$ satisfies $f(\sigma(i)) \leq f(\sigma(j))$ whenever $i \leq j$ ($a \leq b$ here means that $b < a$ fails). *Used for:* ordering n measured values or energy levels from the lowest up, as when filling levels one by one. *Price:* **LLPO**; exact (the lower bound uses no choice).

1093. A tuple of reals with injective values can be sorted. On the line, for every n and every list of n points $f(0), \ldots, f(n-1)$ such that $f(i) = f(j)$ forces $i = j$ (no two places carry equal values), some permutation σ of the places satisfies $f(\sigma(i)) \leq f(\sigma(j))$ whenever $i \leq j$ ($a \leq b$ here means that $b < a$ fails). *Used for:* ordering the levels of a nondegenerate spectrum from the lowest up, when no two levels coincide. *Price:* $\mathbf{MP}^{\vee}$; exact (the lower bound uses no choice); values that are pairwise apart, with a visible gap between any two, would be comparable outright and are not priced here.

1094. Heine–Cantor for a sequence of functions on the interval. On the line, let $f_0, f_1, f_2, \ldots$ be functions on $[0, 1]$ such that at every point x of $[0, 1]$, for every tolerance there is a distance such that every function f_n changes by at most the tolerance between x and any point of $[0, 1]$ within that distance. Then the family is uniformly equicontinuous: for every tolerance there is one distance that serves every function f_n and every pair of points of $[0, 1]$. *Used for:* one mesh for a whole compact interval and a whole family of fields or profiles that are only known to be continuous at each point to one common degree. *Price:* **open**; at least the decidable fan theorem (it gives the Heine–Cantor theorem for one function); at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives), and at most the full fan theorem with no choice.

1095. Arzelà–Ascoli with a convergent subsequence, common modulus. On the line, let $f_0, f_1, f_2, \ldots$ be functions on $[0, 1]$ that are all bounded by one natural number M, and suppose that for every tolerance there is one distance such that every function f_n changes by at most the tolerance between any two points of $[0, 1]$ within that distance. Then some strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ has the following property: at every point x of $[0, 1]$ the values $f(\varphi(0))(x), f(\varphi(1))(x), \ldots$ converge to

some limit, and for every tolerance there is one m_0 such that for all $m \geq m_0$ and every point x of [0, 1], $f(\varphi(m))(x)$ is within the tolerance of the limit at x. *Used for:* a bounded family with one common modulus of continuity has a uniformly convergent subfamily: limiting profiles of variational and evolution problems, given point by point. *Price:* **LPO**; exact: the lower bound LPO uses no choice (a convergent subsequence is uniformly Cauchy); the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance; the limits are given point by point.

1096. Arzelà–Ascoli with a convergent subsequence, pointwise equicontinuity. On the line, let $f_0, f_1, f_2, \ldots$ be functions on [0, 1] that are all bounded by one natural number M, and suppose that at every point x of [0, 1], for every tolerance there is a distance such that every function f_n changes by at most the tolerance between x and any point of [0, 1] within that distance. Then some strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ has the following property: at every point x of [0, 1] the values $f(\varphi(0))(x), f(\varphi(1))(x), \ldots$ converge to some limit, and for every tolerance there is one m_0 such that for all $m \geq m_0$ and every point x of [0, 1], $f(\varphi(m))(x)$ is within the tolerance of the limit at x. *Used for:* limiting profiles exist when continuity is only known at each point, to one common degree for every profile of the family. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance; it goes through the Heine–Cantor theorem for a sequence of functions.

1097. Arzelà–Ascoli, common modulus, convergent subsequence with continuous limits. On the line, let $f_0, f_1, f_2, \ldots$ be functions on [0, 1] that are all bounded by one natural number M, and suppose that for every tolerance there is one distance such that every function f_n changes by at most the tolerance between any two points of [0, 1] within that distance. Then some strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ has the following properties: at every point x of [0, 1] the values $f(\varphi(0))(x), f(\varphi(1))(x), \ldots$ converge to some limit; for every tolerance there is one m_0 such that for all $m \geq m_0$ and every point x of [0, 1], $f(\varphi(m))(x)$ is within the tolerance of the limit at x; and for every tolerance there is a distance such that, for any two points x and y of [0, 1] within that distance, the limit at x and the limit at y are within the tolerance of each other. *Used for:* the limiting profile is itself continuous, with one modulus serving the whole family and its limit. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance; the continuity of the limits needs no further principle.

1098. Arzelà–Ascoli with a limit function, common modulus. On the line, let $f_0, f_1, f_2, \ldots$ be functions on [0, 1] that are all bounded by one natural number M, and suppose that for every tolerance there is one distance such that every function f_n changes by at most the tolerance between any two points of [0, 1] within that distance. Then there are a strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ and a function g (only its values on [0, 1] matter) such that for every tolerance there is one m_0 with $f(\varphi(m))(x)$ within the tolerance of $g(x)$ for all $m \geq m_0$ and every point x of [0, 1]. *Used for:* a bounded family with one common modulus of continuity has a subfamily converging uniformly to a limit profile g: limiting profiles of variational and evolution problems. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance; the function g is built by extension from the rational points of [0, 1], not by choosing a value at each point; compactness of the closure of the family in the sup metric is not stated.

1099. Arzelà–Ascoli with a limit function, pointwise equicontinuity. On the line, let $f_0, f_1, f_2, \ldots$ be functions on [0, 1] that are all bounded by one natural number M, and suppose that at every point x of [0, 1], for every tolerance there is a distance such that every function f_n changes by at most the tolerance between x and any point of [0, 1] within that distance. Then there are a strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ and a function g (only its values on [0, 1] matter) such that for every tolerance there is one m_0 with $f(\varphi(m))(x)$ within the tolerance of $g(x)$ for all $m \geq m_0$ and every point x of [0, 1]. *Used for:* limiting profiles exist when continuity is only known at each point, to one common degree for every profile of the family. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance.

1100. Arzelà–Ascoli, limit function that is continuous. On the line, let $f_0, f_1, f_2, \ldots$ be functions on [0, 1] that are all bounded by one natural number M, and suppose that for every tolerance there is one distance such that every function f_n changes by at most the tolerance between any two points of [0, 1] within that distance. Then there are a strictly increasing sequence of indices $\varphi(0) < \varphi(1) < \ldots$ and a function g (only its values on [0, 1] matter) such that for every tolerance there is one m_0 with $f(\varphi(m))(x)$

within the tolerance of g(x) for all $m \geq m_0$ and every point x of [0, 1], and such that, for every tolerance and every distance that works for all functions f_n at that tolerance, g(x) and g(y) are within the tolerance whenever x and y are points of [0, 1] within that distance. *Used for:* the limiting profile is itself continuous, with the modulus of the family. *Price:* **LPO**; exact: the lower bound LPO uses no choice; the converse uses LPO with countable unique choice of yes-or-no answers and choice of representatives, both inside the free allowance.

1101. Compactness of the Hilbert cube of unit intervals. On the line, let countably many open boxes be given, each restricting only finitely many coordinates: box k restricts the coordinates $i < m(k)$ to open intervals with fraction endpoints and leaves the other coordinates free. If every sequence $x_0, x_1, x_2, \ldots$ of points of [0, 1] lies in some box, then finitely many of the boxes, the first N for some N, already contain every such sequence. *Used for:* the state space of an infinite lattice with one bounded real variable per site is compact: limit states and uniform estimates for infinite systems. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω through weak König's lemma), a price equal to that of Heine–Borel on [0, 1] and on every finite cube; the lower bound is the one-coordinate case.

1102. Lebesgue number lemma on the unit interval. On the line, if countably many open intervals with fraction endpoints cover the unit interval [0, 1] (every point x of [0, 1] lies strictly inside one of them), then there is a natural number d such that for every point x of [0, 1] some interval of the cover contains every point y of the line with $|y - x| < 1/(d + 1)$. *Used for:* a uniform grid size for a compact interval: every window of one fixed width around a point of the interval lies inside a single member of a countable covering family of open intervals with fraction endpoints. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem (so at most LLPO + AC_ω through weak König's lemma), a price equal to that of Heine–Borel on [0, 1]; the lower bound uses a finite grid and a sum of finitely many indices.

1103. Lebesgue number lemma on the unit square. On the line, if countably many open rectangles with fraction corners cover the unit square $[0, 1] \times [0, 1]$ (every point of the square lies strictly inside one of them), then there is a natural number d such that for every point $p = (p_1, p_2)$ of the square some rectangle of the cover contains every point $q = (q_1, q_2)$ with $|q_1 - p_1| < 1/(d + 1)$ and $|q_2 - p_2| < 1/(d + 1)$. *Used for:* a uniform grid size for a compact two-parameter region: every window of one fixed size around a point of the region lies inside a single member of a countable covering family of open rectangles with fraction corners. *Price:* **FAN**; exact: equivalent, with no choice, to the decidable fan theorem and to the Lebesgue number lemma on the unit interval; upper bound at most LLPO + AC_ω through weak König's lemma.

Q.9 Probability

1104. Variance is never negative. For any nonnegative weights on finitely many outcomes, the variance of an observable is zero or positive. *Used for:* Fluctuations of energy and other observables; heat capacity read as an energy variance. *Price:* **free**; exact.

1105. Variance as mean square minus squared mean. For a probability law on finitely many outcomes, the variance of X equals the mean of X^2 minus the square of the mean of X. *Used for:* Energy fluctuations $\langle \Delta E^2 \rangle = \langle E^2 \rangle - \langle E \rangle^2$ in statistical mechanics. *Price:* **free**; exact.

1106. Variance of a scaled observable. For any weights on finitely many outcomes, multiplying an observable by c multiplies its variance by c^2. *Used for:* Changing the units or the scale of a measured quantity. *Price:* **free**; exact.

1107. Variance ignores a constant shift. For a probability law on finitely many outcomes, adding a constant to an observable leaves its variance unchanged. *Used for:* Moving the zero of energy does not change energy fluctuations. *Price:* **free**; exact.

1108. Variance is at most the mean square. For a probability law on finitely many outcomes, the variance of X is at most the mean of X^2. *Used for:* Bounding fluctuations by second moments. *Price:* **free**; exact.

1109. Popoviciu's variance bound. For a probability law on finitely many outcomes, an observable with values between a and b has variance at most $((b - a)/2)^2$. *Used for:* Bounded observables such as spins and occupation numbers have bounded fluctuations. *Price:* **free**; exact.

1110. Mean of a product of independent observables. When the joint law of two finite observables is the product of their separate laws, the mean of their product is the product of their means. *Used for:* Uncoupled subsystems; partition functions

that factorize. *Price:* **free**; exact.

1111. Variances of independent observables add (Bienaymé). When the joint law of two finite observables is the product of their separate laws, the variance of their sum is the sum of their variances. *Used for:* Random-walk diffusion, where the mean square displacement grows linearly with the number of steps; additivity of fluctuations. *Price:* **free**; exact.

1112. Markov's inequality for the exact tail set. For a nonnegative observable on finitely many outcomes and every level c, the set of outcomes where the observable is at least c is an event, and c times its probability is at most the mean. *Used for:* Tail bounds on nonnegative quantities such as energies and counts. *Price:* **WLPO**; exact.

1113. Markov's inequality for recorded tail events. For a nonnegative observable on finitely many outcomes, every event on whose outcomes the observable is at least c has c times its probability at most the mean. *Used for:* Tail bounds on nonnegative quantities, read off any recorded event in the tail. *Price:* **free**; exact.

1114. Chebyshev's inequality for the exact tail set. For an observable on finitely many outcomes and every $c > 0$, the set of outcomes where the observable is at least c away from its mean is an event, and c^2 times its probability is at most the variance. *Used for:* Concentration of measure; the sharpness of thermodynamic limits. *Price:* **WLPO**; exact.

1115. Chebyshev's inequality for recorded tail events. For an observable on finitely many outcomes and $c \geq 0$, every event on whose outcomes the observable is at least c away from its mean has c^2 times its probability at most the variance. *Used for:* Concentration of measure read off any recorded deviation. *Price:* **free**; exact.

1116. Chernoff bound for the exact tail set. For an observable X on finitely many outcomes, a level ε and $t \geq 0$, the set where X is at least ε is an event and its probability is at most $e^{-t\varepsilon}$ times the mean of $e^{t \cdot X}$. *Used for:* Large deviations; exponential concentration of sums. *Price:* **WLPO**; exact.

1117. Chernoff bound for recorded tail events. For an observable X on finitely many outcomes, a level ε and $t \geq 0$, every event on whose outcomes X is at least ε has probability at most $e^{-t\varepsilon}$ times the mean of $e^{t \cdot X}$. *Used for:* Large deviations read off any recorded tail event. *Price:* **free**; exact.

1118. Jensen's inequality for finite averages. For a function f convex on the whole real line and an observable X on a finite probability space, f of the mean of X is at most the mean of f(X). *Used for:* The Gibbs–Bogoliubov free-energy bound; Jarzynski's inequality $\langle e^{-W} \rangle \geq e^{-\langle W \rangle}$. *Price:* **free**; exact.

1119. Concavity of the entropy function. The function $-x \log x$ is concave on the nonnegative numbers. *Used for:* Concavity of entropy; thermodynamic stability. *Price:* **free**; exact.

1120. Gibbs' inequality (relative entropy is nonnegative). For two probability laws on finitely many outcomes, the second giving every outcome positive weight, the relative entropy of the first to the second is zero or positive. *Used for:* The second law of thermodynamics; relative entropy as a one-way distance between laws. *Price:* **free**; exact.

1121. Relative entropy vanishes only at equal laws. For two probability laws on finitely many outcomes, the second giving every outcome positive weight, the relative entropy is zero exactly when the two laws are equal. *Used for:* Equilibrium is the unique law with zero relative entropy to itself. *Price:* **free**; exact.

1122. Binary entropy is at most log 2. For a probability p between 0 and 1, $-p \log p - (1 - p) \log(1 - p)$ is at most log 2. *Used for:* A two-outcome record holds at most one bit of entropy. *Price:* **free**; exact.

1123. Markov's inequality at a resolvable level. For a nonnegative observable on finitely many outcomes, a level c and any tolerance, there is a level c' between c and c plus the tolerance at which the set where the observable is at least c' is an event, and c' times its probability is at most the mean. *Used for:* Tail bounds read at a level a finite record can resolve. *Price:* **free**; exact.

1124. Chebyshev's inequality at a resolvable level. For an observable on finitely many outcomes, a level $c > 0$ and any tolerance, there is a level c' between c and c plus the tolerance at which the set where the observable is at least c' away from its mean is an event, and c'^2 times its probability is at most the variance. *Used for:* Concentration of measure at a level a finite record can resolve. *Price:* **free**; exact.

1125. Variance of a sum of uncorrelated observables. For finitely many observables on finitely many outcomes, pairwise uncorrelated, the variance of their sum is the sum of their variances (uncorrelated is weaker than independent, so this is the stronger statement). *Used for:* Diffusion; fluctuations of extensive sums over many independent parts. *Price:* **free**; exact.

1126. Weak law of large numbers with a rate. On a finite probability space (finitely many outcomes, nonnegative weights summing to 1), take k pairwise uncorrelated observables with variances at most σ^2 and a number $\varepsilon \geq 0$. Every event on which their sum is at least $k\varepsilon$ away from its mean has $(k\varepsilon)^2$ times its probability at most $k\sigma^2$, that is probability at most $\sigma^2/(k\varepsilon^2)$ when $k\varepsilon > 0$. *Used for:* Averages over many

parts concentrate on their mean; sharp thermodynamic limits. *Price:* **free**; exact.

1127. Stationary law of a two-state Markov chain. Every Markov chain on two states has a stationary law: a probability law that one step of the chain leaves unchanged. *Used for:* Equilibrium of a two-level system with given up and down rates. *Price:* **LLPO + AC**$_\omega$; exact.

1128. Stationary law of a moving two-state chain. A Markov chain on two states that leaves at least one state with positive probability, $a = K_{01}$ and $b = K_{10}$ with $a + b > 0$, has the stationary law $(b, a)/(a + b)$. *Used for:* Detailed balance and the equilibrium population of a two-level system. *Price:* **free**; exact.

1129. Stationary law of a three-state Markov chain. Every Markov chain on three states has a stationary law: a probability law on the three states that one step of the chain leaves unchanged. *Used for:* Equilibrium of three-level systems and other small finite Markov models. *Price:* **LLPO + AC**$_\omega$; exact.

1130. Unique stationary law of an ergodic chain (Doeblin). A Markov chain on finitely many states in which some state is entered from every state with probability at least $\delta > 0$ has exactly one stationary law: a probability law that one step of the chain leaves unchanged, and every other such law equals it. *Used for:* Relaxation to a unique equilibrium in ergodic finite systems; Monte Carlo sampling converges. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1131. Approximately stationary laws of finite chains. Every Markov chain on finitely many states (at least one) has, for every tolerance, a probability law that one step of the chain changes by at most that tolerance at every state. *Used for:* Time averages of a finite system's state approach equilibrium. *Price:* **free**; exact.

1132. Strong law of large numbers on finite windows. On a finite probability space (finitely many outcomes, nonnegative weights summing to 1), let X_0, X_1, ... be observables with $|X_k| \le 1$ and mean 0, each uncorrelated with the sum $S_k = X_0 + \dots + X_{k-1}$ of those before it in the four products $S_k X_k$, $S_k^2 X_k^2$, $S_k^3 X_k$ and $S_k X_k^3$. For $\varepsilon > 0$ and a window $N < k \le M$, every event on whose outcomes some k in the window has $|S_k| \ge k\varepsilon$ has $\varepsilon^4 \cdot N$ times its probability at most 3, that is probability at most $3/(\varepsilon^4 N)$ when $N \ge 1$. *Used for:* Running averages of repeated measurements settle on the mean, with an explicit rate for every finite record. *Price:* **free**; exact.

1133. Strong-law window bound from a fourth-moment bound. On a finite probability space (finitely many outcomes, nonnegative weights summing to 1), let S_k be the sum of the first k of a sequence of observables, with mean of S_k^4 at most $C \cdot k^2$ for every k. For $\varepsilon > 0$ and a window $N < k \le M$, every event on whose outcomes some k in the window has $|S_k| \ge k\varepsilon$ has $\varepsilon^4 \cdot N$ times its probability at most C, that is probability at most $C/(\varepsilon^4 N)$ when $N \ge 1$. *Used for:* Almost-sure convergence of averages, made quantitative from moment bounds. *Price:* **free**; exact.

1134. Stationary laws of all finite Markov chains. Every Markov chain on finitely many states, two or more, has a stationary law: a probability law that one step of the chain leaves unchanged. *Used for:* The existence of equilibrium for every finite Markov model, as Perron–Frobenius theory gives it. *Price:* **LLPO + AC**$_\omega$; exact.

1135. Unique stationary law of a primitive chain. A Markov chain on finitely many states whose allowed moves each have probability at least $\delta > 0$, and whose graph of allowed moves reaches one state from every state in exactly m steps, has exactly one stationary law. *Used for:* A single equilibrium for irreducible aperiodic systems; the target law of a Monte Carlo sampler is the only law its moves leave unchanged. *Price:* **free**; exact.

1136. Gaussian integral over the whole line. For every $p > 0$ and every q, the integral of $e^{-p\,y^2 + q\,y}$ over the whole line is $\sqrt{(\pi/p)} \cdot e^{q^2/(4p)}$, and the integral of $y \cdot e^{-p\,y^2 + q\,y}$ over the whole line is $(q/(2p)) \cdot \sqrt{(\pi/p)} \cdot e^{q^2/(4p)}$, with π twice the quarter period of the cosine. *Used for:* Oscillator ground states, heat kernels, Gaussian wave packets and partition functions of quadratic energies. *Price:* **free**; exact. Proved in Theorem 12.95.

1137. Minimum principle on Cantor space. Every uniformly continuous function of infinite sequences of binary digits attains its minimum at some sequence. *Used for:* Ground states of systems with infinitely many two-state sites, such as spin chains, exist. *Price:* **LLPO + AC**$_\omega$; exact.

1138. Minimum principle on the simplex of laws. On the set of probability laws over finitely many outcomes, two or more, every uniformly continuous function attains its minimum. *Used for:* Variational principles over probability laws: minimum free energy, maximum entropy at fixed constraints. *Price:* **LLPO + AC**$_\omega$; exact.

1139. Normal density integrates to one. For every mean μ and variance $v > 0$, the integral of $e^{-(y-\mu)^2/(2v)}$ over the whole line is $\sqrt{(2\pi v)}$, so the normal density integrates to one. *Used for:* Normalisation of Gaussian wave packets, thermal (Maxwell) velocity laws and Gaussian noise. *Price:* **free**; exact.

1140. Mean of the normal law. For every mean μ and variance $v > 0$, the integral of $y \cdot e^{-(y-\mu)^2/(2v)}$ over

the whole line is $\mu\sqrt{(2\pi v)}$: the normal law's mean is μ. *Used for:* The centre of a Gaussian distribution of positions, velocities or measurement errors. *Price:* **free**; exact.

1141. Variance of the normal law. For every mean μ and variance $v > 0$, the integral of $(y - \mu)^2 \cdot e^{-(y-\mu)^2/(2v)}$ over the whole line is $v\sqrt{(2\pi v)}$: the normal law's variance is v. *Used for:* Spread of Brownian displacement; equipartition, where the velocity variance is the temperature times Boltzmann's constant over the mass. *Price:* **free**; exact.

1142. Moment generating function of the normal law. For every mean μ, variance $v > 0$ and real t, the integral of $e^{t\cdot y} \cdot e^{-(y-\mu)^2/(2v)}$ over the whole line is $\sqrt{(2\pi \cdot v)} \cdot e^{\mu \cdot t + v \cdot t^2/2}$. *Used for:* Cumulants of Gaussian noise; large deviations; partition functions of quadratic energies with a linear field. *Price:* **free**; exact.

1143. Even moments of the standard normal law. For every k, the integral of $y^{2k} \cdot e^{-y^2/2}$ over the whole line is $1 \cdot 3 \cdot 5 \cdots (2k - 1)$ times $\sqrt{(2\pi)}$. *Used for:* Wick's theorem for Gaussian fields; higher fluctuations of thermal and quantum ground-state variables. *Price:* **free**; exact.

1144. Characteristic function of the standard normal law. For every real t, the integral of $\cos(t\cdot y) \cdot e^{-y^2/2}$ over the whole line is $\sqrt{(2\pi)} \cdot e^{-t^2/2}$. *Used for:* The Fourier transform of a Gaussian: heat kernels, Gaussian wave packets in momentum space, and the input of the central limit theorem. *Price:* **free**; exact.

1145. Steady state of a finite master equation. Every master equation on finitely many states, two or more, with nonnegative transition rates has a steady state: a probability law that the rates leave unchanged. *Used for:* Steady states of rate equations: chemical kinetics, population dynamics, open quantum systems in the rate limit. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

1146. Unique steady state of a connected master equation. A master equation on finitely many states whose rates are at least $\delta > 0$ along a graph of moves that reaches one state from every state in a fixed number of steps has exactly one steady state. *Used for:* Connected rate equations have exactly one equilibrium, the only candidate for the state they relax to. *Price:* **free**; exact.

1147. Characteristic function of an independent sum. For two observables on finitely many outcomes whose joint law is the product of their separate laws, the characteristic function of their sum (its cosine and sine parts) is the product of their characteristic functions. *Used for:* Sums of independent kicks: random walks, Brownian motion as a limit of steps, the central limit theorem. *Price:* **free**; exact.

1148. Odd moments of the standard normal law vanish. For every k, the integrals of $y^{2k+1} \cdot e^{-y^2/2}$ over the symmetric intervals $[-L, L]$ tend to 0 as the whole number L grows: taken as a symmetric limit, the integral over the whole line is 0. *Used for:* Symmetric Gaussian noise has no skew; odd correlators of free Gaussian fields vanish. *Price:* **free**; exact.

1149. Sine transform of the standard normal density. For every real t, the integrals of $\sin(t\cdot y) \cdot e^{-y^2/2}$ over the symmetric intervals $[-L, L]$ tend to 0 as the whole number L grows: taken as a symmetric limit, the sine part of the characteristic function of the standard normal law (mean 0, variance 1) is 0. *Used for:* A centred Gaussian wave packet carries no phase; centred noise has a real spectrum. *Price:* **free**; exact.

1150. Characteristic function of a shifted normal law. For every mean μ and real t, the integrals of $\cos(t\cdot y)$ and $\sin(t\cdot y)$ against $e^{-(y-\mu)^2/2}$ over the whole line are $\sqrt{(2\pi)} \cdot e^{-t^2/2} \cdot \cos(\mu t)$ and $\sqrt{(2\pi)} \cdot e^{-t^2/2} \cdot \sin(\mu t)$. *Used for:* Gaussian wave packets centred away from the origin: momentum-space phase $e^{i\mu t}$. *Price:* **free**; exact.

1151. Detailed balance gives a stationary law. If a probability law and a Markov chain on finitely many states satisfy detailed balance (the weight of i times the rate from i to j equals the weight of j times the rate from j to i, for every pair of states), the law is stationary for the chain. *Used for:* Reversible dynamics and equilibrium: Metropolis and heat-bath sampling, microscopic reversibility. *Price:* **free**; exact.

1152. Stationary law of a birth–death chain. A Markov chain on the states $0, 1, \ldots, n$ that moves only between neighbouring states, with every downward rate from $i + 1$ to i positive, has a stationary probability law in detailed balance with it: the weight of $i + 1$ times the down-rate from $i + 1$ equals the weight of i times the up-rate from i. *Used for:* The Ehrenfest urn, one-dimensional diffusion between sites, queues and population models. *Price:* **free**; exact.

1153. Law of independent copies. For a probability law on finitely many outcomes and every k, the weights of k independent copies (the product of the k individual weights) are nonnegative and sum to 1. *Used for:* Repeated independent trials; ideal gases of independent particles; the outcome space of many independent measurements. *Price:* **free**; exact.

1154. Characteristic function of a sum of independent copies. For a probability law on finitely many values and every k, the characteristic function of the sum of k independent copies is the k-th complex power of the law's characteristic function. *Used for:* Random walks after k steps; the characteristic function behind the central limit

theorem for sums. *Price:* **free**; exact.

1155. Kolmogorov's criterion for reversibility. A Markov chain on finitely many states with every transition probability positive has a probability law in detailed balance with it exactly when, for every two states, the product of transition probabilities around the triangle through a fixed state is equal in both directions. *Used for:* Telling equilibrium dynamics from driven ones by reading the rates; reversible Markov models in chemistry and sampling. *Price:* **free**; exact.

1156. Deciding whether a chain is reversible. Deciding, for every Markov chain on finitely many states with all transition probabilities positive, whether it has a law in detailed balance with it. *Used for:* Deciding whether a steady state is an equilibrium or a driven nonequilibrium state. *Price:* **WLPO**; exact.

1157. Integral of a product of functions. If k functions each have an integral over the whole line, the product of the functions, one per coordinate, has as its iterated integral over k dimensions the product of the k integrals. *Used for:* Integrals over independent coordinates factor: partition functions of uncoupled degrees of freedom. *Price:* **free**; exact.

1158. Gaussian integral in k dimensions. For positive a_1, ..., a_k, the iterated integral of $e^{-(a_1 y_1^2 + \cdots + a_k y_k^2)}$ over k dimensions, taken one coordinate at a time over the whole line, is the product of the square roots of π/a_i. *Used for:* Partition functions of independent oscillators; momentum integrals of the ideal gas; multivariate normal laws with independent coordinates. *Price:* **free**; exact.

1159. Gaussian integral of a positive-definite form. For a quadratic form in k variables that equals a weighted sum of squares $d_1(y_1)^2 + d_2(y_2 + m_{21}y_1)^2 + d_3(y_3 + m_{31}y_1 + m_{32}y_2)^2 + \cdots$ with every weight d_i positive (its triangular factorisation), the iterated integral of $e^{-\text{form}}$ over k dimensions, taken one coordinate at a time over the whole line, is the product of the square roots of π/d_i. *Used for:* Normalisation of multivariate normal laws; partition functions of coupled oscillators and of free Gaussian fields. *Price:* **free**; exact.

1160. Every Markov chain on a tree is reversible. A Markov chain on finitely many states whose moves go only along the edges of a tree, with both directions of every edge possible, has a law in detailed balance with it. *Used for:* Branching state spaces (polymer and hierarchical models): equilibrium is automatic when the moves form a tree. *Price:* **free**; exact.

1161. Factorising a uniformly positive quadratic form. Every symmetric quadratic form in k variables that is at least $c > 0$ times the squared length is a weighted sum of k squares, each square combining one variable with the earlier ones, with every weight at least c. *Used for:* Diagonalising covariance, stiffness and inertia matrices; Gaussian elimination when every pivot is kept away from zero. *Price:* **free**; exact.

1162. Gaussian integral of a uniformly positive form. For every symmetric quadratic form in k variables that is at least $c > 0$ times the squared length, the integral of $e^{-\text{form}}$ over k dimensions, taken one coordinate at a time over the whole line, exists, and its square times the product of the form's pivots is π^k. *Used for:* Normalisation of every multivariate normal law; partition functions of coupled oscillators and lattice Gaussian fields. *Price:* **free**; exact.

1163. Kolmogorov's criterion for sparse chains (Wegscheider). A Markov chain whose possible moves form a symmetric network containing a spanning tree is reversible exactly when, on every move of the network, the products of rates along the tree paths balance, so that the rate products around every cycle agree in both directions. *Used for:* Wegscheider's condition for chemical reaction networks; equilibrium of Markov models on sparse state graphs. *Price:* **free**; exact.

1164. Deciding whether a sparse chain is reversible. Deciding, for every Markov chain whose possible moves form a symmetric network containing a spanning tree, whether it has a law in detailed balance with it. *Used for:* Deciding whether a reaction network's steady state is an equilibrium or a driven nonequilibrium state. *Price:* **WLPO**; exact.

1165. Triangular factorisation of a semidefinite quadratic form. Every symmetric quadratic form in finitely many variables that is never negative is a weighted sum of squares, each square combining one variable with the earlier ones, with every weight zero or positive. *Used for:* Degenerate covariance matrices and zero modes: factorising them requires knowing which pivots vanish exactly. *Price:* **LPO**; exact.

1166. Generating function of an independent sum. For two observables on finitely many outcomes whose joint law is the product of their separate laws, the mean of $e^{t(X+Y)}$ is the product of the means of e^{tX} and e^{tY}, for every real t. *Used for:* Cumulants of independent parts add; partition functions of uncoupled systems multiply. *Price:* **free**; exact.

1167. Generating function of a sum of independent copies. For a probability law on finitely many values, every k and every real t, the mean of e^{tS} over k independent copies, S their sum, is the k-th power of the mean of e^{tX}. *Used for:* Every moment of a sum of independent copies is read off one function; large deviations of averages; the free energy of k independent particles. *Price:* **free**; exact.

1168. Principal component of a covariance matrix. For every probability law on finitely many outcomes of a vector observable, the covariance matrix has a unit eigenvector whose eigenvalue is the largest variance of the observable along any unit direction. *Used for:* Principal component analysis; the dominant normal mode of thermal fluctuations; the direction of largest spread of a measurement. *Price:* **LLPO + AC**$_\omega$; exact.

1169. Chernoff–Cramér bound for sums of independent copies. For k independent copies of a law on finitely many values, a level a and a tilt $t \geq 0$, every event on which the sum is at least $k \cdot a$ has probability at most $e^{-t \cdot k \cdot a}$ times the k-th power of the mean of $e^{t \cdot X}$. *Used for:* Exponential concentration of averages of many independent measurements; large deviations of extensive quantities. *Price:* **free**; exact.

1170. Chernoff–Cramér bound for the exact tail set of a sum. For k independent copies of a law on finitely many values, a level a and a tilt $t \geq 0$, the set of outcomes on which the sum is at least $k \cdot a$ is an event and its probability is at most $e^{-t \cdot k \cdot a}$ times the k-th power of the mean of $e^{t \cdot X}$. *Used for:* Large-deviation bounds stated for the exact tail set of a sum. *Price:* **WLPO**; exact.

1171. Chernoff's optimal constant for sums of independent copies. For a law on finitely many values that gives positive weight to some value above a level a, the greatest lower bound ρ over tilts $t \geq 0$ of $e^{-t \cdot a}$ times the mean of $e^{t \cdot X}$ exists as a number, approached at some tilts; and for k independent copies every event on which the sum is at least $k \cdot a$ has probability at most ρ^k. *Used for:* Cramér's rate function of large deviations (ρ is e to the minus the rate); optimal exponential bounds on rare fluctuations of extensive quantities. *Price:* **AC**$_\omega$; exact (no decision principle); the upper bound uses countable choice.

1172. Largest variance along a unit direction. For a law on finitely many values of a vector observable, the largest variance along a unit direction exists as a number: no unit direction has larger variance, and unit directions come within any tolerance of it. *Used for:* Largest normal-mode amplitude of thermal fluctuations; the leading variance in principal component analysis; the top eigenvalue of a covariance or stiffness matrix. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1173. Optimal Chernoff tilt as a point. For a law on finitely many values that gives positive weight to some value above a level a and to some value below it, there is a tilt τ at which the tilted mean equals a, that is the mean of $(X - a) \cdot e^{\tau \cdot (X - a)}$ is zero, and the function $t \mapsto e^{-t \cdot a}$ times the mean of $e^{t \cdot X}$ is least at τ over every real t. *Used for:* Choosing the inverse temperature that gives a prescribed mean energy; the saddle point of Cramér's large deviations. *Price:* **AC**$_\omega$; exact (no decision principle); the upper bound uses countable choice.

1174. Ordered variances along the principal axes. For a law on finitely many values of a vector observable with $d + 1$ components, there are $d + 1$ numbers in decreasing order and a constant K such that, at every precision $1/(m+1)$, the covariance has an orthonormal basis with values whose eigen-equations hold within $1/(m+1)$ in every coordinate, and for every such basis and values the j-th largest value lies within $K/(m+1)$ of the j-th number. *Used for:* Variances along the principal axes of fluctuations; energies of normal modes; the spectrum of a covariance in principal component analysis. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1175. Markov chain tree theorem. For every square matrix P, let w(r) be the sum, over all trees on the states directed to r, of the product of the entries $P(k, f(k))$ along the tree's edges. Then for every state j, the sum over i of $w(i) \cdot P(i, j)$ equals w(j) times the sum over k of $P(j, k)$. *Used for:* Kirchhoff's and Hill's diagram method for steady states of master equations and of networks of chemical and biochemical reactions. *Price:* **free**; exact.

1176. Stationary law from tree weights. For a Markov chain on finitely many states whose total tree weight is positive, the tree weights divided by their total form a stationary law. *Used for:* Explicit steady states of finite Markov chains and master equations; steady-state populations of reaction networks. *Price:* **free**; exact.

1177. Positive tree weight of a reachable chain. For a square matrix with nonnegative entries off the diagonal and a graph of allowed moves, each with entry at least $\delta > 0$, that reaches one state r from every state in exactly m steps, the tree weight of r (the sum over trees directed to r of the products of their entries) is positive. *Used for:* Kirchhoff's and Hill's diagram method: steady states of connected chains and reaction networks are given by positive tree weights. *Price:* **free**; exact.

1178. Cramér's rate function at every interior level. For a law on finitely many values that gives positive weight to some value above a level a and to some value below it, there is a number $I \geq 0$ such that $e^{t \cdot a - I}$ is at most the mean of $e^{t \cdot X}$ for every real t, with equality at some t; that is, I is the largest value of $t \cdot a$ minus the logarithm of the mean of $e^{t \cdot X}$, and it is attained. *Used for:* Large-deviation rate of averages of many independent measurements; entropy as a Legendre transform in statistical mechanics. *Price:* **AC**$_\omega$; exact (no decision principle); the upper bound

uses countable choice.

1179. Cramér's rate function is convex. For a law on finitely many values, levels a and b and a weight s between 0 and 1, if Ia, Ib and Ic are the rates at a, b and s·a + (1 − s)·b, each in the attained form ($e^{t\cdot\text{level} - \text{rate}}$ at most the mean of $e^{t\cdot X}$ for every t, with equality at some t), then Ic is at most s·Ia + (1 − s)·Ib. *Used for:* Convexity of large-deviation rate functions; concavity of the microcanonical entropy. *Price:* **free**; exact.

1180. Weyl's bound for ordered variances. If the variances of two laws of a vector observable along every direction v differ by at most e times the squared length of v, then the j-th largest variances along the principal axes of the two laws differ by at most e, for every j. *Used for:* Stability of normal-mode spectra under small changes; how close sample principal variances are to the true ones. *Price:* **free**; exact.

1181. Cramér's lower bound: the rate is exact. For a law on finitely many values that gives positive weight to some value above a level a and to some value below it, let I be Cramér's rate at a in its attained form: $e^{t\cdot a - I}$ is at most the mean of $e^{t\cdot X}$ for every real t, with equality at some t. Then for every tolerance $\varepsilon = 1/(m+1)$ there is k_0 such that for every $k \geq k_0$ some event on which the sum of k independent copies is at least k·a has probability at least $e^{-k\cdot(I+\varepsilon)}$. *Used for:* Large deviations of averages of many independent measurements: the probability of a rare average decays exactly at Cramér's rate. *Price:* $\mathbf{AC}_{\omega}$; exact (no decision principle); the upper bound uses countable choice.

1182. Geometric convergence to equilibrium. A Markov chain on finitely many states whose allowed moves each have probability at least $\delta > 0$, and whose graph of allowed moves reaches one state from every state in exactly m steps, has a stationary law π, and from every initial law the law after q·m steps is within $2\cdot(1 - \delta^m)^q$ of π in total variation. *Used for:* Relaxation of finite systems to equilibrium at an explicit rate; convergence of Monte Carlo samplers. *Price:* **free**; exact.

1183. Kirchhoff's matrix-tree theorem. For every square matrix P, let L be its Laplacian: off the diagonal L(i, j) = −P(i, j), and on the diagonal L(i, i) is the sum of P(i, k) over $k \neq i$. Then for every state r, the tree weight of r (the sum over trees directed to r of the products of their entries) equals the determinant of L with row r and column r removed. *Used for:* Kirchhoff's 1847 counting of spanning trees in electrical networks; determinant formulas for steady states of master equations and reaction networks. *Price:* **free**; exact.

1184. Method of types: probability of a type class. For k independent copies of a law p on n letters and letter counts $c_1, \ldots, c_n$ summing to k, let P be the probability that the copies show exactly these counts. Then P times the product of $c_a^{c_a}$ is at most k^k times the product of $p_a^{c_a}$, and k^k times the product of $p_a^{c_a}$ is at most $(k + 1)^n$ times P times the product of $c_a^{c_a}$. With logarithms: P lies between $(k + 1)^{-n}\cdot e^{-k\cdot D}$ and $e^{-k\cdot D}$, where D is the relative entropy of the frequencies c/k from p. *Used for:* Boltzmann's counting of microstates (k^k over the product of $c_a^{c_a}$ is e to the k times the entropy of the frequencies); Sanov's large deviations of empirical frequencies. *Price:* **free**; exact.

1185. Steady states are Lipschitz in the rates. For two square matrices of size n with nonnegative entries off the diagonal, all entries at most B in size ($B \geq 1$), entries differing by at most ε, and total tree weights at least $w_0 > 0$, the laws proportional to the tree weights differ at every state by at most $(n + 1)\cdot n^n\cdot n\cdot B^n\cdot\varepsilon / w_0$. *Used for:* Response of nonequilibrium steady states of master equations and reaction networks to changes in the rates. *Price:* **free**; exact.

1186. Continuous-time relaxation of a master equation. Let Q be a matrix of transition rates on finitely many states: rows summing to zero, off-diagonal rates nonnegative, every diagonal entry at least −c with $c > 0$. Suppose the moves of a graph, each with rate at least e·c with $e > 0$, reach one state from every state in exactly m steps. Then Q has a steady state π, and for every initial law μ, every time $t \geq 0$, every limit E of the partial sums of $t^j/j!$ times the j-th power of Q (the exponential of t·Q) and every q, the law $\mu\cdot E$ is within $2\cdot(1 - e^m)^q + 2\cdot e^{-c\cdot t}$ times the sum over $j < q\cdot m$ of $(c\cdot t)^j/j!$ of π in total variation. *Used for:* Relaxation of continuous-time master equations (chemical kinetics, population dynamics, open quantum systems in the rate limit) to their steady state at an explicit rate. *Price:* **free**; exact.

1187. Sanov's upper bound for a set of types. For k independent copies of a law p on n letters, a number D and a decided set A of letter counts such that every count vector c in A summing to k satisfies k^k times the product of $p_a^{c_a}$ at most $e^{-k\cdot D}$ times the product of $c_a^{c_a}$ (relative entropy of the frequencies from p at least D), the probability that the letter counts of the copies lie in A is at most $(k + 1)^n\cdot e^{-k\cdot D}$. *Used for:* Large deviations of empirical frequencies (Sanov's theorem); the improbability of macrostates of lower entropy in Boltzmann's counting. *Price:* **free**; exact.

1188. Linear response of steady states. For square matrices Q and E whose total tree weight for Q is at least $w_0 > 0$, there are numbers D(j), a radius $s_0 > 0$ and a constant C such that for every s between $-s_0$ and s_0 the law proportional to the tree weights of Q + s·E differs from the law proportional to the tree

weights of Q by $s \cdot D(j)$ at every state j, up to an error of at most $C \cdot s^2$. *Used for:* Linear response of nonequilibrium steady states of master equations and reaction networks to small changes of the rates. *Price:* **free**; exact.

1189. Exponential of a matrix exists. For every square matrix Q on the line and every number t, the partial sums of $t^j/j!$ times the j-th power of Q converge at every entry. *Used for:* Time evolution of finite linear systems: master equations and finite quantum systems evolve by the exponential of t times their generator. *Price:* **free**; exact.

1190. Exponential of a rate matrix is stochastic. For a matrix of transition rates on finitely many states (rows summing to zero, off-diagonal rates nonnegative) and every time $t \geq 0$, every limit of the partial sums of the exponential of t times the rate matrix has nonnegative entries and rows summing to one. *Used for:* The solution of a master equation at every time is a probability law; the exponential of the generator is a Markov transition matrix. *Price:* **free**; exact.

1191. Static fluctuation–dissipation theorem. For finitely many states with energies H, an observable B coupled with strength s, an inverse temperature β and an observable A, the mean of A under the Gibbs law proportional to $e^{-\beta \cdot (H - s \cdot B)}$ equals its mean at $s = 0$ plus $s \cdot \beta$ times the covariance of A and B at $s = 0$, up to an error of at most $C \cdot s^2$ for all s between $-s_0$ and s_0, for some $s_0 > 0$ and C. *Used for:* Static susceptibilities equal β times equilibrium fluctuations (magnetic susceptibility, compressibility, heat capacity). *Price:* **free**; exact.

1192. Gibbs conditioning principle for types. For k independent copies of a law p on n letters, numbers D and η, and decided sets A and B of letter counts: suppose some count vector c in A with $c_1 + \ldots + c_n = k$ satisfies $e^{-k \cdot D}$ times the product of $c_a^{\,c_a}$ is at most k^k times the product of $p_a^{\,c_a}$ (the relative entropy of its frequencies from p is at most D), and every count vector c in B with $c_1 + \ldots + c_n = k$ satisfies k^k times the product of $p_a^{\,c_a}$ is at most $e^{-k \cdot (D + \eta)}$ times the product of $c_a^{\,c_a}$ (relative entropy at least $D + \eta$). Then the probability that the counts lie in B is at most $(k + 1)^{2n} \cdot e^{-k \cdot \eta}$ times the probability that they lie in A. *Used for:* Equivalence of ensembles and the maximum-entropy principle: under a macroscopic constraint the empirical frequencies concentrate on the frequencies of least relative entropy. *Price:* **free**; exact.

Q.10 Functional and Fourier analysis

1193. Cauchy–Schwarz inequality for inner products. In every real inner product space, the square of the inner product of two vectors is at most the product of their squared lengths: $\langle x, y\rangle^2 \leq \langle x, x\rangle \cdot \langle y, y\rangle$. *Used for:* Uncertainty relations and every bound on a correlation or a transition amplitude between two states. *Price:* **free**; exact.

1194. Cauchy–Schwarz inequality with norms. In every real inner product space, the absolute value of the inner product of two vectors is at most the product of their lengths: $|\langle x, y\rangle| \leq \|x\| \cdot \|y\|$. *Used for:* Bounding the overlap of two quantum states by their norms. *Price:* **free**; exact.

1195. Triangle inequality in an inner product space. In every real inner product space, the length of a sum of two vectors is at most the sum of their lengths: $\|x + y\| \leq \|x\| + \|y\|$. *Used for:* Distances between states and error bounds on approximate state preparation. *Price:* **free**; exact.

1196. Parallelogram law for inner products. In every real inner product space, $\langle x + y, x + y\rangle + \langle x - y, x - y\rangle = 2(\langle x, x\rangle + \langle y, y\rangle)$. *Used for:* Recovering inner products from norms (polarization) and recognizing which norms come from an inner product. *Price:* **free**; exact.

1197. Pythagorean theorem for orthogonal vectors. In every real inner product space, if two vectors are orthogonal then the squared length of their sum is the sum of their squared lengths. *Used for:* Probabilities of mutually exclusive (orthogonal) outcomes add. *Price:* **free**; exact.

1198. Bessel's inequality for orthonormal families. For an orthonormal family of vectors and any finite set of its indices, the sum of the squared inner products of a vector x with those family members is at most $\|x\|^2$. *Used for:* The measured weights of a state on a set of orthogonal outcomes sum to at most its total norm. *Price:* **free**; exact.

1199. Orthonormal vectors are linearly independent. For an orthonormal family indexed by any set, a finite linear combination of its members that equals zero has every coefficient zero. *Used for:* Distinct orthonormal eigenstates are independent, so expansions in them are unique. *Price:* **free**; exact.

1200. Expansion in a finite orthonormal basis. If finitely many orthonormal vectors span the space, every vector x equals the sum over the basis of $\langle b, x\rangle$ times b. *Used for:* Expanding a quantum state in a finite basis of states. *Price:* **free**; exact.

1201. Parseval's identity in a finite basis. If

finitely many orthonormal vectors span the space, the inner product of any two vectors x and y equals the sum over the basis of $\langle x, b\rangle \cdot \langle b, y\rangle$. *Used for:* Inserting a resolution of the identity between two states. *Price:* **free**; exact.

1202. Eigenvectors of a symmetric operator are orthogonal. For a symmetric linear operator, an eigenvector for one eigenvalue and an eigenvector for a different eigenvalue are orthogonal. *Used for:* Eigenstates of an observable at different measured values are orthogonal. *Price:* **free**; exact.

1203. Nearest point characterized by orthogonality. For a subspace K and a point v of K, v is the point of K nearest to u exactly when u − v is orthogonal to every vector of K. *Used for:* Least-squares fitting and the variational principle for approximate states. *Price:* **free**; exact.

1204. Riesz representation in finite dimension. If finitely many orthonormal vectors span the space, every linear functional f equals the inner product with exactly one vector a: $f(x) = \langle a, x\rangle$ for all x. *Used for:* Bras and kets in a finite-dimensional quantum system. *Price:* **free**; exact.

1205. Orthogonal projection onto a line. For any vectors v and u in a real inner product space, there is a number t such that u − t·v is orthogonal to every multiple of v. *Used for:* Applying the measurement projector onto a state ψ, written $\psi\psi^*/\langle\psi, \psi\rangle$, to another state. *Price:* **LPO**; exact.

1206. Splitting a vector along and across a line. For any vectors v and u in a real inner product space, u is a multiple of v plus a vector orthogonal to every multiple of v. *Used for:* Splitting a state into its component along a reference state and the part orthogonal to it. *Price:* **LPO**; exact.

1207. Nearest multiple of a vector. For any vectors v and u in a real inner product space, some multiple of v is at least as close to u as every other multiple of v. *Used for:* The best fit of a state by multiples of one trial state. *Price:* **LPO**; exact.

1208. Double orthogonal complement of a line. For any vectors v and x in a real inner product space, x is orthogonal to every vector that is orthogonal to v exactly when x is a multiple of v. *Used for:* Identifying the one-dimensional subspace of a pure state from its orthogonal complement. *Price:* **LPO**; exact.

1209. Gram–Schmidt orthonormalization of independent vectors. Every linearly independent finite list of vectors in a real inner product space has an orthonormal list of equal length whose first k members span the space spanned by the first k given vectors, for every k. *Used for:* Building an orthonormal basis of states from independent states. *Price:* **MP**; exact.

1210. Existence of an orthonormal basis. Every real inner product space spanned by finitely many vectors has a finite orthonormal basis. *Used for:* Choosing a basis of states for a finite quantum system given by spanning states. *Price:* **LPO**; exact.

1211. Riesz representation on square-summable sequences. Every bounded linear functional f on the space of square-summable sequences is given by one square-summable sequence a: f(x) is the limit, as N grows, of the sums $a_0x_0 + a_1x_1 + \dots$ up to the N-th term, for every x. *Used for:* Bras and kets in infinite dimension: every bounded linear readout of a state is an overlap with a fixed state. *Price:* **LPO**; exact (limit points use the completeness of the line: countable choice of representatives).

1212. Norm of a bounded linear functional. Every bounded linear functional f on the space of square-summable sequences has a norm $L \geq 0$: $|f(x)| \leq L\cdot\|x\|$ for every x, and for every margin some x of length at most 1 has |f(x)| within that margin of L. *Used for:* The largest response of a linear measurement over normalized states. *Price:* **LPO**; exact (limit points use the completeness of the line: countable choice of representatives).

1213. Orthogonal projection onto any subspace of the line. Every subspace K of the real line, described by any condition at all, contains a point p such that u − p is orthogonal to every point of K. *Used for:* Projecting onto a subspace described only by a membership condition, with no spanning vectors given; it shows such descriptions can encode any yes-or-no question. *Price:* **EM**; exact.

1214. Orthogonal projection onto any subspace in finite dimension. In every real inner product space spanned by finitely many vectors, every subspace K, described by any condition at all, contains a point p such that u − p is orthogonal to every point of K, for every vector u. *Used for:* Projecting a state onto a subspace of a finite quantum system that is described only by a membership condition; it shows such descriptions can encode any yes-or-no question. *Price:* **EM**; exact.

1215. Inner product of square-summable sequences exists. For any two square-summable sequences x and y, the sums $x_0y_0 + x_1y_1 + \dots$ up to the N-th term converge to a number as N grows. *Used for:* The overlap of two states given by their amplitudes in an infinite basis. *Price:* **free**; exact.

1216. Norm of a square-summable sequence exists. For any square-summable sequence x there is a number $L \geq 0$ such that the sums $x_0^2 + x_1^2 + \dots$ up to the N-th term converge to L^2 as N grows. *Used for:* The total probability (norm) of a state given by its amplitudes in an infinite basis. *Price:* **free**; exact.

1217. Cauchy–Schwarz inequality for square-summable sequences. For square-summable sequences x and y, if the sums of $x_n y_n$ converge to I, the sums of x_n^2 to A and the sums of y_n^2 to B, then $I^2 \le A \cdot B$. *Used for:* Bounding transition amplitudes between states of an infinite-dimensional system. *Price:* **free**; exact.

1218. Completeness of the space of square-summable sequences. Every sequence of square-summable sequences of real numbers that is Cauchy in the square-summable distance converges, in that distance, to a square-summable sequence of real numbers. *Used for:* Limits of approximating states (perturbation series, variational sequences) are themselves states. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of representatives).

1219. Parseval's identity for an orthonormal basis. If an orthonormal sequence of square-summable sequences of real numbers has dense span, then for every square-summable sequence x the sums of the squared inner products of x with the first N basis members converge, as N grows, to the squared norm of x. *Used for:* Probabilities of the outcomes of a complete measurement add up to one. *Price:* **free**; exact.

1220. Parseval's identity for inner products. If an orthonormal sequence $b_0, b_1, b_2, \ldots$ of square-summable sequences of real numbers has dense span, then for all square-summable sequences x and y the sums of $\langle x, b_i\rangle \cdot \langle b_i, y\rangle$ over the first N basis members converge, as N grows, to $\langle x, y\rangle$. *Used for:* Inserting a complete set of states between two states in infinite dimension. *Price:* **free**; exact.

1221. Parseval's identity from a trivial orthogonal complement. If an orthonormal sequence of square-summable sequences of real numbers has no nonzero square-summable sequence orthogonal to all its members, then for every square-summable sequence x the sums of the squared inner products of x with the first N members converge, as N grows, to the squared norm of x. *Used for:* Recognizing a complete set of states from the fact that no state is orthogonal to all of them. *Price:* **open**; at least MP, with no choice; with the choice of representatives that the free allowance contains, exactly MP together with the double negation of LPO for sequences, one instance at a time: for every sequence of binary sequences, it is not false that some yes-or-no sequence says which of them contain a 1 (a principle that is not one of the letters); at most LPO, and at most MP together with the double negation shift (if $\neg\neg Q(n)$ for every n, then $\neg\neg$(Q(n) for every n)).

1222. Inversion of the discrete Fourier transform. For every $N \ge 1$ and every list f of N complex numbers, transforming f with the phases $e^{-2\pi i m k / N}$, transforming back with the phases $e^{2\pi i j k / N}$ and dividing by N returns f exactly. *Used for:* Bloch waves on a ring of N lattice sites are complete: every lattice state is recovered from its lattice-momentum amplitudes. *Price:* **free**; exact.

1223. Plancherel identity for the discrete Fourier transform. For every $N \ge 1$ and every list f of N complex numbers, the sum of the squared magnitudes of the discrete Fourier transform of f is N times the sum of the squared magnitudes of f. *Used for:* Passing to lattice momentum space preserves total probability (up to the normalization N). *Price:* **free**; exact.

1224. Orthogonality of the characters of a cyclic group. For every $N \ge 1$ and all j and m below N, the sum over k below N of $e^{2\pi i j k / N} \cdot e^{-2\pi i m k / N}$ is N when j = m and 0 otherwise. *Used for:* Plane waves of different lattice momenta on a ring are orthogonal. *Price:* **free**; exact.

1225. Numerical-radius bound for symmetric operators. For a symmetric linear operator T on a real inner product space and a number $M \ge 0$: if $|\langle T\,x, x\rangle| \le M \cdot \langle x, x\rangle$ for every x, then $|\langle T\,x, y\rangle| \le M \cdot \|x\| \cdot \|y\|$ for all x and y. *Used for:* Bounding all transition amplitudes of an observable by its largest expectation value on normalized states. *Price:* **free**; exact.

1226. Variational principle for the largest value. If a unit vector x_0 maximizes $\langle T\,x, x\rangle$ over all unit vectors x, for a bounded symmetric linear operator T on a real inner product space, then $T\,x_0 = \langle T\,x_0, x_0\rangle \cdot x_0$: x_0 is an eigenvector with that eigenvalue. *Used for:* The state of highest energy (or highest expectation of any observable) found by maximizing is an eigenstate. *Price:* **free**; exact.

1227. Variational principle for the ground state. If a unit vector x_0 minimizes $\langle T\,x, x\rangle$ over all unit vectors x, for a bounded symmetric linear operator T on a real inner product space, then $T\,x_0 = \langle T\,x_0, x_0\rangle \cdot x_0$: x_0 is an eigenvector with that eigenvalue. *Used for:* A ground state found by minimizing the energy over normalized states is an eigenstate of the Hamiltonian (the Rayleigh–Ritz principle). *Price:* **free**; exact.

1228. Variational principle with a nonzero maximizer of any length. If a vector x_0 that is not zero maximizes $\langle T\,x, x\rangle$ over all vectors x whose length equals the length of x_0, for a bounded symmetric linear operator T on a real inner product space, then there is a number μ with $\mu \cdot \langle x_0, x_0\rangle = \langle T\,x_0, x_0\rangle$ and $T\,x_0 = \mu \cdot x_0$. *Used for:* The variational principle when the trial state is not normalized, only known to be nonzero: the maximizing state is an eigenstate. *Price:* $\mathbf{MP}^{\vee}$; exact (the converse uses countable choice

of rational pairs, which the free allowance contains).

1229. Variational principle for a local extremum. If a unit vector x_0 is a local maximum or a local minimum of $\langle T\,x, x\rangle$ among the unit vectors within a fixed positive distance of x_0, for a bounded symmetric operator T on a real inner product space, then $T\,x_0 = \langle T\,x_0, x_0\rangle \cdot x_0$. *Used for:* A normalized state at which the energy is locally lowest or locally highest, even when it is not the ground state, is an eigenstate of the Hamiltonian. *Price:* **free**; exact.

1230. The trace does not depend on the basis. For a linear operator T on a real inner product space with two finite orthonormal bases b and c, the sum of $\langle T\,b_i, b_i\rangle$ over b equals the sum of $\langle T\,c_j, c_j\rangle$ over c. *Used for:* The trace of an observable or a density matrix takes one value whichever orthonormal basis computes it, so expectation values computed by traces are basis independent. *Price:* **free**; exact.

1231. The trace is the sum of the eigenvalues. If a linear operator T on a finite-dimensional real inner product space has an orthonormal basis of eigenvectors with eigenvalues λ_i, then the sum of $\langle T\,c_j, c_j\rangle$ over any orthonormal basis c equals the sum of the λ_i. *Used for:* The sum of the energy levels of a finite-level system equals the trace of its Hamiltonian. *Price:* **free**; exact.

1232. Uniform boundedness principle for functionals. If a sequence of bounded linear functionals on the space of square-summable sequences is bounded at each point, then one bound M works for all of them: the square of each value at x is at most M times the squared norm of x. *Used for:* Pointwise bounded families of linear measurements are uniformly bounded, which controls limits of measurement procedures. *Price:* **BD-N**; exact: the statement implies BD-N with no choice, and the converse uses only the choice of representatives that the free allowance contains; LPO also gives the statement.

1233. Existence of a Hilbert basis for a separable subspace. For every sequence v of square-summable sequences there are flags and vectors b such that the flagged vectors are orthonormal, the unflagged ones are zero, every b lies in the closed span of v, and every member of v lies in the closed span of b. *Used for:* Building a complete orthonormal set of states for any separable state space, such as the bound states of an atom or the modes of a field. *Price:* **free**; exact.

1234. Gram–Schmidt for an infinite independent sequence. Every linearly independent sequence of square-summable sequences has an orthonormal sequence such that, for each n, the first n members of each sequence are finite combinations of the first n members of the other. *Used for:* Building an orthonormal basis of states from independent states in an infinite-dimensional system, such as orthogonal polynomials or atomic orbitals. *Price:* **MP**; exact.

1235. Orthogonal projection onto the closed span of a sequence. For every sequence v of square-summable sequences and every square-summable x there is a point p in the closed span of v with $\langle x, v_j\rangle = \langle p, v_j\rangle$ for every j. *Used for:* Projecting a state onto the subspace spanned by infinitely many states, such as a band of energy levels or a symmetry sector. *Price:* **LPO**; exact (limit points use the completeness of the line: countable choice of representatives).

1236. Orthogonal projection onto a located closed subspace. For every sequence v of square-summable sequences, every square-summable x and every number d that is the distance from x to the closed span of v, there is a point p in that closed span with $\langle x, v_j\rangle = \langle p, v_j\rangle$ for every j. *Used for:* Projecting a state onto a subspace when the distance to it (for example the residual of a best fit) is known: then the projection costs nothing, whereas without the distance it costs LPO. *Price:* **free**; exact.

1237. Polarization identity for real inner products. In every real inner product space, $4\langle x, y\rangle = \|x + y\|^2 - \|x - y\|^2$. *Used for:* Recovering transition amplitudes from measured norms (probabilities) of superpositions. *Price:* **free**; exact.

1238. Equality in Cauchy–Schwarz, forward direction. In a real inner product space, if x and y are not zero and $|\langle x, y\rangle| = \|x\|\cdot\|y\|$, then y is a multiple of x. *Used for:* Two states whose overlap is as large as their lengths allow differ only by a factor. *Price:* **MP**; exact.

1239. Pythagorean theorem for finitely many orthogonal vectors. In a real inner product space, if finitely many vectors are pairwise orthogonal, the squared length of their sum is the sum of their squared lengths. *Used for:* Probabilities of finitely many mutually exclusive outcomes add. *Price:* **free**; exact.

1240. A symmetric operator with vanishing expectation values is zero. If a symmetric linear operator T on a real inner product space has $\langle Tx, x\rangle = 0$ for every x, then $T\,x = 0$ for every x. *Used for:* An observable whose expectation value vanishes in every state is the zero observable. *Price:* **free**; exact.

1241. Isometries preserve inner products. A linear map between real inner product spaces that preserves the length of every vector preserves the inner product of every pair of vectors. *Used for:* A transformation that preserves all probabilities of single states preserves all transition amplitudes (the real-linear part of Wigner's theorem). *Price:* **free**; exact.

1242. The projector onto a state is idempotent and symmetric. For a unit vector e in a real inner product space, the map $x \mapsto \langle e, x\rangle \cdot e$ applied twice equals itself applied once, and $\langle Px, y\rangle = \langle x, Py\rangle$ for all x and y. *Used for:* Repeating a measurement returns its first outcome, and the measurement projector is an observable. *Price:* **free**; exact.

1243. Uniform boundedness principle for operators. If a sequence of bounded linear operators on the space of square-summable sequences of real numbers is bounded at each point, then one bound M works for all of them: the squared norm of each image of x is at most M times the squared norm of x. *Used for:* Pointwise bounded families of evolutions or measurement maps are uniformly bounded, which controls limits of approximating dynamics. *Price:* **BD-N**; exact: the statement implies BD-N with no choice, and the converse uses only the choice of representatives that the free allowance contains.

1244. Riesz representation for functionals with a known norm. Every bounded linear functional f on the space of square-summable sequences of real numbers whose norm L is given is the inner product with one square-summable sequence a: f(x) is the limit of the sums $a_0x_0 + a_1x_1 + \dots$ up to the N-th term, for every x. *Used for:* Bras and kets in infinite dimension when the size of the readout is known: then the reference state is computed, with no decision. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of representatives).

1245. Equality in Cauchy–Schwarz, both directions. In a real inner product space, for nonzero x and y, $|\langle x, y\rangle| = \|x\|\cdot\|y\|$ exactly when $y = r\cdot x$ for some nonzero number r. *Used for:* Two states have maximal overlap exactly when one is a nonzero multiple of the other. *Price:* **MP**; exact.

1246. Top expectation value of a compact symmetric operator. For every compact symmetric operator T on the space of square-summable sequences of real numbers (compact: for every margin, the truncation of T to some finite number of coordinates is within that margin of T in operator norm) there is a number λ such that $\langle T\,x, x\rangle \le \lambda\cdot\|x\|^2$ for every x, and for every margin some unit vector x has $\langle T\,x, x\rangle$ within that margin of λ. *Used for:* The top (or, for $-T$, the ground) energy of a compact observable such as a bounded potential's resolvent, as a supremum over normalized states. *Price:* **free**; exact (no decision principle; the upper bound collects the top levels of the finite truncations, each determined uniquely, and forms their limit point, choices that the free allowance contains).

1247. Top eigenvector of a compact symmetric operator, positive case. For every compact symmetric operator T on the space of square-summable sequences of real numbers (compact: for every margin, the truncation of T to some finite number of coordinates is within that margin of T in operator norm) whose top expectation value λ over unit vectors is positive, some unit vector x satisfies $T\,x = \lambda\cdot x$. Without the positivity the statement is false: the diagonal operator with entries $-1/(n+1)$ has top value 0 and no eigenvector for it. *Used for:* A top eigenstate of a compact observable, the state of largest expectation value when that value is positive, exists as an actual eigenstate. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact; the lower bound uses no choice, the upper bound uses countable choice (through the compactness of a Hilbert cube, row 1251).

1248. Norm of a bounded operator. Every bounded linear operator T on the space of square-summable sequences of real numbers has a norm $L \ge 0$: $\|T\,x\|^2 \le L^2\|x\|^2$ for every x, and for every margin some x of norm at most 1 has $\|T\,x\|^2$ within that margin of L^2. *Used for:* The largest amplification of a linear evolution or response over normalized states. *Price:* **LPO**; exact (limit points use the completeness of the line: countable choice of representatives).

1249. Adjoint of a bounded operator. For every bounded linear operator T on the space of square-summable sequences of real numbers and every y there is z with $\langle T\,x, y\rangle = \langle x, z\rangle$ for every x. *Used for:* Moving an observable or evolution from kets to bras (the Hermitian conjugate) in infinite dimension. *Price:* **LPO**; exact (limit points use the completeness of the line: countable choice of representatives).

1250. Norm of a compact symmetric operator. Every compact symmetric operator T on the space of square-summable sequences of real numbers (compact: for every margin, the truncation of T to some finite number of coordinates is within that margin of T in operator norm) has a norm $L \ge 0$: $\|T\,x\|^2 \le L^2\|x\|^2$ for every x, and for every margin some x of norm at most 1 has $\|T\,x\|^2$ within that margin of L^2. *Used for:* The largest response of a compact observable, the larger of its top and bottom expectation values in absolute size. *Price:* **free**; exact (no decision principle; the upper bound collects the top levels of the finite truncations, each determined uniquely, and forms their limit point, choices that the free allowance contains); for a general bounded operator the same statement costs LPO (row 1248).

1251. Zero of a nonnegative Lipschitz function on a Hilbert cube. Fix tail bounds: the cube is the set of square-summable sequences of real numbers of norm at most 1 whose sum of squares beyond a given index for each margin is within that margin. Let F be a nonnegative function on the cube with a constant L

such that $(F(x) - F(y))^2$ is at most L times the squared distance of x and y for all points x and y of the cube. If F comes arbitrarily close to 0 on the cube, then F takes the value 0 at some point of the cube. *Used for:* Existence of minimizers by compactness in infinite dimension: ground states and best approximations found as limits of near-minimizers. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact; the lower bound uses no choice (one coordinate already gives LLPO), the upper bound uses countable choice.

1252. Adjoint of a bounded operator with a known column modulus. For a bounded linear operator T on the space of square-summable sequences and a vector y, if the numbers $\langle T\, e_n, y\rangle$ come with a known rate at which their squares sum, then the vector z of these numbers satisfies $\langle Tx, y\rangle = \langle x, z\rangle$ for every x. *Used for:* Moving an observable to the other side of an inner product (the adjoint of a measurement) when its matrix column is known with a convergence rate. *Price:* **free**; exact (no choice); without the rate the same statement costs LPO (row 1249).

1253. Riesz representation from the values on the unit vectors. A bounded linear functional f on the space of square-summable sequences equals $\langle x, w\rangle$ for every x, for any presented square-summable w whose n-th coordinate is $f(e_n)$. *Used for:* A linear measurement is the overlap with one fixed state, read off from its values on the basis states. *Price:* **free**; exact (no choice); finding w without it costs LPO (row 1211).

1254. Spectral theorem for compact symmetric operators, approximation form. For every compact symmetric operator T on the space of square-summable sequences and every margin, finitely many orthonormal eigenvectors $u_1, \ldots, u_m$ with eigenvalues $\mu_1, \ldots, \mu_m$ make $T - \Sigma\, \mu_i\langle\cdot, u_i\rangle u_i$ smaller than the margin in norm. *Used for:* Expanding a compact observable in its eigenstates up to any accuracy: the finite-mode truncation of a spectral decomposition. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact; the lower bound uses no choice (a two-by-two test block), the upper bound uses countable choice.

1255. Spectral theorem for compact symmetric operators, sequence form. Every compact symmetric operator T on the space of square-summable sequences has a sequence of pairwise orthogonal eigenvectors $u_0, u_1, \ldots$, each a unit vector or zero, with eigenvalues $\mu_0, \mu_1, \ldots$, such that the partial sums $\Sigma\, \mu_j\langle x, u_j\rangle u_j$ approach Tx uniformly on the unit ball. *Used for:* The full eigenmode expansion of a compact observable, as used for Hilbert–Schmidt integral operators and Green's functions. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact; the lower bound uses no choice, the upper bound uses countable choice (an earlier proof used dependent choice; the margins are now chosen independently).

1256. Riesz representation with a known rate for the functional's values. A bounded linear functional f on the space of square-summable sequences whose values $f(e_n)$ come with a known rate at which their squares sum equals $\langle x, w\rangle$ for some square-summable w and every x. *Used for:* A linear measurement is the overlap with one fixed state, when the size of its response to far basis states is known. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of representatives).

Q.11 A first survey across the areas

1257. Preorder axioms for the order of the line. On the line, $\le$ and $<$ satisfy the preorder axioms: $\le$ is reflexive and transitive, and $x < y$ holds exactly when $x \le y$ and not $y \le x$. *Used for:* comparing physical quantities in every bound and inequality. *Price:* **MP**; exact.

1258. Partial order axioms for the order of the line. On the line, $\le$ and $<$ satisfy the partial order axioms: $\le$ is reflexive, transitive and antisymmetric, and $x < y$ holds exactly when $x \le y$ and not $y \le x$. *Used for:* comparing physical quantities; concluding equality from bounds in both directions. *Price:* **MP**; exact.

1259. No zero divisors on the line. On the line, the ring of numbers has no zero divisors: whenever $x \cdot y = 0$, $x = 0$ or $y = 0$. *Used for:* solving factored equations, such as finding roots of characteristic polynomials. *Price:* **LLPO**; exact.

1260. Inverses of nonzero numbers. On the line, there are two different numbers, multiplication is commutative, and every number that is not equal to 0 has a multiplicative inverse. *Used for:* all algebra with division: ratios, rates and solving linear equations. *Price:* **MP**; exact. Proved in Theorem 28.9(6).

1261. Trichotomy of the order. For any two numbers x and y on the line, $x < y$, $x = y$ or $y < x$. *Used for:* deciding whether a quantity is below, at or above a threshold. *Price:* **LPO**; exact.

1262. Totality of the order $\le$. For any two numbers x and y on the line, $x \le y$ or $y \le x$. *Used for:* ranking quantities, such as ordering energy levels. *Price:* **LLPO**; exact.

1263. Order dichotomy: $x < y$ or $y \le x$. For any two numbers x and y on the line, $x < y$ or $y \le x$. *Used for:* case splits at a threshold: below a critical value, or at or above it. *Price:* **LPO**; exact.

1264. Order dichotomy: $x \le y$ or $y < x$. For any two numbers x and y on the line, $x \le y$ or $y < x$. *Used for:* case splits at a threshold: at or below a critical value, or above it. *Price:* **LPO**; exact.

1265. Deciding equality of two numbers. Any two numbers x and y on the line are either equal or not equal. *Used for:* testing whether two quantities agree exactly, such as a resonance condition. *Price:* **WLPO**; exact. Proved in Corollary 12.18.

1266. Splitting $\le$ into $<$ or $=$. On the line, $x \le y$ implies $x < y$ or $x = y$. *Used for:* separating strict from borderline cases, such as marginal stability. *Price:* **LPO**; exact.

1267. Absolute value equals x or −x. For every number x on the line, the absolute value of x equals x or equals −x. *Used for:* removing absolute values in magnitude and distance calculations. *Price:* **LLPO**; exact.

1268. The maximum is one of its arguments. For any two numbers x and y on the line, max(x, y) equals x or equals y. *Used for:* picking the larger of two quantities in piecewise and threshold laws. *Price:* **LLPO**; exact.

1269. Zero product rule. On the line, if $x \cdot y = 0$ then $x = 0$ or $y = 0$. *Used for:* solving factored equations for equilibria and roots. *Price:* **LLPO**; exact.

1270. Integer floor of a number. Every number x on the line has an integer floor: an integer m with $m \le x < m + 1$. *Used for:* counting whole periods, cycles or lattice cells; binning measured values. *Price:* **LPO**; exact.

1271. Unequal numbers are strictly ordered. On the line, if $x \ne y$ then $x < y$ or $y < x$. *Used for:* turning a difference between two quantities into a definite sign. *Price:* **MP**; exact.

1272. Weak inequality between unequal numbers is strict. On the line, if $x \le y$ and $x \ne y$ then $x < y$. *Used for:* strict bounds from a weak bound plus an exclusion, such as a nonzero energy gap. *Price:* **MP**; exact.

1273. Failure of $x \le y$ gives $y < x$. On the line, if $x \le y$ fails then $y < x$. *Used for:* arguments by contradiction about inequalities between physical quantities. *Price:* **MP**; exact.

1274. Failure of $y \le x$ gives $x < y$. On the line, if $y \le x$ fails then $x < y$. *Used for:* arguments by contradiction about inequalities between physical quantities. *Price:* **MP**; exact.

1275. Nonzero numbers have positive absolute value. On the line, every number $x \ne 0$ has an absolute value strictly greater than 0. *Used for:* positive magnitudes of nonzero quantities, needed before dividing by them. *Price:* **MP**; exact.

1276. Inverse of a nonzero number. On the line, every number $x \ne 0$ has a number y with $x \cdot y = 1$. *Used for:* dividing by nonzero quantities: ratios, rates and unit conversions. *Price:* **MP**; exact.

1277. Negation of $<$ is the reverse $\le$. On the line, $x < y$ fails exactly when $y \le x$. *Used for:* comparing physical quantities in every bound and inequality. *Price:* **free**; exact.

1278. Failure of $y < x$ gives $x \le y$. On the line, if $y < x$ fails then $x \le y$. *Used for:* deriving bounds by ruling out the opposite strict inequality. *Price:* **free**; exact.

1279. Antisymmetry of $\le$ on the line. On the line, $x \le y$ and $y \le x$ together give $x = y$. *Used for:* proving two quantities equal from bounds in both directions. *Price:* **free**; exact.

1280. Transitivity of $\le$. On the line, $x \le y$ and $y \le z$ give $x \le z$. *Used for:* chaining bounds, as in every error estimate. *Price:* **free**; exact.

1281. Irreflexivity of $<$. No number x on the line satisfies $x < x$. *Used for:* consistency of strict comparisons: no quantity exceeds itself. *Price:* **free**; exact.

1282. Strict then weak inequality gives strict. On the line, $x < y$ and $y \le z$ give $x < z$. *Used for:* chaining strict and weak bounds in estimates. *Price:* **free**; exact.

1283. Absolute values are nonnegative. For every number x on the line, the absolute value of x is at least 0. *Used for:* magnitudes, distances and error sizes are never negative. *Price:* **free**; exact.

1284. Triangle inequality for absolute values. For all numbers x and y on the line, $|x + y| \le |x| + |y|$. *Used for:* combining error bounds and adding displacements. *Price:* **free**; exact.

1285. Reverse triangle inequality. For all numbers x and y on the line, $|x| - |y| \le |x - y|$. *Used for:* bounding how much a magnitude changes under a perturbation. *Price:* **free**; exact.

1286. Absolute value of a product. For all numbers x and y on the line, $|x \cdot y| = |x| \cdot |y|$. *Used for:* magnitudes of products: gains, scale factors and relative errors. *Price:* **free**; exact.

1287. Zero absolute value means zero. For every number x on the line, $|x| = 0$ exactly when $x = 0$. *Used for:* a quantity of zero magnitude vanishes; zero error means exact agreement. *Price:* **free**; exact.

1288. A number is at most the maximum. For all numbers x and y on the line, $x \le \max(x, y)$. *Used for:*

bounding a quantity by the larger of two bounds. *Price:* **free**; exact.

1289. Maximum below a common upper bound. On the line, if $x \le z$ and $y \le z$ then $\max(x, y) \le z$. *Used for:* worst-case bounds over several cases. *Price:* **free**; exact.

1290. The minimum is at most each number. For all numbers x and y on the line, $\min(x, y) \le x$. *Used for:* taking the tighter of two bounds. *Price:* **free**; exact.

1291. Squares are nonnegative. For every number x on the line, $0 \le x \cdot x$. *Used for:* kinetic energies, intensities and variances are never negative. *Price:* **free**; exact.

1292. Sum of positive numbers is positive. On the line, if $0 < x$ and $0 < y$ then $0 < x + y$. *Used for:* adding positive masses, energies or probabilities stays positive. *Price:* **free**; exact.

1293. Product of positive numbers is positive. On the line, if $0 < x$ and $0 < y$ then $0 < x \cdot y$. *Used for:* signs of products, such as density times volume. *Price:* **free**; exact.

1294. Inverse of a positive number is positive. On the line, for every number x with $0 < x$, the inverse $1/x$ also satisfies $0 < 1/x$. *Used for:* periods from frequencies and resistances from conductances stay positive. *Price:* **free**; exact.

1295. A rational number between any two numbers. On the line, if $x < y$ then some rational number q satisfies $x < q < y$. *Used for:* approximating any real quantity by finite-precision rational readings. *Price:* **free**; exact.

1296. Density of the order. On the line, if $x < y$ then some number z satisfies $x < z < y$. *Used for:* continuum models: between any two positions or times lies another. *Price:* **free**; exact.

1297. Archimedean property of the line. For every number x on the line, some natural number n satisfies $x < n$. *Used for:* exceeding any quantity by enough unit steps; choosing scales and counts. *Price:* **free**; exact.

1298. Nonnegative square roots. On the line, every number $x \ge 0$ has a square root y with $y \ge 0$ and $y \cdot y = x$. *Used for:* magnitudes from sums of squares: lengths, speeds and root-mean-square values. *Price:* **free**; exact.

1299. Square of a sum. For all numbers a and b on the line, $(a + b)^2 = a^2 + 2ab + b^2$. *Used for:* expanding energies with cross terms, such as interference terms. *Price:* **free**; exact.

1300. Cauchy–Schwarz inequality in the plane. For all numbers a, b, c, d on the line, $(ac + bd)^2 \le (a^2 + b^2)(c^2 + d^2)$: the two-dimensional case, in squared form. *Used for:* bounding dot products: work, projections and correlation coefficients. *Price:* **free**; exact.

1301. Least upper bounds of sets. On the line, every set of numbers that has a member and an upper bound has a least upper bound. *Used for:* defining suprema: peak values, best constants and spectral bounds. *Price:* **WEM**; exact (the converse uses countable choice once, at pairs of ratios). Proved in Theorem 12.50.

1302. Monotone convergence theorem. On the line, every nondecreasing sequence that is bounded above converges to a limit. *Used for:* sums of positive contributions, such as total probability or accumulated energy. *Price:* **LPO**; exact (the converse chooses representatives and uses countable choice once at pairs of ratios, both inside the free allowance). Proved in Theorem 12.45.

1303. Monotone convergence for decreasing sequences. On the line, every nonincreasing sequence that is bounded below converges to a limit. *Used for:* improving variational upper bounds, such as ground-state energy estimates. *Price:* **LPO**; exact (apply row 1302 to $-x$). Proved in Theorem 12.45, applied to $-x$.

1304. Bolzano–Weierstrass theorem for bounded sequences. On the line, every bounded sequence has a convergent subsequence. *Used for:* extracting limiting states from bounded trajectories or approximations. *Price:* **LPO**; exact (the converse chooses representatives, yes-or-no decisions and indices, all inside the free allowance). Proved in Theorem 12.47(i).

1305. Every sequence has a monotone subsequence. On the line, every sequence has a subsequence that is nondecreasing or nonincreasing. *Used for:* a step in proving that bounded motions have limiting states. *Price:* **LPO**; exact (the converse chooses representatives, yes-or-no decisions and indices, all inside the free allowance). Proved in Theorem 12.47(iii).

1306. Bounded sequences have a cluster point. On the line, read with a bounded set in place of the compact set: every bounded sequence has a cluster point, approached within every tolerance $1/(k+1)$ by terms of arbitrarily late index. *Used for:* long-time behavior of bounded motions: recurrence and limit cycles. *Price:* **LPO**; exact (the converse chooses representatives, yes-or-no decisions and indices, all inside the free allowance). Proved in Theorem 12.47(ii).

1307. Least upper bound of a sequence bounded above. On the line, every sequence that is bounded above has a least upper bound. *Used for:* peak values over infinitely many times or cases. *Price:* **WLPO**;

exact (the converse chooses representatives and uses countable choice once at pairs of ratios, both inside the free allowance). Proved in Theorem 12.48.

1308. Greatest lower bound of a sequence bounded below. On the line, every sequence that is bounded below has a greatest lower bound. *Used for:* lowest energy over a sequence of trial states or configurations. *Price:* **WLPO**; exact (apply row 1307 to −x). Proved in Theorem 12.48, applied to $-x$.

1309. Terms of a sequence approach its supremum. On the line, every sequence bounded above has a least upper bound L such that every rational number below L is exceeded by some term. *Used for:* approaching a peak value by actual terms, such as maximal energy along an orbit. *Price:* **LPO**; exact (the converse chooses representatives and uses countable choice once at pairs of ratios, both inside the free allowance). Proved in Theorem 12.49.

1310. Limit superior of a bounded sequence. On the line, every bounded sequence has a limit superior: each tail has a least upper bound, and these bounds have a greatest lower bound. *Used for:* long-run worst-case values: asymptotic amplitudes and upper growth rates. *Price:* **WLPO**; exact (the converse applies row 1307 to every tail and row 1308 to the tail bounds; collecting those bounds, each a single point, uses only the free allowance).

1311. Completeness: Cauchy sequences converge. On the line, every Cauchy sequence converges to a limit. *Used for:* convergence of iterative computations and series, such as perturbation series. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Theorem 12.26.

1312. Intermediate value theorem on [0, 1]. On the line, every uniformly continuous function f on [0, 1] with f(0) ≤ 0 ≤ f(1) has a zero: some x in [0, 1] with f(x) = 0. *Used for:* existence of roots and equilibria, such as a balance point or crossing time. *Price:* **LLPO**; exact (the converse tabulates one yes-or-no answer for every dyadic ratio, a choice inside the free allowance). Proved in Theorem 12.54.

1313. Extreme value theorem: the maximum is attained. On the line, every uniformly continuous function f on [0, 1] attains a maximum: some x in [0, 1] has f(y) ≤ f(x) for every y in [0, 1]. *Used for:* existence of extreme configurations, such as turning points and peak energies. *Price:* **LLPO**; exact (the converse tabulates yes-or-no answers for adjacent dyadic intervals and uses countable choice at pairs of ratios for the suprema, both inside the free allowance). Proved in Theorem 12.60.

1314. Extreme value theorem: the minimum is attained. On the line, every uniformly continuous function f on [0, 1] attains a minimum: some x in [0, 1] has f(x) ≤ f(y) for every y in [0, 1]. *Used for:* existence of ground states and stable equilibria at minimum energy. *Price:* **LLPO**; exact (apply row 1313 to −f). Proved in Theorem 12.60, applied to $-f$.

1315. Continuous functions on [0, 1] are bounded above. On the line, every uniformly continuous function f on [0, 1] is bounded above there: some b has f(y) ≤ b for every y in [0, 1]. *Used for:* a priori bounds on fields and signals over a finite range. *Price:* **free**; exact.

1316. Supremum of a uniformly continuous function on [0, 1]. On the line, every uniformly continuous f on [0, 1] has a supremum s: f(y) ≤ s for every y in [0, 1], and values of f come within any tolerance of s. *Used for:* peak values of signals, potentials or fields over a finite range. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs). Proved in Theorem 12.58.

1317. Riemann sums of a uniformly continuous function converge. On the line, for every uniformly continuous f on [0, 1], the left Riemann sums over 2^n equal pieces of [0, 1] converge to a number. *Used for:* work, charge, mass and probability as integrals of continuous densities. *Price:* **free**; exact (a modulus of uniform continuity is chosen by countable choice of natural numbers; the Riemann sums then form a Cauchy sequence with a known modulus, and its limit point uses the completeness of the line: countable choice of rational pairs, Corollary 12.35).

1318. Limits of sequences are unique. On the line, a sequence that converges to L and also to L′ has L = L′. *Used for:* well-defined limiting values, such as one equilibrium or one extrapolated measurement. *Price:* **free**; exact.

1319. Limit of a sum. On the line, if sequences x and y converge to L and M, then the termwise sum x + y converges to L + M. *Used for:* adding limits of approximations, such as a total energy from its parts. *Price:* **free**; exact.

1320. Limit of a constant multiple. On the line, if a sequence x converges to L, then for every number c the sequence c · x converges to c · L. *Used for:* rescaling limits: unit changes and coupling constants. *Price:* **free**; exact.

1321. Squeeze theorem for sequences. On the line, if x ≤ y ≤ z termwise and the sequences x and z both converge to L, then y converges to L. *Used for:* pinning a quantity between lower and upper estimates that agree in the limit. *Price:* **free**; exact.

1322. 1/(n+1) tends to zero. On the line, the sequence 1/(n+1) converges to 0. *Used for:* vanishing step sizes and errors in discretizations. *Price:* **free**;

exact.

1323. A nondecreasing sequence stays below its limit. On the line, if a nondecreasing sequence converges to L, then every term is at most L. *Used for:* monotone approximations bound their limit, such as partial sums of positive terms. *Price:* **free**; exact.

1324. The identity function is continuous. On the line, the function $x \mapsto x$ is continuous at every point. *Used for:* the starting point for continuity of every formula built from a variable. *Price:* **free**; exact.

1325. Constant functions are continuous. On the line, for every number c, the constant function with value c is continuous at every point. *Used for:* constant fields and parameters as continuous ingredients of physical laws. *Price:* **free**; exact.

1326. Composition of continuous functions is continuous. On the line, if f and g are continuous functions, then $x \mapsto f(g(x))$ is continuous. *Used for:* continuity of composite laws, such as a potential evaluated along a path. *Price:* **free**; exact.

1327. Sum of continuous functions is continuous. On the line, if f and g are continuous functions, then $x \mapsto f(x) + g(x)$ is continuous. *Used for:* continuity of superposed fields and summed potentials. *Price:* **free**; exact.

1328. Maximum of continuous functions is continuous. On the line, if f and g are continuous functions, then $x \mapsto \max(f(x), g(x))$ is continuous. *Used for:* continuity of piecewise laws, such as thresholds and rectified signals. *Price:* **free**; exact.

1329. Absolute value is continuous. On the line, the function $x \mapsto |x|$ is continuous at every point. *Used for:* magnitudes and distances that vary continuously with the state. *Price:* **free**; exact.

1330. Continuity on a set passes to subsets. On the line, if f is continuous on a set T and S is a subset of T, then f is continuous on S. *Used for:* restricting a law to a smaller region or time interval. *Price:* **free**; exact.

1331. Epsilon-delta definition of continuity. On the line, f is continuous exactly when, for every x and every tolerance $1/(k+1)$, some $1/(j+1)$ works: points within $1/(j+1)$ of x have values within $1/(k+1)$ of $f(x)$. *Used for:* turning continuity into explicit error tolerances in calculations. *Price:* **free**; exact.

1332. Composition of uniformly continuous functions. On the line, if f and g are uniformly continuous functions, then $x \mapsto f(g(x))$ is uniformly continuous. *Used for:* error control through chained calculations, with one tolerance valid everywhere. *Price:* **free**; exact.

1333. Lipschitz functions are uniformly continuous. On the line, if $|f(x) - f(y)| \le K \cdot |x - y|$ for all x and y, with K a natural number, then f is uniformly continuous. *Used for:* stable dependence on data: bounded sensitivity in models and numerical schemes. *Price:* **free**; exact.

1334. Epsilon-delta definition of uniform continuity. On the line, f is uniformly continuous exactly when, for every tolerance $1/(k+1)$, one $1/(j+1)$ works everywhere: points within $1/(j+1)$ have values within $1/(k+1)$. *Used for:* uniform error tolerances in discretizations and numerical simulations. *Price:* **free**; exact.

1335. Banach fixed point theorem on the line. On the line, a contraction f with factor q ($0 \le q < 1$) has a fixed point p; iterates from any x_0 converge to p, with $(1 - q) \cdot |f^n(x_0) - p| \le q^n \cdot |f(x_0) - x_0|$. *Used for:* self-consistent solutions found by iteration, such as Picard iteration for equations of motion. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1336. A contraction has at most one fixed point. On the line, a contraction f with factor q ($0 \le q < 1$) has at most one fixed point: $f(p) = p$ and $f(p') = p'$ give $p = p'$. *Used for:* uniqueness of equilibria and of self-consistent solutions. *Price:* **free**; exact.

1337. Iterates of a contraction converge to a given fixed point. On the line, if a contraction f with factor q ($0 \le q < 1$) has a fixed point p, the iterates $f^n(x_0)$ from any start x_0 converge to p. *Used for:* convergence of iterative solvers to an equilibrium or steady state. *Price:* **free**; exact.

1338. A priori error bound for contraction iterates. On the line, if a contraction f with factor q ($0 \le q < 1$) has a fixed point p, then $(1 - q) \cdot |f^n(x_0) - p| \le q^n \cdot |f(x_0) - x_0|$ for every start x_0 and every n. *Used for:* estimating in advance how many iterations a self-consistent calculation needs. *Price:* **free**; exact.

1339. A posteriori error bound for contraction iterates. On the line, if a contraction f with factor q ($0 \le q < 1$) has a fixed point p, then $(1 - q) \cdot |f^n(x) - p| \le |f^{n+1}(x) - f^n(x)|$ for every x and every n. *Used for:* stopping rules for iterative solvers, read from the size of the last step. *Price:* **free**; exact.

1340. Distance to the fixed point from one step. On the line, if a contraction f with factor q ($0 \le q < 1$) has a fixed point p, then $(1 - q) \cdot |x - p| \le |f(x) - x|$ for every x. *Used for:* error estimates for approximate equilibria from their residual. *Price:* **free**; exact.

1341. Powers of a number below one tend to zero. On the line, for every r with $0 \le r < 1$, the powers r^n converge to 0. *Used for:* exponential decay step by step: damping, attenuation and radioactive decay. *Price:* **free**; exact.

1342. Geometrically shrinking steps give a Cauchy sequence. On the line, if $|u_n - u_{n+1}| \le C \cdot r^n$

for every n, with $0 \le r < 1$, then the sequence u is Cauchy. *Used for:* convergence of iterations whose corrections shrink geometrically. *Price:* **free**; exact.

1343. Sum of the geometric series. On the line, for every r with $0 \le r < 1$, the partial sums of $1 + r + r^2 + \cdots$ converge to the number s with $(1 - r) \cdot s = 1$. *Used for:* summing multiple reflections and repeated fractional losses or returns. *Price:* **free**; exact.

1344. The geometric series converges. On the line, for every r with $0 \le r < 1$, the partial sums of $1 + r + r^2 + \cdots$ converge. *Used for:* bounding perturbation series and iterated corrections by a geometric series. *Price:* **free**; exact.

1345. Terms of a convergent series tend to zero. On the line, if the partial sums of a series converge, then its terms converge to 0. *Used for:* a quick divergence test for series expansions. *Price:* **free**; exact.

1346. Absolute convergence implies convergence. On the line, if the partial sums of $|a_n|$ converge, then the partial sums of a_n converge. *Used for:* convergence of Fourier and perturbation series whose term sizes are summable. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1347. Comparison test for series. On the line, if $0 \le a_n \le b_n$ for every n and the partial sums of b_n converge, then the partial sums of a_n converge. *Used for:* proving sums of positive terms converge by bounding them, such as partition functions. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1348. Sum rule for derivatives. On the line, if f has derivative d_1 and g has derivative d_2 at x, then f + g has derivative $d_1 + d_2$ at x. *Used for:* rates of change of summed quantities, such as total energy or net force. *Price:* **free**; exact.

1349. Derivative of the identity function. On the line, the function $x \mapsto x$ has derivative 1 at every point. *Used for:* the base case for differentiating every polynomial law of motion. *Price:* **free**; exact.

1350. Derivative of a constant is zero. On the line, every constant function has derivative 0 at every point. *Used for:* constant quantities have zero rate of change: static and conserved values. *Price:* **free**; exact.

1351. Differentiable functions are continuous. On the line, a function that has a derivative at x is continuous at x. *Used for:* a trajectory that has a velocity has no jumps. *Price:* **free**; exact.

1352. The derivative at a point is unique. On the line, if f has derivative d_1 and also derivative d_2 at one point x, then $d_1 = d_2$. *Used for:* well-defined velocities, rates and slopes. *Price:* **free**; exact.

1353. Fermat's theorem at a local maximum. On the line, if f has derivative d at x and a local maximum at x, then $d = 0$. *Used for:* locating turning points and peaks, such as the top of a projectile's flight. *Price:* **free**; exact.

1354. Fermat's theorem at a local minimum. On the line, if f has derivative d at x and a local minimum at x, then $d = 0$. *Used for:* locating equilibria at potential minima and turning points of motion. *Price:* **free**; exact.

1355. Mean value inequality on [0, 1]. If f' is a uniform derivative of f on [0, 1] with $|f'| \le C$ there, then $|f(y) - f(x)| \le C \cdot |y - x|$ for all x, y in [0, 1]. *Used for:* bounding a change by its largest rate, such as distance by top speed times time. *Price:* **free**; exact.

1356. Nonnegative derivative gives an increasing function, on [0, 1]. If f' is a uniform derivative of f on [0, 1] and $f' \ge 0$ there, then $f(x) \le f(y)$ whenever $x \le y$ in [0, 1]. *Used for:* a quantity with a nonnegative rate of change, such as entropy, never decreases. *Price:* **free**; exact.

1357. Zero derivative gives a constant, on [0, 1]. If f' is a uniform derivative of f on [0, 1] and $f' = 0$ there, then $f(x) = f(y)$ for all x and y in [0, 1]. *Used for:* conservation laws: zero time derivative means constant energy or momentum. *Price:* **free**; exact.

1358. Rolle's theorem on [0, 1] with a uniform derivative. If f' is a uniform derivative of f on [0, 1] and $f(0) = f(1)$, then $f'(c) = 0$ at some point c of the closed interval [0, 1]. *Used for:* turning points: zero vertical velocity at the top of a throw landing at launch height. *Price:* **LLPO**; exact (the converse uses the choices of row 1312 and row 1313, which the free allowance contains). Proved in Theorem 12.87.

1359. Mean value theorem on [0, 1] with a uniform derivative. If f' is a uniform derivative of f on [0, 1], then $f'(c) = f(1) - f(0)$ at some point c of the closed interval [0, 1]. *Used for:* average velocity over a trip equals the instantaneous velocity at some moment. *Price:* **LLPO**; exact (the converse uses the choices of row 1312 and row 1313, which the free allowance contains). Proved in Theorem 12.87.

1360. Cauchy mean value theorem on [0, 1], closed-interval point. If f' and g' are uniform derivatives of f and g on [0, 1], then $(g(1) - g(0)) \cdot f'(c) = (f(1) - f(0)) \cdot g'(c)$ at some c in [0, 1]. *Used for:* limits of ratios by l'Hôpital's rule; comparing two rates along one motion. *Price:* **LLPO**; exact (the converse uses the choices of row 1312 and row 1313, which the free allowance contains). Proved in Theorem 12.87.

1361. Determinant of a product, 2 × 2. For 2 × 2 matrices A and B with entries on the line, the determinant of AB is $\det(A) \cdot \det(B)$. *Used for:* area factors of successive changes of variables multiply, as

Jacobians do. *Price:* **free**; exact.

1362. Determinant of the transpose, 2 × 2. Every 2 × 2 matrix with entries on the line and its transpose have equal determinants. *Used for:* Jacobians and linear systems give equal determinants by rows or by columns. *Price:* **free**; exact.

1363. Determinant of the identity, 2 × 2. The 2 × 2 identity matrix on the line has determinant 1. *Used for:* the identity map preserves areas and phase-space volume. *Price:* **free**; exact.

1364. Determinant of a scalar multiple, 2 × 2. For every point s of the line and every 2 × 2 matrix A, the determinant of s times A is $s^2 \cdot \det(A)$. *Used for:* scaling lengths by s scales areas by s^2. *Price:* **free**; exact.

1365. Cyclic property of the trace, 2 × 2. For 2 × 2 matrices A and B with entries on the line, the trace of AB equals the trace of BA. *Used for:* quantum expectation values as traces, and basis independence of the trace. *Price:* **free**; exact.

1366. Invertible exactly when the determinant is invertible, 2 × 2. A 2 × 2 matrix with entries on the line has a two-sided inverse exactly when its determinant has an inverse. *Used for:* deciding when two coupled linear equations have a unique solution. *Price:* **free**; exact.

1367. Left inverse gives an invertible determinant, 2 × 2. If BA is the identity for 2 × 2 matrices A and B with entries on the line, then det(A) has an inverse. *Used for:* reversible linear transformations, such as changes of basis, have nonzero volume factor. *Price:* **free**; exact.

1368. Inverse matrix from an invertible determinant, 2 × 2. If the determinant of a 2 × 2 matrix A on the line has an inverse, some matrix B gives AB equal to the identity. *Used for:* solving two coupled linear equations, such as a two-loop circuit, by matrix inversion. *Price:* **free**; exact.

1369. Inverse matrix from a nonzero determinant, 2 × 2. If the determinant of a 2 × 2 matrix A on the line is not equal to 0, then A has a two-sided inverse. *Used for:* solving linear equations when the determinant is known only to be nonzero. *Price:* **MP**; exact.

1370. Nonzero kernel vector forces zero determinant, 2 × 2. If a 2 × 2 matrix A on the line sends some vector not equal to zero to the zero vector, then det(A) = 0. *Used for:* normal modes: a nonzero mode vector requires the secular determinant to vanish. *Price:* **free**; exact.

1371. Injective implies surjective, 2 × 2. A 2 × 2 matrix on the line that sends only the zero vector to the zero vector reaches every vector of the plane. *Used for:* for linear equations, uniqueness of solutions gives existence for every source. *Price:* **MP**; exact.

1372. Surjective implies injective, 2 × 2. A 2 × 2 matrix on the line that reaches every vector of the plane sends only the zero vector to the zero vector. *Used for:* for linear equations, existence of solutions for every source gives uniqueness. *Price:* **free**; exact.

1373. Powers are monotone on nonnegative numbers. For points $0 \le a \le b$ of the line and every whole number n, $a^n \le b^n$. *Used for:* comparing energies such as $\frac{1}{2}mv^2$ or radiated power σT^4 as speed or temperature grows. *Price:* **free**; exact.

1374. Powers of a number below one become small. If $0 \le b < 1$ and $a > 0$ on the line, then some power b^n is less than a. *Used for:* geometric decay, such as attenuation through layers, falls below any threshold. *Price:* **free**; exact.

1375. Archimedean property through reciprocals 1/(n + 1). For every positive point x of the line, some whole number n has $1/(n + 1) < x$. *Used for:* refining a grid or time step below any required resolution. *Price:* **free**; exact.

1376. Limit of a product of sequences. If x(n) converges to L and y(n) converges to M on the line, then $x(n) \cdot y(n)$ converges to $L \cdot M$. *Used for:* limits of products, such as power as force times velocity. *Price:* **free**; exact.

1377. Cauchy sequences are bounded. For every Cauchy sequence x on the line there is a positive R with $|x(m) - x(n)| < R$ for all m and n. *Used for:* keeping iterates of a converging approximation scheme within fixed bounds. *Price:* **free**; exact.

1378. Product of continuous functions is continuous. If f and g are continuous at every point of the line, then so is the product $f \cdot g$. *Used for:* continuity of products such as pressure times volume or charge density times potential. *Price:* **free**; exact.

1379. Powers of continuous functions are continuous. If f is continuous at every point of the line, then so is $f(x)^n$ for every whole number n. *Used for:* continuity of power laws such as spring energy $\frac{1}{2}kx^2$ and T^4 radiation. *Price:* **free**; exact.

1380. Polynomials are continuous. Every polynomial, given by a finite list of coefficients on the line, is continuous at every point of the line. *Used for:* polynomial potentials, such as the anharmonic oscillator, vary continuously. *Price:* **free**; exact.

1381. Integral of a sum on [0, 1]. If I and J are the integrals of f and g over [0, 1], as limits of Riemann sums, then I + J is the integral of f + g. *Used for:* adding the work of several forces, or charge from several densities. *Price:* **free**; exact.

1382. Integral of a constant on [0, 1]. For every point c of the line, the Riemann sums of the constant function c over [0, 1] converge to c. *Used for:* work

done by a constant force; distance covered at constant speed. *Price:* **free**; exact.

1383. Monotonicity of the integral on [0, 1]. If f ≤ g on [0, 1] and I and J are their integrals over [0, 1], as limits of Riemann sums, then I ≤ J. *Used for:* bounding total energy or charge by integrating a larger density. *Price:* **free**; exact.

1384. Absolute value bound, non-strict form. For points a and b of the line, |a| ≤ b exactly when −b ≤ a ≤ b. *Used for:* tolerance bands: a measurement within plus or minus b of its target. *Price:* **free**; exact.

1385. Absolute value bound, strict form. For points a and b of the line, |a| < b exactly when −b < a < b. *Used for:* strict error bounds, such as an oscillation amplitude kept below a limit. *Price:* **free**; exact.

1386. The sequence 1/n tends to zero. The sequence 1/n on the line, with its term at n = 0 read as 0, converges to 0. *Used for:* vanishing of finite-size corrections of order 1/N. *Price:* **free**; exact.

1387. Cauchy criterion through distance bounds. A sequence x on the line is Cauchy exactly when, for every k, some N gives |x(m) − x(n)| ≤ 1/(k + 1) for all m, n ≥ N. *Used for:* testing convergence of iterative numerical solutions without knowing the limit. *Price:* **free**; exact.

1388. Convergent subsequence of a frequently bounded sequence. If |x(n)| ≤ b for infinitely many n, that is, for every N some n ≥ N has |x(n)| ≤ b, then some subsequence of x converges to a point of the line. *Used for:* extracting limiting states from bounded trajectories or minimizing sequences. *Price:* **LPO**; exact: a bounded sequence is frequently bounded, so the statement gives the Bolzano–Weierstrass theorem (row 1304) and LPO with no choice; conversely, choosing for every N an index n ≥ N with |x(n)| ≤ b, a choice of natural numbers inside the free allowance, gives a bounded subsequence, and the Bolzano–Weierstrass theorem at LPO finishes.

1389. Root of a linear equation. For points a and b of the line with a not equal to 0, some point x satisfies a·x + b = 0. *Used for:* solving linear balance equations, such as a spring's equilibrium kx = F. *Price:* **MP**; exact.

1390. Determinant formula for 2 × 2 matrices. A 2 × 2 matrix on the line with first row a, b and second row c, d has determinant ad − bc. *Used for:* area of a parallelogram; solving two linear equations by Cramer's rule. *Price:* **free**; exact.

1391. Inverse of the inverse, 2 × 2. If B is a two-sided inverse of the 2 × 2 matrix A on the line, and C is a two-sided inverse of B, then C = A. *Used for:* undoing the inverse of a change of basis returns the original transformation. *Price:* **free**; exact.

1392. Cayley–Hamilton theorem, 2 × 2. Every 2 × 2 matrix A on the line satisfies $A^2 - \mathrm{tr}(A)\cdot A + \det(A)\cdot I = 0$, where I is the identity. *Used for:* closed forms for powers and exponentials of 2 × 2 matrices, such as spin rotations. *Price:* **free**; exact.

1393. Real eigenvalue of a symmetric 2 × 2 matrix. For every symmetric 2 × 2 matrix on the line with rows a, b and b, d, some point μ satisfies (a − μ)(d − μ) − b^2 = 0. *Used for:* energy levels of a two-level system with real couplings; two coupled oscillators. *Price:* **free**; exact.

1394. Product rule for derivatives. If f has derivative d_1 and g has derivative d_2 at x on the line, then f·g has derivative $d_1\cdot g(x) + f(x)\cdot d_2$ at x. *Used for:* rates of change of products, such as momentum when both mass and velocity vary. *Price:* **free**; exact.

1395. Power rule for derivatives. If f has derivative d at x on the line, then f to the power n + 1 has derivative $(n + 1)\cdot f(x)^n\cdot d$ at x. *Used for:* forces from power-law potentials, such as kx from ½kx^2. *Price:* **free**; exact.

1396. Derivative of a polynomial. Every polynomial, given by a finite list of coefficients on the line, has at every point the derivative computed term by term from its coefficients. *Used for:* forces from polynomial potentials; velocities from polynomial trajectories. *Price:* **free**; exact.

1397. Monotone sequence converges to its least upper bound. If x(n) is nondecreasing on the line and L is its least upper bound, then x(n) converges to L. *Used for:* convergence of increasing lower bounds, such as partial sums of positive terms. *Price:* **MP + $\mathbf{AC}_\omega$**; exact.

1398. Cauchy sequences of fractions converge. Every Cauchy sequence of fractions, read as points of the line, converges to a point of the line. *Used for:* real quantities as limits of finite-precision rational measurements. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1399. A supremum is a limit of members. If L is an upper bound of a set S on the line and members of S come within every tolerance of L, then some sequence of members converges to L. *Used for:* approaching a best value, such as maximal work or efficiency, by actual processes. *Price:* $\mathbf{AC}_\omega$; exact.

1400. Image of [0, 1] is the interval [min, max]. For f uniformly continuous on [0, 1], there are m and M with m ≤ f ≤ M on [0, 1], and f takes every value between m and M on [0, 1]. *Used for:* a continuous profile on a segment, such as temperature, takes every value between its extremes. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

1401. Bound on an integral over [0, 1]. If $|f| \le C$ on [0, 1] and I is the integral of f over [0, 1], as a limit of Riemann sums, then $|I| \le C$. *Used for:* estimating impulse or work from a bound on the force. *Price:* **free**; exact.

1402. Lipschitz condition from a distance bound. If $|f(x) - f(y)| \le K \cdot |x - y|$ for all points x, y of the line, with K a whole number, then f is Lipschitz with constant K. *Used for:* bounded sensitivity of force laws, which makes solutions of equations of motion unique. *Price:* **free**; exact.

1403. Approximation from below by an increasing sequence. Every point x of the line is the limit of a strictly increasing sequence of points, each less than x. *Used for:* approaching a threshold value from below, such as a critical temperature. *Price:* **free**; exact.

1404. Bernoulli's inequality for a ≥ −2. For every point $a \ge -2$ of the line and every whole number n, $1 + n \cdot a \le (1 + a)^n$. *Used for:* bounds on compound growth and on first-order approximations of $(1 + x)^n$. *Price:* **free**; exact.

1405. Adding fractions with nonzero denominators. If b and d on the line are not equal to 0, then b, d and bd have inverses and $a/b + c/d = (ad + bc)/(bd)$. *Used for:* combining rates and resistances, such as parallel resistors $1/R_1 + 1/R_2$. *Price:* **MP**; exact.

1406. Chain rule for derivatives. If f has derivative a at x and g has derivative b at f(x) on the line, then g applied after f has derivative $b \cdot a$ at x. *Used for:* rate of change of potential energy along a path: slope times velocity. *Price:* **free**; exact.

1407. The derivative as a linear map. If f has derivative d at x on the line, then the linear map $h \mapsto h \cdot d$ is the derivative of f at x in the linear-map sense. *Used for:* linearizing dynamics near a point, as in small-oscillation and stability analysis. *Price:* **free**; exact.

1408. Comparison of functions through derivatives, on [0, 1]. If f′ and B′ are uniform derivatives of f and B on [0, 1], with $f(0) \le B(0)$ and $f' \le B'$ there, then $f \le B$ on [0, 1]. *Used for:* differential inequalities, such as Grönwall-type bounds on the growth of errors. *Price:* **free**; exact.

1409. The harmonic series diverges. For every point M of the line, the partial sums $1 + 1/2 + \ldots + 1/n$ are at least M from some n on. *Used for:* logarithmic divergences, such as mode sums and the potential of a long wire. *Price:* **free**; exact.

1410. Fundamental theorem of calculus, evaluation form, on [0, 1]. If f′ is a uniform derivative of f on [0, 1], then the Riemann sums of f′ over [0, 1] converge to $f(1) - f(0)$. *Used for:* work as a change in potential energy; displacement as the integral of velocity. *Price:* **free**; exact.

1411. Integral of x over [0, 1]. The Riemann sums of the function x over [0, 1] converge to 1/2. *Used for:* work done stretching a spring: integrating kx gives $\frac{1}{2}kx^2$. *Price:* **free**; exact.

1412. Integral of x^n over [0, 1]. For every whole number n, the Riemann sums of x^n over [0, 1] converge to $1/(n + 1)$. *Used for:* moments of inertia and fields of power-law densities. *Price:* **free**; exact.

1413. Monotone sequence diverges or converges. Every nondecreasing sequence on the line either exceeds every point from some index on, or converges to a point of the line. *Used for:* an increasing quantity, such as accumulated energy, either grows without bound or settles. *Price:* **LPO + $\mathbf{AC}_\omega$**; exact.

1414. Intermediate value theorem, point inside (0, 1). If f is uniformly continuous on [0, 1] and $f(0) < v < f(1)$, then $f(c) = v$ at some point c with $0 < c < 1$. *Used for:* existence of equilibria and zero crossings, such as where a force changes sign. *Price:* **LLPO**; exact (the zero that row 1312 gives for $f - v$ lies at a positive distance from both ends, since $f(0) < v < f(1)$ and f is uniformly continuous).

1415. Ratio bound gives a convergent series. If $0 \le r < 1$ and $|a(n + 1)| \le r \cdot |a(n)|$ from some n on, then the partial sums of a converge on the line. *Used for:* convergence of perturbation and power series with geometric decay. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1416. Ratio test for series. If $|a(n + 1)| = q(n) \cdot |a(n)|$ for every n and q(n) converges to a limit below 1, then the partial sums of a converge. *Used for:* radius of convergence of series solutions, such as those for the hydrogen atom. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1417. Convergence of the p-series. For a whole number p, the sum of $1/(n + 1)^p$ over all n converges on the line exactly when $p > 1$. *Used for:* convergence of lattice sums and of power-law tails. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1418. Heine–Borel theorem on [0, 1]. Every countable cover of [0, 1] by open intervals with fraction endpoints has a finite subcover: the first N intervals already cover [0, 1]. *Used for:* finite coverings of a bounded region, behind extreme values and uniform estimates. *Price:* **FAN**; exact (equivalent to the decidable fan theorem). Proved in Theorem 13.6.

1419. Positive derivative gives a strictly increasing function, on [0, 1]. If f′ is a uniform

derivative of f on [0, 1] and $f' > 0$ there, then $f(x) < f(y)$ whenever $x < y$ in [0, 1]. *Used for:* a quantity with a strictly positive rate, such as a heated body's temperature, keeps rising. *Price:* **free**; exact.

1420. Monotonicity of the limit superior. If $x(n) \le y(n)$ from some index on, and L and M are the limits superior of x and y (lowest tail least upper bounds), then $L \le M$. *Used for:* comparing long-run upper envelopes of fluctuating signals or trajectories. *Price:* **free**; exact.

1421. Square roots preserve strict order. For points $a \ge 0$ and $b \ge 0$ of the line, if $a^2 < b^2$ then $a < b$. *Used for:* comparing magnitudes, such as speeds, from their squares, such as kinetic energies. *Price:* **free**; exact.

1422. Continuity of the square root, read on roots. For each $a_0 \ge 0$ on the line and each tolerance, every $a \ge 0$ whose square is close enough to a_0^2 lies within that tolerance of a_0. *Used for:* stable magnitudes and speeds computed from squared quantities. *Price:* **free**; exact.

1423. Integration by parts on [0, 1]. If u', v' are uniform derivatives of u, v on [0, 1] and the Riemann sums of $u'v$ converge to J, those of uv' converge to $u(1)v(1) - u(0)v(0) - J$. *Used for:* deriving equations of motion from an action; boundary terms in field theory. *Price:* **free**; exact.

1424. Substitution rule for integrals on [0, 1]. If $F' = f$ and g' are uniform derivatives on [0, 1] and g maps [0, 1] into itself, the Riemann sums of $f(g(x))\cdot g'(x)$ converge to $F(g(1)) - F(g(0))$. *Used for:* changing variables in integrals, such as from time to position in energy integrals. *Price:* **free**; exact.

1425. Derivative of the square root. Given a function s with $s(y) \ge 0$ and $s(y)^2 = y$ for every $y \ge 0$, at each $x > 0$ its derivative is the point c with $c\cdot 2s(x) = 1$. *Used for:* rates of quantities under a root, such as speed computed from kinetic energy. *Price:* **free**; exact.

1426. Rank of a 2 × 2 matrix. Every 2 × 2 matrix on the line has a rank $r \le 2$: 0 for the zero matrix, 2 if its determinant is not 0, and 1 otherwise. *Used for:* counting independent equations or degrees of freedom in a linear system. *Price:* **WLPO**; exact.

1427. Quotient rule for derivatives. If c, d have derivatives c', d' at x on the line and e is a function with $d(y)\cdot e(y) = 1$ for every y, then $c\cdot e$ has derivative $(c'\cdot d(x) - c(x)\cdot d')\cdot e(x)^2$ at x. *Used for:* rates of ratios, such as the derivative of a potential falling off as $1/r$. *Price:* **free**; exact.

1428. Positive function has a positive integral, on [0, 1]. If f is uniformly continuous on [0, 1], positive at every point strictly between 0 and 1, and I is its integral over [0, 1], then $I > 0$. *Used for:* a positive density gives a positive total mass, charge or probability. *Price:* **free**; exact.

1429. Field structure on the line. the line, with its own sum and product, is a field in the standard sense: a total inverse with $0^{-1} = 0$ that inverts every point not equal to 0. *Used for:* the algebra of physical quantities: dividing by any nonzero quantity. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorem 28.15.

1430. Decidable linear order on the line. the order of the line is a linear order in the standard sense: any two points compare, and a procedure decides $x \le y$ and $x < y$ for every pair. *Used for:* ordering measured values, such as energies, times or temperatures. *Price:* **LPO function**; exact (equivalent to LPO as a function). Proved in Theorems 28.15 and 28.3(3).

1431. Unconditional summability equals absolute summability. A sequence on the line is summable, meaning its sums over finite sets of indices converge, exactly when its absolute values are summable. *Used for:* rearranging series freely, such as lattice sums and perturbation expansions. *Price:* **free**; exact (limit points use the completeness of the line: countable choice of rational pairs).

1432. The exponential grows without bound. For every point M of the line there is a point N with $\exp(x) \ge M$ for every $x \ge N$. *Used for:* runaway exponential growth, such as chain reactions and unstable modes. *Price:* **free**; exact.

1433. Floor of x divided by x tends to 1. For each k there is M such that, for every $x \ge M$, every integer floor m of x and every y with $y\cdot x = m$ satisfy $|y - 1| \le 1/(k + 1)$. *Used for:* counting whole periods or lattice sites in a long length: count over length tends to 1. *Price:* **free**; exact.

1434. Cauchy for fractions exactly when Cauchy on the line. A sequence of fractions is Cauchy for every positive fraction tolerance exactly when, read as points of the line, it is Cauchy for every positive tolerance on the line. *Used for:* trusting finite-precision rational computations to converge to real values. *Price:* **free**; exact.

1435. Continuity of the exponential function. The exponential function on the line is continuous at every point. *Used for:* small changes in a rate or exponent give small changes in decay factors. *Price:* **free**; exact.

1436. A closed interval is connected. If two open sets of the line together cover [a, b] and each contains a point of [a, b], then they share a point of [a, b]. *Used for:* intermediate-value arguments along a path, such as crossing a phase boundary. *Price:* $\mathbf{AC}_{\omega}$; exact.

1437. Continuous function unbounded both ways takes every value. A function continuous at every point of the line that tends to $+\infty$ at $+\infty$ and to $-\infty$ at $-\infty$ takes every value. *Used for:* existence of solutions of equations of state, such as a temperature for every energy. *Price:* **LLPO + $\mathbf{AC}_\omega$**; exact.

1438. Injective continuous function is strictly monotone. A function f continuous at every point of the line, with f(x) = f(y) only when x = y, is strictly increasing or strictly decreasing. *Used for:* inverting monotone calibration curves, such as a thermometer reading to a temperature. *Price:* **MP + $\mathbf{AC}_\omega$**; exact.

1439. Preimages of open sets are open. If f is continuous on the line and a set U contains a neighborhood of each of its points, then so does the set of x with f(x) in U. *Used for:* robust conditions: a strict inequality on a measured value survives small perturbations. *Price:* **free**; exact.

1440. Heine–Cantor theorem on a compact set. If K on the line is compact (every countable cover by open fraction-endpoint intervals has a finite subcover) and f is continuous on K, then f is uniformly continuous on K. *Used for:* one grid spacing that controls errors over a whole bounded region. *Price:* **open**; at most EM + AC_ω, and at most WEM.

1441. Heine–Cantor theorem on [0, 1]. A function continuous at every point of [0, 1], with points of [0, 1] as inputs, is uniformly continuous on [0, 1]. *Used for:* one grid spacing that controls numerical errors over a whole interval. *Price:* **open**; at least FAN; at most EM + AC_ω; at most WLPO (one yes-or-no answer for every row of a table of bits, collected by the free allowance, with representatives), and at most the full fan theorem with no choice; equivalent, with no choice, to the decidable fan theorem together with a presentation of the local control data by countable covers.

1442. Compact sets are bounded. If a set of the line is compact (every countable cover by open fraction-endpoint intervals has a finite subcover), it lies inside some interval [−B, B] with B a whole number. *Used for:* confined configurations, such as bound orbits, occupy a bounded region. *Price:* **free**; exact.

1443. Compact sets are closed. If a set of the line is compact (every countable cover by open fraction-endpoint intervals has a finite subcover), it contains every one of its limit points. *Used for:* limits of allowed configurations remain allowed configurations. *Price:* **EM**; exact.

1444. Sequentially compact implies compact. If every sequence in a set K of the line has a subsequence converging in K, then every countable cover of K by open fraction-endpoint intervals has a finite subcover. *Used for:* passing from limiting arguments to finite coverings in existence proofs. *Price:* **open**; at least LPO; at most EM + AC_ω.

1445. Compact exactly when sequentially compact. A set K of the line is compact (every countable cover by open fraction-endpoint intervals has a finite subcover) exactly when every sequence in K has a subsequence converging in K. *Used for:* existence of minimizers and limiting states in variational problems. *Price:* **EM + $\mathbf{AC}_\omega$**; exact.

1446. A compact set has a least element. A nonempty set of the line that is compact (every countable cover by open fraction-endpoint intervals has a finite subcover) has a least member. *Used for:* existence of a lowest energy or shortest time among allowed values. *Price:* **EM + $\mathbf{AC}_\omega$**; exact.

1447. Continuous image of a compact set is compact. If K is compact (every countable cover by open fraction-endpoint intervals has a finite subcover) and f is continuous on K, then the set of values of f on K is compact. *Used for:* a continuous observable on a closed bounded set of states has bounded, attained values. *Price:* **open**; at most EM + AC_ω, and at most WEM; equivalent to the margin property: for every countable cover of the values of f on K by open intervals with fraction endpoints, there are N and m such that every value lies in one of the first N intervals at distance at least 1/(m+1) from its ends.

1448. Compact exactly when totally bounded and complete. A set K of the line is compact (every countable cover by open fraction-endpoint intervals has a finite subcover) exactly when K has finite nets at every tolerance and is complete. *Used for:* approximating a bounded set of states by finitely many sample states. *Price:* **EM + $\mathbf{AC}_\omega$**; exact.

1449. Total boundedness by finite nets. A set of the line has a finite net for every relation containing a band $|x - y| \le 1/(k + 1)$ exactly when it has a finite net within each $1/(k + 1)$. *Used for:* discretizing a bounded region by a finite grid at any resolution. *Price:* **free**; exact.

1450. Closed subset of a compact set is compact. If C contains its limit points and lies inside a compact set K of the line (every countable cover by open fraction-endpoint intervals has a finite subcover), then C is compact too. *Used for:* restricting to a closed constraint set inside a bounded region. *Price:* **open**; at least LPO; at most EM + AC_ω.

1451. Compact space [0, 1] is a compact set. The interval [0, 1] is compact: every countable cover of [0, 1] by open intervals with fraction endpoints has a finite subcover, its first N intervals. *Used for:* finite coverings of a bounded region, behind extreme values and uniform estimates. *Price:* **FAN**; exact (equivalent

to the decidable fan theorem).

1452. The exponential is its own derivative. The exponential function on the line has derivative exp(x) at every point x. *Used for:* exponential decay and growth, where the rate is proportional to the amount. *Price:* **free**; exact.

1453. Fundamental theorem of calculus, derivative form. If F(x) is the integral of f from a to x for every x on the line, and f is continuous at b, then F has derivative f(b) at b. *Used for:* recovering a rate from an accumulated quantity, such as power from energy delivered. *Price:* **free**; exact.

1454. Integrals over adjacent intervals add. Where they exist, integrals of f on the line add: from a to b plus from b to c gives from a to c, for a, b and c in any order. *Used for:* splitting work or travel time over the segments of a path. *Price:* **free**; exact.

1455. Laplace expansion along the first row. For every square matrix on the line, the determinant, defined by cofactor expansion down the first column, equals the cofactor expansion along the first row. *Used for:* computing determinants of secular equations and Jacobians by cofactors. *Price:* **free**; exact.

1456. Rank–nullity theorem for matrices. Every matrix on the line has columns forming a basis of its column space, and a basis of its kernel indexed by the remaining columns: rank plus nullity is the column count. *Used for:* counting independent solutions of linear constraints and degrees of freedom. *Price:* **WLPO**; exact (the proof also collects yes-or-no answers by countable unique choice, which the free allowance contains).

1457. Rank of the transpose equals the rank. Every matrix on the line has a rank r, the size of a largest square minor with determinant not equal to 0, and its transpose also has rank r. *Used for:* row and column counts of independent equations agree in linear systems. *Price:* **WLPO**; exact.

1458. Injective linear map cannot lower dimension. If an $n \times m$ matrix on the line sends only the zero vector to the zero vector, then $m \le n$. *Used for:* a linear system with unique solutions needs at least as many equations as unknowns. *Price:* **free**; exact.

1459. A spanning family contains a basis. Every finite family of vectors in n-space on the line has a linearly independent subfamily that spans every vector of the family. *Used for:* removing redundant constraints or generators, such as dependent conservation laws. *Price:* **WLPO**; exact (the proof also collects yes-or-no answers by countable unique choice, which the free allowance contains).

1460. Basis of a finitely spanned space. The space spanned by finitely many vectors in n-space on the line has a basis drawn from those vectors. *Used for:* choosing independent coordinates or modes from an overcomplete set. *Price:* **WLPO**; exact (the proof also collects yes-or-no answers by countable unique choice, which the free allowance contains).

1461. Spectral theorem for symmetric matrices. For every n, every symmetric $n \times n$ matrix on the line has an orthonormal basis of eigenvectors, each with its eigenvalue. *Used for:* normal modes of coupled oscillators; diagonalizing real Hamiltonians and inertia tensors. *Price:* **LLPO**; exact (the converse uses weak König's lemma, whose choice collects a finite table for every depth, and rational approximations, both inside the free allowance). Proved in Theorem 28.66.

1462. Characteristic polynomial is monic. For every $n \times n$ matrix M on the line, the function $t \mapsto \det(t \cdot I - M)$ equals t^n plus a polynomial of degree below n. *Used for:* secular equations for energy levels and normal-mode frequencies. *Price:* **free**; exact.

1463. Determinant is the product of the eigenvalues. If the characteristic polynomial of an $n \times n$ matrix M on the line is given split as the product of $t - \lambda_i$, then det(M) is the product of the λ_i. *Used for:* volume change under a linear flow; products over modes in partition functions. *Price:* **free**; exact.

1464. Independent vectors number at most the dimension. A linearly independent family of k vectors in n-space on the line has $k \le n$. *Used for:* counting degrees of freedom, such as at most three independent directions in space. *Price:* **free**; exact.

1465. Existence of the exponential function. There is a function E on the line with $E(0) = 1$ whose derivative at every point x is E(x). *Used for:* radioactive decay, growth and damping, where the rate is proportional to the amount. *Price:* **free**; exact. Proved in Proposition 12.88.

1466. Exponential turns sums into products. For all points x and y of the line, $\exp(x + y) = \exp(x) \cdot \exp(y)$. *Used for:* evolution over successive time intervals; Boltzmann factors of independent systems multiply. *Price:* **free**; exact. Proved in Proposition 12.88.

1467. Integrals of uniformly continuous functions exist. If f is uniformly continuous on all of the line, then for all points a and b the integral of f from a to b exists as a point. *Used for:* total work, charge or probability from continuous densities. *Price:* **free**; exact (a modulus of uniform continuity is chosen by countable choice of natural numbers; the Riemann sums then form a Cauchy sequence with a known modulus, and its limit point uses the completeness of the line: countable choice of rational pairs, Corollary 12.35).
